Valuable breeding queens are commonly brought to a veterinarian for evaluation as a result of failure to reproduce at an expected rate. It is essential that, in addition to ensuring that clients have realistic expectations, the clinician take a logical and thorough approach to evaluation of the animal's reproductive performance and health. *Subfertility* in the queen refers to failure to produce an expected number of live kittens successfully; this may occur as a result of failure to breed or conceive or failure to carry fetuses to term. *Infertility* refers to the absolute inability to reproduce. Prior to any examination, cattery and breeding management must be evaluated to ensure that true subfertility or infertility exists. Good husbandry has a significant impact on reproductive performance in any species. Stocking density must be low enough to reduce stress associated with social situations and crowded conditions. Noise pollution should be avoided. Transport of animals between cages, and properties should be minimal. An adequate plane of nutrition should be maintained. Prophylactic techniques for common conditions should be performed on a regular basis, including routine retrovirus evaluation, appropriate vaccinations, grooming, nail trimming, dental care, external and internal parasite control, and appropriate quarantine.

Cattery owners should have a basic understanding of feline reproductive physiology so that estrous behavior, mating, and queening can be accurately recorded. Queens should be mated with a proven tomcat prior to infertility evaluation and ideally should be 1 to 6 years of age.

After ensuring that breeding management is adequate, the clinician should take a complete history and perform a thorough physical examination. The queen should then be further categorized based on her reproductive status.

255.3.1.7.1 Failure to cycle

A combination of silent heat and spontaneous ovulation may lead an owner to believe that a queen has chronic anestrus. Regardless of whether the owner believes that the queen cycles, evidence for ovarian activity should be obtained. Vaginal cytology provides a convenient bioassay for the influence of estrogen during intervals of increasing photoperiod. Animals that fail to show signs of estrus during appropriate light exposure may be categorized as having prolonged anestrus.

Differential diagnoses for prolonged anestrus should include inadequate light exposure, prior gonadectomy, stress, abnormalities of sexual development, and drug administration. If all differentials have been excluded, attempts can be made to induce estrus by housing a tomcat nearby and increasing the day length. Where appropriate, pharmacologic induction through administration of dopamine agonists or FSH analogs can be attempted.

255.3.1.7.2 Prolonged estrus

As previously mentioned, overlapping waves of follicular activity in the queen may result in signs of persistent estrus. Other explanations include ovarian follicular cysts and exogenous estrogen administration. Abdominal ultrasound is useful for detecting ovarian cysts. The cysts are typically greater than 4 mm in diameter and are visible in the parenchyma of the ovary; however, they may be difficult to differentiate from follicles. Ovariohysterectomy is curative.

255.3.1.7.3

Failure to ovulate

Queens with ovulatory failure maintain an interestrous interval of approximately 10 days during the breeding season. Successful ovulation depends on the presence of mature follicles and an adequate LH surge, which is dependent on the frequency and number of copulations (if spontaneous ovulation does not occur). Failure to ovulate indicates that mating was incomplete or that it occurred too infrequently or at the wrong time. Breeding management should be re-evaluated.

255.3.1.7.4

Failure to conceive (prolonged interestrous interval) and pregnancy loss

An interestrous interval greater than 25 days indicates that ovulation likely occurred. Explanations for failure to conceive include true conception failure and early fetal resorption. Ovulation should be confirmed by measurement of an increased serum progesterone concentration 48 to 72 hours after cessation of mating. Abdominal ultrasonography may also be used to evaluate for implantation. Fetal resorption occurs most commonly in association with congenital defects, which may occur secondary to teratogen exposure. Feline leukemia virus is an important viral cause of embryonic death, fetal death, and abortion in the queen. Other infectious causes of fetal resorption include chlamydia, feline panleukopenia virus, feline coronavirus, and feline respiratory virus complex. *Toxoplasma* infection has been implicated in feline infertility. Bacterial infections (e.g., *Salmonella* spp.) are more likely to result in abortion than resorption.

255.3.1.7.5

Uterine monitoring for prevention of early pregnancy loss

Uterine monitoring may be used during gestation to evaluate for premature uterine contractions (Figure 255-7). Pregnancy loss as a result of hypoluteoidism has not been documented in the queen. It is more likely that any decrease in serum progesterone associated with premature contractions occurs secondary to endogenous prostaglandin release and destruction of the CL. Clinical signs associated with premature contractions are typically limited to an abnormal vaginal discharge (usually hemorrhagic) prior to term in the pregnant queen. Tocolytic agents (e.g., terbutaline) have been tried successfully in queens to reduce uterine contractions and carry pregnancy to term.

255.3.1.7.6

Abnormal sexual behavior

Infrequently, queens may exhibit intense dislike for particular males and refuse to allow breeding. Selection of an alternate male or artificial insemination resolves the problem. In queens that fail to show signs of estrus or that refuse to permit copulation, induction of ovulation followed by artificial insemination may be required.

1703

1704

Figure 255-7 Pregnant queen with uterine monitor in place. (Courtesy Karen Copeley, Veterinary Perinatal Services, Colorado.)

255.3.1.7.7 Uterine pathology

Cystic endometrial hyperplasia may be associated with infertility in the older queen. Definitive diagnosis requires uterine biopsy. No effective treatment is available.

255.3.2 The Tomcat

Tomcats are not typically brought to the veterinarian for reproductive evaluation unless they have an external abnormality of the genital tract, are exhibiting poor libido, or show evidence of infertility.[14]

255.3.2.1 Abnormalities of the Genitalia

255.3.2.1.1 Trauma

Injury to the external genitalia and other parts of the body is common in tomcats as a result of intermale aggression and fighting behavior. Routine wound management, consisting of cleaning, debridement, and antimicrobial therapy, is appropriate. Animals not intended for breeding should be castrated.

255.3.2.1.2 Cryptorchidism

Testicular descent in the tomcat is usually complete at birth. However, because continued movement of the testicles in the inguinal canal is noted until puberty, it is wise to delay evaluation for cryptorchidism in the tomcat until 6 months of age. The incidence of cryptorchidism in the tomcat is low, and there appears to be no predilection for the left or right side. In one retrospective study, cats were more likely to be unilaterally cryptorchid.[15] In the cats with bilateral cryptorchidism, both testicles were in the

abdominal cavity. Persian cats were over-represented.[15] Medical therapy for the treatment of feline cryptorchidism cannot be advocated due to suspected heritability. Surgical castration is curative.

There is a single report of estrous behavior in a bilaterally cryptorchid tomcat in association with interstitial cell hyperplasia.[16] Feminizing syndromes in association with cryptorchid testicles and Sertoli cell tumors are extremely rare in the cat.

255.3.2.1.3 Testicular hypoplasia

Testicular hypoplasia is rarely reported in the tomcat, because most male cats are castrated. However, it has been detected in association with prepu-bertal panleukopenia infection, as a result of fever-induced germinal layer destruction, and in association with vitamin A deficiency.

255.3.2.1.4 Orchitis

Orchitis is rare in the tomcat and usually occurs secondary to a bite wound. It may also be the result of extension of peritoneal infection through the inguinal ring in association with feline infectious peritonitis. Cats are naturally resistant to *Brucella canis* infection.

255.3.2.1.5 Persistent penile frenulum

In the cat, breakdown of the penile and preputial mucosal surface adhesion is an androgen-dependent phenomenon. Persistent penile frenulum is associated with early castration (before 7 weeks of age).

255.3.2.1.6 Phimosis, paraphimosis, and priapism

Phimosis (constriction of the orifice of the prepuce) and *paraphimosis* (inability to retract the penis into the prepuce) are unusual in cats but may occur secondary to preputial trauma, or to entanglement of the hairs of the prepuce. *Priapism* (persistent erection) is also uncommon but has been reported in association with hemostasis, thrombosis, and failure of detumescence.[17]

255.3.2.2 Prostatic Disease

The prostate is rudimentary and generally of little clinical concern. However, both bacterial prostatitis and prostatic neoplasia have been reported in the cat.[18,19] Clinical signs include dyschezia and intermittent constipation and hematuria.

255.3.2.3 Urine Spraying and Masturbation

The tomcat sprays urine to identify territory, and this is considered normal behavior for an intact male. Castration resolves urine spraying in 80% of cats.[20] Urine spraying may persist in the castrated cat and is considered undesirable by most owners. It is important for the clinician to distinguish between urine spraying (typically on vertical surfaces) and inappropriate elimination. Selective serotonin reuptake inhibitors and tricyclic antidepressants are commonly used to reduce the occurrence of urine spraying in castrated males. There is a single case report describing the successful use of cyproheptadine for the treatment of urine spraying and masturbation in a tomcat.[20]

255.3.2.4 Infertility

Evaluation of the tomcat for infertility is uncommon. Limited data are available regarding common problems and their successful management. Reported reasons for reproductive evaluation of the tomcat associated with infertility include lack of libido, behavioral abnormalities, trauma, and infections. Tomcats infrequently undergo semen evaluation because of the reluctance of most owners to permit general anesthesia and electroejaculation to enable semen evaluation and because of the general lack of availability of this service in private practice. Evaluation of infertility in the tomcat should include cattery management evaluation as described for the queen. A complete physical examination should be performed and a routine clinicopathologic and infectious disease database should be obtained, in addition to evaluation of the genital tract for signs of trauma or abnormality.

255.3.2.5 Lack of Libido

Gonadal abnormalities or sexual immaturity may result in a lack of libido in the male cat. In breeds that are typically late maturing, the evaluation should be delayed until 3 years of age. The penis should be examined to document the influence of testosterone. Testicular palpation and measurement of testicular volume should be performed; however, currently, little published data correlate reproductive performance with testicular volume in the cat. Breeding management should be reviewed to ensure that husbandry or stress is not a contributing factor. If permitted, electroejaculation, semen evaluation, and artificial insemination are advised if the cat appears to be clinically normal and management problems have been excluded. Testosterone supplementation is not recommended in tom cats as it results in negative feedback on endogenous hormone production, thereby exacerbating the problem.

255.4 NEOPLASIA OF THE GENITAL TRACT

Please refer to Chapter 188.

255.5 PREGNANCY AND PARTURITION

Fertilization takes place in the uterine tube. Morulae enter the uterus approximately 5 days after coitus, and embryos are distributed evenly in the left and right uterine horns. Superfecundation is possible. The hormonal profile during pregnancy reveals increased serum progesterone and relaxin concentrations and a low serum estrogen concentration. The serum prolactin concentration increases in the latter half of gestation. The main source of progesterone support is the corpora lutea. Waves of ovarian follicular activity may occur during pregnancy, resulting in fluctuations in the serum estrogen concentration, which can result in estrous behavior during gestation.

Figure 255-8 Ultrasound image of a gravid uterine horn with an intraluminal fetus and fetal membranes. (Courtesy Tom Baker, University of California, Davis.)

Pregnancy diagnosis by means of transabdominal palpation in the queen is best performed during the second and third weeks of gestation. During this time, palpation of the uterus reveals grape-sized vesicles. Later in pregnancy, the segmental nature of the uterine lumen is lost, and transabdominal palpation is more challenging. Abdominal ultrasonography is the preferred technique for diagnosing pregnancy in the queen, because it is easy to perform during all stages of gestation and it provides information regarding fetal viability (Figure 255-8). The normal fetal heart rate in the cat exceeds 200 beats per minute, and heart rates are detectable as early as 25 days after mating. Radiographic detection of the fetal skeleton is possible at 45 days after breeding.

A mild, transient increase in the serum estrogen level is noted several days prior to parturition; this is associated with upregulation of oxytocin receptor expression in preparation for parturition.

255.5.1 Care of the Pregnant Feline

Metabolic requirements do not increase until the second half of gestation. The current recommendation is to feed pregnant queens a commercially prepared, AAFCO-approved kitten diet at the time of pregnancy diagnosis; to increase the amount of food by 25% for weeks 5 and 6 of gestation; and to make an additional 25% increase for weeks 7 and 8 of gestation. Food intake may be increased a further 25% in the final week of gestation. Commonly, cat breeders supplement pregnant queens with raw liver during early pregnancy because of concerns about hypovitaminosis A; this is not necessary when queens are fed commercial cat food. Pregnant cats should be weighed once weekly and kept indoors. Weight gains in the range of 5% of body weight are anticipated per week. Routine vaccinations should be avoided because of the risk of cerebellar hypoplasia with the modified-live panleukopenia vaccine. Griseofulvin and glucocorticoids are known teratogens in the queen, and their use should be avoided during pregnancy.

255.5.2 Clinicopathic Changes in the Pregnant Queen

Plasma volume expansion in the queen results in a mild normocytic-normochromic nonregenerative anemia during late gestation. Queens should be given access to a box prior to their anticipated due date. A private

cardboard box lined with towels provides the queen with a quiet, dark environment while also permitting observation. Reports of the length of gestation in the cat vary because of the inability to establish the time of ovulation accurately. As a general rule, parturition occurs 65 days from the first known breeding.

Some queens have a decrease in rectal temperature approximately 12 hours prior to the onset of parturition. Stage one labor (cervical dilatation) commences with the onset of uterine activity and ends with complete cervical dilatation. During this stage, nesting behavior, increased licking of the perineum, and restlessness may be noted. Queens typically choose to stay in the queening box at this time. Some cats that are particularly bonded to their owners may actively seek them.

Typically, visible abdominal contractions indicate the start of stage two labor. This stage is defined by coordinated uterine contractions and expulsion of the neonate. The first delivery should occur within 1 to 2 hours of visible contractions. Clear, blood-tinged fluid is generally expelled from the vulva prior to delivery of the first kitten. It should be noted that posterior presentation of the neonate is common and is not necessarily associated with dystocia. Queening is typically completed within 12 hours. Litter size is breed dependent and ranges from one to 10 kittens per litter.

Dystocia is less common in the queen than in the bitch. Uterine monitoring as described in the bitch has been used successfully in the queen to identify impending labor and to aid in evaluation of dystocia.[21] Medical therapy with oxytocin and calcium gluconate may be attempted without uterine monitoring. Uterine monitoring, when possible, may demonstrate the nature of the problem, and response to therapy can then be accurately judged. Uteroverdin (green discharge) present prior to presentation of a kitten; an interval longer than 1 hour between kittens; a sick queen; or stage one labor that lasts longer than 24 hours without the onset of stage two labor warrants examination of the queen by a veterinarian. The initial evaluation should consist of a physical examination, digital vaginal examination, radiography of the abdomen to establish the presence of kittens, and abdominal ultrasonography to ascertain fetal heart rates. Generally speaking, fetal heart rates less than 150 beats per minute indicate fetal distress, and cesarean section is advised to reduce neonatal mortality and queen morbidity. If available, uterine monitoring may be used to direct medical management of dystocia.

Colostrum is produced as long as 72 hours postpartum. Neonates should nurse within 1 hour of birth. The typical duration of lactation in the queen is 4 to 6 weeks, depending on the time of weaning. Lactational anestrus is typical in nursing queens; however, signs of estrus may occur as early as 2 weeks postpartum.

255.5.3 Care of the Partum Queen

During lactation the metabolic demand doubles. In the immediate postpartum period, many queens are reluctant to leave their kittens and may show transient anorexia. A continuous supply of palatable, easily digestible, calorie-dense food should be available, in addition to an ample supply of fresh water. If possible, the food and water should be placed in the queening box during the first week of lactation to encourage consumption. Postpartum lochial discharge is normal in the queen and should be scant and reddish brown. Nursing queens should be monitored closely for signs of illness, such as excessive or abnormal vaginal discharge (putrid odor, black or green color), fever, inappetence, vomiting, or diarrhea.

Involution in the queen varies between nursing and non-nursing queens. In the non-nursing queen, uterine size and tone return to those of a prepartum queen by 4 weeks postpartum. In the nursing queen, continued hyperinvolution occurs, resulting in a uterus similar in tone and thickness to that seen during ovarian quiescence.[22]

255.6 PARTURIENT AND PERIPARTURIENT PRESENTATIONS

255.6.1 Neonatal Care

Please refer to Chapter 256.

255.6.2 Uterine Torsion

There are several reports of uterine torsion in the queen (Figure 255-9). Uterine torsion should be considered a possible problem in any queen seen in late pregnancy or during parturition with dystocia, abdominal pain, or hypovolemic shock.[23] Medical stabilization is essential to reduce mortality. Intravenous colloids may be indicated for blood volume expansion. In addition, pain relief, antimicrobial therapy, and plasma products may be indicated. After stabilization, exploratory celiotomy permits definitive diagnosis, and surgical ovariohysterectomy is curative.

255.6.3 Retained Placenta

Any excessive, malodorous vaginal discharge in the postpartum queen is abnormal. Placental retention should be a considered in any queen with a fever and increased or purulent, foul-smelling vaginal discharge in the immediate postpartum period. The diagnosis of retained fetal membranes is best made by means of ultrasonographic evaluation of the uterus, because owner observations may be unreliable. In these cases, abdominal ultrasonography reveals uterine horn distension and focal hyperechoic intrauterine contents in association with a retained placenta. Medical therapy, consisting of administration of PGF_2-α (Lutalyse), 0.1 mg/kg given subcutaneously once a day for 3 to 5 days, is typically effective. Concurrent antimicrobial administration is indicated in queens with a fever or marked leukocytosis.

255.6.4 Metritis

Acute metritis may occur in association with retained fetal membranes or as a result of ascending bacterial infection in the immediate postpartum period. Clinical signs of metritis include anorexia, fever, vomiting, kitten neglect, decreased milk production, and a purulent, sanguineous vaginal discharge. Medical therapy with PGF_2-α (Lutalyse) and antimicrobials may be attempted, providing that the queen is stable and the cervix is open.

255.6.5 Prolapsed Uterus

Uterine prolapse has been reported in the queen (Figure 255-10). Queens suspected of having uterine prolapse should be examined promptly to reduce desiccation and trauma to the exposed tissue. Manual replacement of the uterus can be attempted; however, because repeated prolapse tends to occur, ovariohysterectomy is advised.

Figure 255-9 Torsion of a gravid uterine horn. (Courtesy Dr. Gerald Ling, University of California, Davis.)

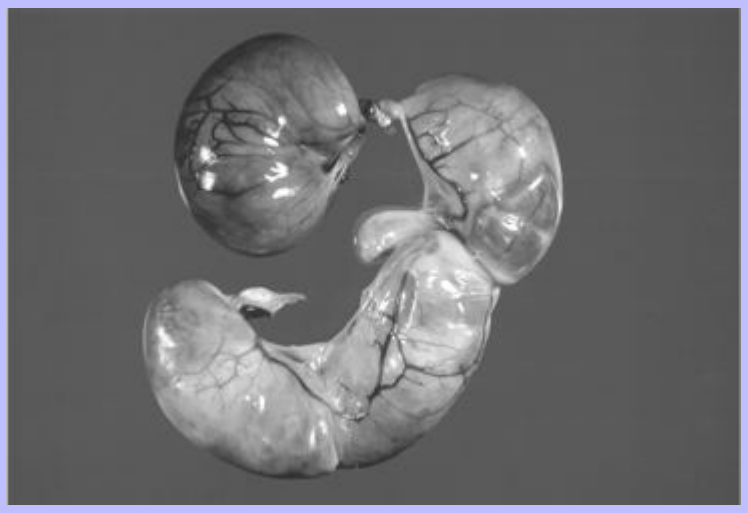

Figure 255-10 Uterine prolapse in a cat. (Courtesy Dr. Richard Nelson, University of California, Davis.)

255.6.6 Hypocalcemia

Hypocalcemia (eclampsia) may occur early in lactation as a result of the sudden increase in calcium loss associated with milk production. Clinical signs include incoordination, stiff gait, facial pruritus, muscle fasciculation, hyperthermia, and seizure activity. The diagnosis is based on clinical observations in the

lactating queen. Immediate medical therapy consists of slow intravenous administration of 2 to 5 mL of 10% calcium gluconate over 5 minutes. Repeated administration may be required to achieve resolution of clinical signs. The electrical activity of the heart should be monitored during intravenous calcium administration to evaluate for arrhythmia. Long-term therapy should include daily calcium carbonate supplementation (TUMS, 500 mg/day). If necessary, kittens should be prevented from nursing and should be hand raised after receiving colostrum.

255.6.7 Mastitis

Inflammation and subsequent bacterial infection of the mammary glands during lactation are common. Clinical signs include anorexia, lethargy, fever, and vomiting. Neonates may have diarrhea. Affected glands appear red and swollen and are warm and painful. Palpation may reveal firm areas associated with inflammation. The milk expressed from the affected glands may be grossly purulent and red or grayish, and the queen's body temperature may be increased. The most common bacterial isolates include *Enterobacter* sp., staphylococci, and streptococci. Medical treatment, consisting of warm compresses, stripping of the affected mammary glands, and administration of broad-spectrum antibiotics usually is curative. In severe cases, when inflammation results in tissue necrosis, surgical debridement may be required.

255.7 ASSISTED REPRODUCTION

255.7.1 Electroejaculation

Although male cats may be trained to ejaculate using an artificial vagina, most client-owned cats presented for semen collection are untrained. Semen collection and evaluation in the untrained tomcat are best achieved using electroejaculation techniques with the cat under general anesthesia. Many drugs commonly used for sedation in the cat interfere with urethral sphincter function. When electroejaculation is performed, urine contamination negatively affects the quality of the ejaculate. The preferred drug combination for electroejaculation in the cat is ketamine and xylazine. An alternate option, in a cooperative tom that permits placement of an intravenous catheter, is a constant-rate infusion of propofol. In a recent study, a propofol infusion was shown to have a minimal impact on urethral sphincter function in dog; however, studies in the cat have not been completed.[24]

1706

1707

Once sedated, tomcats are placed in lateral recumbency, and a well-lubricated rectal electroejaculation probe of appropriate size is inserted into the rectum. The penis should be gently exteriorized and held in the normal caudal orientation for semen collection. For electroejaculation in the carnivore, probes with longitudinal electrodes are preferred.[25] The rectal probe is connected to a standard electroejaculator unit capable of measuring voltage and amplitude. The standard electroejaculation regimen uses a total of 80 electrical stimuli delivered in three series, consisting of 30 (series 1: 10 stimulations at 2, 3, and 4 V), 30 (series 2: 10 stimulations at 3, 4, and 5 V), and 20 (series 3: 10 stimulations at 4 and 5V) stimulations.[25]

Care should be taken to ensure light ventral pressure to maximize ejaculate yield. Semen should be collected in plastic supplies prewarmed to body temperature.

255.7.1.1 Semen Evaluation

Evaluation of the ejaculate should include determination of the semen volume, pH, and color, as well as the sperm count, percentage motility, progressive motility, gross morphology, and acrosomal integrity.[25] In comparison to the dog, cat ejaculate contains a higher concentration of spermatozoa (1.5 to 2×10^9/mL). Counts are best performed manually using a hemocytometer. The volume obtained varies with the skill of the person performing the electroejaculation; however, an ejaculate volume of 50 to 100 μL per series may be considered normal. The ejaculate should be cloudy. The normal pH of feline ejaculate is 7.4 to 8.3. Urine contamination is suggested by a yellow discoloration and is confirmed by a pH less than 7.4.

Immediately after collection, the ejaculate should be evaluated at body temperature for the percentage motility and progressive motility of sperm. Normal progressive motility of sperm in the cat is 50% to 80%. Sperm morphology is a commonly used indicator of fertility in the male. In general, lower fertility is thought to be associated with a higher percentage of morphologically abnormal spermatozoa and/or a lower percentage motility. However, studies evaluating the percentage of normal spermatozoa required for consistent fertility have not been completed.[26] The gross morphology of feline spermatozoa may be determined by fixing an ejaculate aliquot (20 μL) in 500 μL of glutaraldehyde (1% solution), followed by phase contrast light microscopic evaluation at ×1000.[25] If phase contrast microscopy is not available, morphologic assessment can be performed by staining an air-dried smear of ejaculate with Diff Quick. Some domestic cats consistently ejaculate a high proportion (greater than 50%) of morphologically abnormal spermatozoa without associated infertility.[27]

Evaluation of acrosomal integrity is a useful adjunct to semen evaluation because it is critical to the fertilization process. Examination of the unstained feline acrosome may be challenging because of the small size of spermatozoa (26 μm long). Acrosomal staining prior to evaluation may be done in the cat using the protocol described by Larson and Miller,[28] or it may be completed with phase microscopy if available.

255.7.2 Semen Freezing

Cryopreservation of feline semen is important for the preservation of genetically valuable animals. Although semen freezing in the cat is not routinely performed in private practice, electroejaculation and semen collection and evaluation for the tomcat are not difficult. Numerous protocols have been described for cryopreservation of feline spermatozoa, the details of which are outside the scope of this chapter.[29,30] Of importance is the susceptibility of feline spermatozoa to cold shock. To minimize damage, extreme care must be taken to ensure that everything that comes in contact with feline spermatozoa is at the same temperature as the sperm cells themselves. As a general rule, anything that is added to feline spermatozoa should be added slowly, with gentle mixing. Because of the high incidence of pyometra associated with feline artificial insemination, antimicrobials (commonly penicillin and streptomycin) typically are added prior to insemination.

255.7.3 Induction of Estrus and Induction of Ovulation in the Queen

Infrequently, induction of estrus may be required in the queen for artificial insemination with frozen semen or for queens that fail to exhibit clinically detectable signs of estrus. Induction of estrus in the sexually mature queen has been successfully achieved using exposure to long photoperiod or with administration of exogenous gonadotropins. Various protocols and dosing regimens have been described. Dosing regimens are described

per cat, because ovulatory response is not related to body weight. Typically, 100 to 200 IU of equine chorionic gonadotropin (ECG; Sigma Chemical Co., St. Louis, Missouri) is used to stimulate follicular development, and 100 to 150 IU of human chorionic gonadotropin (HCG; Sigma Chemical Co.) is used to stimulate final follicle maturation and ovulation.[31,32] Ovulation occurs approximately 24 to 36 hours after administration of HCG.

The authors' preferred protocol is ECG, 100 to 150 IU, given subcutaneously or intramuscularly on day 1, followed by HCG, 50 to 100 IU, given subcutaneously or intramuscularly 84 hours later. Insemination should be performed 2 to 3 days after HCG administration. Alternatively, cabergoline (5 µg/kg given orally every 24 hours) can be administered for a maximum of 15 days. Insemination should be performed on day 3 of estrus. Ovulation in the cat is compromised by preovulatory anesthesia. If artificial insemination is to be performed, it is important that ovulation occur prior to anesthesia or it may be inhibited. Because of the molecular size of exogenous gonadotropins, repeated administration may be associated with antibody formation and reduced ovarian response. The immunologic consequences of exogenous gonadotropin administration may be minimized by reducing the frequency and number of times they are used during an animal's reproductive life.

255.7.4 Artificial Insemination

Cervical patency varies during the feline estrous cycle. Vaginal insemination is readily achieved using a bulb-tipped, 20-gauge needle and 1 mL syringe. Blind transcervical catheterization under general anesthesia has also been described.[33] The suggested insemination dose for artificial insemination is 50 million progressively motile spermatozoa.

Laparoscopic insemination in felines is well described. The suggested insemination dose is 10 million progressively motile spermatozoa per uterine horn.

255.8 CONTRACEPTION

256 CHAPTER • 256 Care of the Neonate and Fading Pups

Gary C.W. England

The incidence of neonatal death is surprisingly high in domestic dogs born in pet homes and to private breeders. The incidence of stillbirth is 6% to 33% of all births, and the neonatal death rate ranges from 6% to 11%. Some of these cases can be attributed to genetic factors or dystocia, which can be difficult to avoid. However, in many such deaths, inappropriate or poor husbandry practices are the cause or a contributing factor. It is clear, however, that this need not be the case; in a survey of 1342 puppy births at the Guide Dogs for the Blind Association in the United Kingdom, the total rate for stillbirth and neonatal loss (up to 6 weeks of age) was less than 5%.

Understanding the challenges facing the fetus at the end of gestation and during parturition, as well as the normal biology of the neonate, enables the veterinarian and breeder to better deal with neonatal problems. This chapter discusses those challenges and methods that may be used to overcome them.

256.1 CHALLENGES TO THE FETUS AND NEONATE

A number of factors may affect the survival of the neonate by challenging (1) the fetus during late gestation, (2) the fetus at parturition, and (3) the neonate immediately after birth.

256.1.1 Fetal Challenges during Late Gestation

Any challenge that adversely affects fetal development and results in the birth of an underweight neonate is likely to influence the newborn's subsequent survival. In humans, low birth weight can result in immaturity of the cardiovascular system and other physiologic functions (Barker hypothesis),[1] and this likely is also true in the dog. Such influences may make the puppy more susceptible to subsequent challenges, such as hypoxia, hypothermia, and neonatal infections.

A small or underweight puppy may be the result of inappropriate nutrition or generalized debility of the dam, the parasite burden of the dam, specific or generalized placental lesions, or infection of the dam with agents that cross the placenta (e.g., canine herpes virus).

256.1.2 Challenges at Parturition

During the change from fetal to neonatal life, a number of significant challenges can arise that may compromise subsequent survival. For example, although uterine contractions are essential to propel the fetus into the birth canal, this process also creates the opportunity for a decrease in the placental blood supply, constriction of the umbilical vessels, and early placental separation. Most, if not all, pups are born with mild to moderate hypoxia and slight to severe acidosis. The acidosis is generally respiratory in origin, but a metabolic component also is often present. In an adult, acidosis usually results in increased respiratory effort to remove the excess carbon dioxide. However, this is not always observed in the neonate (which suggests that carbon dioxide is not such a potent stimulator of respiratory drive in the neonate as it is in the adult).

Also, body temperature declines rapidly after birth, because the wet neonate is born into an environment cooler than the maternal temperature. Although a brief period of hypothermia may actually be useful as a mechanism to protect against the effects of hypoxia, it is clear that persistence of hypothermia contributes to neonatal mortality. In the normal neonate, hypoxia and hypothermia are rapidly reversed and a stable state is

reached within 3 to 4 hours after birth. If the acid-base disturbance or hypothermia are maintained beyond this period, a fatal cycle of decline may ensue. Clearly, conditions such as dystocia (including, ultimately, cesarean operation) and poor mothering behavior prolong both hypoxia and hypothermia, resulting in increased neonatal mortality.

256.1.3 Neonatal Challenges

The common challenges met by the neonate are persistence of the previously mentioned hypoxia, as a result of a delay in the removal of fetal membranes or fluid by the dam; persistence of hypothermia, associated with a delay in drying of the neonate; and a cold or drafty environment. Poor mothering behavior by an inexperienced primiparous bitch may be the primary cause of both hypoxia and hypothermia.

Adequate intake of fluid is the next major hurdle for the neonate, not only because of the requirement to absorb colostrum (see discussion below) but also because adequate fluid maintenance is important for recovery from acidosis. Neonates have a relatively higher percentage of fluid in the extracellular space and relatively poorer renal function than do adults. This situation, combined with the neonate's ability to lose fluid because of a high surface area to body ratio, results in a greater susceptibility to changes in fluid balance for neonates compared to adults.

Furthermore, the neonatal immune system is incompletely developed until at least 10 days after birth, which makes newborns susceptible to bacterial and viral infection. The dog has an endothelial-chorial placenta that allows approximately 20% of passive immunity to be acquired by the fetus in the uterus. The remaining 80% of antibodies must be absorbed across the intestine within the first 24 to 48 hours of life. The absorption of immunoglobulin G (IgG) from colostrum decreases markedly after this time, because the ability of the intestinal wall to absorb intact proteins declines. Failure to consume sufficient colostrum during the interval when the intestinal wall is open to the absorption of intact protein seriously compromises the immune status of the neonate.

Neonates have limited reserves of body fat, and their ability to generate energy from precursors is poor. Also, because glycogen reserves are depleted shortly after birth (only limited storage of glycogen occurs), the neonate requires a prompt intake of energy. A short time without food can result in a significant hypoglycemia, particularly in neonates that have been hypoxic or hypothermic. In humans, it has been suggested that anoxia can reduce gut motility and result in abnormal uptake of ingested nutrients. Clearly, food intake can be restricted in its availability from the dam because of illness, poor mothering, poor milk production or letdown, or a large litter size. Several of these factors may occur concomitantly with hypoxia or hypothermia, compounding the problems.

1708

1709

The neonate may also be faced with a number of challenges from potential pathogenic organisms. In many cases these are normally commensal bacteria that become pathogenic in a debilitated animal. In some cases, primary pathogenic organisms are involved (e.g., canine herpes virus, discussed later).

256.1.4 Characteristics of Normal Neonates

Neonatal pups are unable to stand at birth, although they are quite mobile, using their front limbs to crawl. They normally spend 90% of the time asleep and cry only when they are disturbed or hungry. During normal sleep, pups make frequent small movements of the limbs, characteristic of rapid eye movement (REM) sleep.

The normal rectal temperature for the first week after birth is 32° to 34° C. Respiration should be regular and even, usually 15 to 40 breaths per minute. The heart rate is usually 200 to 220 beats per minute (bpm), and heart murmurs may be functional. The capillary refill time is normally 1 to 1.5 seconds.

Normal birth weight varies according to breed, with pups of most medium breeds weighing 200 to 300 g at birth. The birth weight of healthy neonates increases by 5% to 10% per day, and failure to achieve this weight gain may indicate poor health.

Pups are born with their eyes closed; separation of the upper and lower lids, with opening of the eyes, occurs at approximately 10 to 14 days of life.

256.2 OPTIMIZING NEONATAL SURVIVAL

It is clear that during late pregnancy, parturition, and the early neonatal period, a number of significant challenges arise that, if not overcome, can result in the ultimate demise of the neonate. Having an understanding of these challenges allows the veterinarian or breeder to manage the pregnant, parturient, and nursing bitch and her litter so as to reduce subsequent mortality.

256.2.1 Care of the Bitch Before and During Pregnancy

Prior to mating, due consideration should have been given to routine anthelmintic treatment, although this does not necessarily reduce the potential for transplacental infection with *Uncinaria* sp. or transplacental and transmammary infection with *Toxocara* organisms. If a significant problem has been identified in a kennel, daily oral administration of 25 mg/kg fenbendazole from day 40 of gestation until 2 days past whelping may reduce transmission to the fetus.

During pregnancy, voluntary food intake usually increases; however, the body condition score of the bitch should be examined to ensure that she is not too fat or too thin. It is normal to increase the amount of food offered in the last 20 days of pregnancy, at which time a diet consisting of at least 30% protein, 18% fat, and 20% to 30% carbohydrate is suitable. At whelping the bitch will be eating 60% more food than usual. Obesity during pregnancy and poor nutrition both can contribute to poor neonatal survival, resulting in fetal oversize or lactational problems and fetal undersize, respectively.

One week prior to anticipated parturition, the bitch should be encouraged to accept a nest in a suitable environment. This should be a warm, clean, draft-and damp-proof room that can be heated. The room is best isolated from the main thoroughfare of the household. Ideally, the bed should be large enough to allow the dam to stretch, and it should provide sufficient room for a large litter. The sides should be high enough to prevent the puppies from escaping until they are approximately 4 weeks old.

In the last week of pregnancy, it is prudent to record the bitch's rectal temperature at least twice daily to detect the prepartum hypothermia that precedes the onset of parturition by 24 to 36 hours. This decline in body temperature is mediated by a sudden reduction in the serum progesterone concentration. The rectal temperature usually changes from approximately 39° C to less than 37° C.

256.2.2 Care of the Bitch at Parturition

Careful monitoring of the bitch at parturition can reduce neonatal mortality by reducing the risk of hypoxia and hypothermia and ensuring adequate intake of colostrum. Education of the whelping attendant is essential

to ensure that this individual understands the normal stages and time sequence of parturition. Uterine activity can be monitored by observation of the bitch's abdomen when she is relaxed, but monitoring is more accurate if external monitoring devices, such as a tocodynomometer, are used.[2]

Prompt veterinary attention should be sought if evidence of any form of dystocia arises. It is not possible to give definitive guidelines for every potential case of dystocia, but veterinary examination is warranted in certain situations, such as when the bitch (1) has exceeded 70 days from the last mating and has no signs of impending parturition; (2) is unsettled and strains forcefully but infrequently; (3) shows signs of straining, which then cease; (4) has a black/green vulval discharge with no signs of parturition; (5) shows a decline in rectal temperature but parturition has not commenced within 48 hours; (6) has been straining ineffectually for 1 hour or longer; (7) has produced the last pup more than 2 hours previously but still is restless; and (8) has produced the last pup more than 2 hours ago, and a larger litter is expected.

256.2.3 Care of the Neonate

The first essential steps after the pup's birth are to establish a clear airway, stimulate respiration, dry and warm it, and encourage it to suck. Normally this is achieved by the dam licking and nuzzling the pup. Young or maiden bitches may need help and encouragement with the immediate licking and cleaning. Failure of this behavior to occur, for whatever reason, can be catastrophic.

It is essential that a clear airway be established as soon as a fetus has been born. If human help is required, this involves removing the surrounding fetal membranes and clearing the mouth and nose of fetal fluid with either a dry towel or a small pipette. Gentle compression of the chest usually establishes respiratory effort. If this does not occur but the heart is beating, respiratory stimulation should continue by means of rubbing of the thorax and removal of more fluid by gently swinging the neonate in a small arc (however, the latter course should be avoided unless absolutely necessary because of the risk of brain trauma). In certain cases, administration of a respiratory stimulant (e.g., doxapram hydrochloride) may be efficacious, as may administration of oxygen. If respiration does not commence, artificial respiration can be attempted. This should be done carefully so as to induce only slight lung expansion and not overinflate the lungs. If the heart is not beating, external cardiac massage combined with artificial respiration may be attempted.

The umbilicus should be cut approximately 3 cm from the fetal abdomen; excessive bleeding can be prevented by application of a ligature.

Once regular respiratory efforts are maintained, the neonate may be placed in a prewarmed box or incubator until it is active, at which point it may be returned to the dam and encouraged to suck. Sucking normally occurs immediately after birth and at intervals of 2 to 3 hours for the first few days. 1709 1710

Hypothermia is a major cause of neonatal mortality, therefore the environmental temperature is a critical factor. Because neonates are unable to regulate their own temperature for the first week of life, they rely on the dam and other neonates for warmth. A chilled neonate does not respond normally or move properly, nor is it able to suck; this may cause the dam to neglect it, exacerbating the problem. The whelping area should be heated to 25° to 30° C for the first few days. This temperature may be almost unbearable for the dam, but it can be safely reduced to approximately 24° C after this time. It is most important that the litter be kept well away from any drafts.

The area where parturition and rearing are to take place is also a concern. Although it is important that this room not be near a thoroughfare, it is beneficial for socialization of the puppies if noise can be heard, such as

from a washing machine, a radio, or people talking. The room should be of sufficient size to allow the growing puppies to play and, where possible, to have access to an outside area.

256.2.4 Care of Older Neonates

During the first few weeks of life, the dam normally takes care of the needs of the litter. Nevertheless, the pups should be examined regularly. It is most important to assess for the general demeanor, weight gain, and general characteristics of healthy neonates described previously.

Normally the dam licks the neonate's perineal region to stimulate it to defecate and urinate. After the first 2 to 3 weeks, pups urinate and defecate voluntarily, which increases the amount of soiling in the whelping bed. The environment should always be kept clean, warm, and dry.

An important neonatal assessment is the correct rate of development. At 10 to 14 days, a pup's eyes should open, and it gradually should become able to focus on objects. It also should gain strength and begin to crawl around.

256.2.5 Artificial Rearing of Neonates

For a number of reasons, some or all of the litter may need to be reared artificially; such reasons include the death of the dam, the birth of a large litter, a sick dam, poor mothering ability, eclampsia, or inadequate milk production. When possible, artificial rearing is best avoided. A good alternative is to foster the pups onto another dam, such as a lactating bitch that has just whelped and lost its litter or a bitch with pseudopregnancy. With an excessively large litter, it may be possible to alternate some of the litter between artificial rearing and rearing by the dam. Whenever possible pups should remain in the nest with the dam to ensure normal socialization.

It is essential that all neonates receive colostrum from the dam to ensure an adequate uptake of immunoglobulins. If the dam has died, it may still be possible to express some colostrum from her as long as it is not contaminated with drugs or toxins. Colostrum from a different species may be used as an alternative to bitch colostrum, although the antibody protection offered is limited. Despite this, some nonspecific defense against infectious agents may be afforded by compounds such as lysozyme, lactoferrin, oligosaccharides, and lactoperoxidases.[3] Furthermore, some evidence indicates that the lipid-dependent antimicrobial activity present in bovine milk may be effective in the neonatal puppy.[3] Clearly, the best alternative is to store colostrum for such a possibility by freezing or to purchase a commercially available preparation. Some veterinarians claim reasonable success with the technique of subcutaneously injecting the neonate with serum from vaccinated dogs.[4]

With artificial rearing, consideration must be given to the nutritional requirements of the neonate. An important factor that is often overlooked is the changing composition of mammary secretions during lactation.

The optimum milk protein concentration, total lipid concentration, and milk fatty acid and amino acid composition vary markedly among the different species, and it is not appropriate to substitute milk from another species, at least on a long-term basis. The preferred option is to use a commercially manufactured milk replacer because of the quality and consistency of these products. The milk should be warmed to body temperature (approximately 34°C) and should be fed according to the manufacturer's instructions, with regard to the pup's body weight and age.

Artificial rearing is both demanding and time-consuming, especially if rearing is undertaken entirely without the bitch. Pups normally feed every 2 to 4 hours during the first 5 days of life, after which feeding declines to every 4 hours. Feeding can be achieved by using a commercial feeding kit, which contains a bottle and teat. This encourages normal sucking, but it can be time-consuming. The teat aperture should be large enough to prevent the pup from sucking in air but small enough to prevent the flow of excessive volumes of milk. Feeding can also be done with a dropper bottle or 2 mL syringe. In some cases it may be beneficial to use a stomach tube to feed the pups, especially during the first few days of life. This is especially useful for sick neonates or when the litter is large and the attendant faces time constraints.

As previously discussed, neonates do not voluntarily urinate or defecate until 2 to 3 weeks of age. In the absence of the dam, the perineal region must be stimulated every 3 to 4 hours with a moistened piece of cotton to ensure normal voiding.

256.3 SICK PUPPIES

256.3.1 Known Causes of Mortality

Pups may fail to thrive and ultimately die for many reasons, including poor husbandry, maternal factors (e.g., illness and poor nutrition, which usually result in low birth weight pups), congenital defects, problems at parturition (usually dystocia, resulting in anoxia or hypoxia), poor mothering behavior, trauma, immune insufficiency, and infection with viruses, bacteria, or parasites. These causes, most of which were described previously (except for infectious causes), account for approximately 45% of all cases of neonatal mortality.

Infectious organisms are often given much prominence as the cause of neonatal death, although they account only for about 20% of mortality cases, depending on the country. Some infectious agents are specific pathogens, whereas others are opportunistic organisms that can colonize a compromised neonate. Specific examples of agents that can cause neonatal death include canine herpes virus, canine parvovirus, canine distemper virus, and some protozoa.

Exposure of an immunologically naive bitch to canine herpes virus during late pregnancy can result in abortion or in neonatal death, usually 7 to 21 days after birth. Earlier demise of the pups does not occur, and on this ground alone herpes virus infection can be differentiated clinically from true fading puppy syndrome (see below). Canine parvovirus type 1 may cross the placenta if the bitch is exposed in early pregnancy; although such disease is rare, it may result in resorption of the fetuses or in acute neonatal death 7 to 21 days after parturition. Infection with canine parvovirus type 2 may cause myocarditis in neonates, although this now is uncommon. Similarly, congenital infection with canine distemper virus is rarely seen.

Interestingly, a number of bacteria have been isolated from dead pups with peritonitis, pneumonia, pleuritis, and enteritis. These include beta-hemolytic streptococci, staphylococci, *Pasteurella* sp., *Escherichia coli,* *Campylobacter* sp., *Salmonella* sp. and, less commonly, *Ureaplasma* and *Mycoplasma* organisms. Most of these organisms are part of the commensal flora of the bitch's genital tract, and they cause disease only when the neonate has succumbed to one of the previously mentioned challenges. The inherent vulnerability of a neonate puts it at risk for colonization by these organisms, which may result in rapid death with few initial clinical signs.

Transplacental infection with *Toxoplasma gondii* is uncommon, although experimental infection may result in neonatal death. Similarly, although the incidence of natural transplacental transmission of *Neospora caninum* is unknown, experimental infection results in stillbirth with evidence of myocarditis. *Toxocara canis* infection

usually causes disease in pups over 2 weeks of age, by which time the worms have grown large enough to cause gastrointestinal obstruction or to migrate up the biliary tract and cause hepatitis.

256.3.2 Unknown Causes of Mortality (True Fading Puppy Syndrome)

In approximately 55% of pups that die, no specific cause can be determined; these pups are correctly termed *fading puppies*. Such pups usually have a normal birth weight but appear depressed and show poor sucking with persistent crying. The condition progresses to generalized weakness and ultimately to death, usually between day 3 and day 5 after birth.[5] Fading puppies usually have no macroscopic lesions (except often a small liver), no identifiable congenital defects, and no histologic lesions, and they simply have an absence of contents within the large and small intestine. They constitute a distinct category, separate from most other causes of neonatal death. These other "known" causes ultimately result in puppies that "fade," but most often from day 7 after birth onward.

Interestingly, Blunden et al.[6] found that true fading puppies (those with no other known cause) had significantly lower phosphatidylcholine components of lung surfactant than pups that died of known causes. Lung surfactant is required for normal respiratory adaptation and maintenance after birth. A significant reduction of surfactant is observed in sudden infant death syndrome in humans, and the low values in fading puppies suggest that faulty production of surfactant may similarly be involved in the etiology of this condition. In the normal animal, increased respiratory effort tends to stimulate surfactant production; it may be that pups with true fading puppy syndrome are born marginally hypoxic and, because carbon dioxide stimulation of respiration is absent, they do not breathe deeply; they thereby enter a downward spiral of low surfactant, hypoxia, failure to thrive, failure to suck, hypothermia and, ultimately, death.

Despite the clear difference in clinical presentation between true fading puppies and puppies with identifiable causes of disease, it is common for any puppy that becomes ill to enter a downward course of failure to feed, resultant dehydration, and death. Many veterinarians use the term "fading puppy" to describe this demise regardless of its cause.

256.3.3 Clinical Signs of Sick or Fading Puppies

True fading puppy syndrome generally is observed from day 2 after birth onward, and most such pups die between day 3 and day 5. The pups usually show progressive weight loss, depression (or occasionally unusual restlessness early in the disease process), persistent crying, failure to suck, generalized weakness, dehydration, hypothermia and, ultimately, death.

In conditions in which the cause of the illness is identifiable, ill health usually results in frequent crying, restlessness, and hypothermia, progressing to clinical signs of diarrhea and/or dyspnea with resultant dehydration or cyanosis and, ultimately, death, usually later than 7 days after birth. In certain circumstances some neonates are more chronically affected and fail to grow as expected prior to the onset of obvious clinical disease.

256.3.4 Consequences of Disease in Canine Neonates

Whatever the initial challenge, the inherent susceptibility of the newborn results in its ultimate demise. Neonates have poor mechanisms of thermoregulation, which leaves them susceptible to hypothermia. They are unable to shiver and have poor reserves of brown adipose tissue. Puppies have approximately one fifth the glomerular filtration ability of adults and almost twice the water requirement, which makes them susceptible

to dehydration. At birth, they have high red and white cell counts, which decline rapidly over the first week, and immature liver enzyme systems. The neonate's ability to regulate blood glucose concentration also is immature, and the newborn relies almost entirely on hepatic glycogen reserves over the first 24 hours. With prolonged parturition or a prolonged interval to feeding, the reserves may be exhausted, and hypoglycemia may complicate hypothermia.

256.3.5 Treatment of the Sick Puppy

256.3.5.1 Minor Disease

Any neonate with minor signs of disease (lethargy, slowness to feed, lack of weight gain) requires early supplemental feeding. If the intake of colostrum is a concern, a source of frozen-thawed or replacement colostrum should be given, as discussed earlier, preferably before day 3 of life. Thereafter milk supplements should be fed by stomach tube every 2 hours. During this early phase, it is essential that the pup's body temperature be maintained at approximately 34° C and the temperature should be recorded every few hours. The environmental temperature should also be monitored using a thermometer placed adjacent to the neonates and maintained at 25° C to 30° C. Adequate hydration should be ensured and can be estimated from recordings of weight gain (measured three times daily), by evaluation of the skin's elasticity, and by examination of the urine. Because normal neonatal urine is colorless, the presence of color in the urine may be a useful and simple indicator of dehydration. General nursing care also is important and should include regular perineal stimulation to ensure urinary and fecal voiding.

The use of antimicrobials may be considered in an ill neonate, not necessarily because of a primary infectious cause of the illness, but rather because a sick neonate is highly susceptible to colonization from otherwise commensal organisms. A commonly used antibiotic is clavulanic acid–potentiated amoxicillin, administered at a dosage of 12.5 to 25 mg/kg given orally twice daily.

256.3.5.2 Significant Disease

In a neonate with anything other than mild clinical signs, rapid and aggressive treatment is essential, including oxygen administration, fluid therapy, and administration of broad-spectrum antimicrobial agents.[7] Despite such treatment, the mortality rate can be high. Absence of feeding, dehydration, or other clinical signs are indicators for immediate initiation of aggressive treatment.

If significant disease is suspected, it is important that a regimen of rigorous clinical examination and evaluation every 4 hours be established; it should include recording of the rectal temperature, assessment of the mucous membrane color and capillary refill time, recording of the respiratory and heart rates, and evaluation of skin elasticity and urine color. At specific points in time, evaluation of blood hematology and biochemistry may be useful. Many pups are hypoglycemic, and a rapid evaluation can be done by placing a drop of blood on a glucose reagent stick.

It is important that normal laboratory values be interpreted with respect to the age of the neonate (Table 256-1), because the hematologic and biochemical parameters of neonates differ significantly from those of adults.

An incubator or a homemade oxygen tent system can provide an oxygen-enriched environment for the pup. *1711*
Alternatively, a tracheal catheter can be placed, a technique that is especially useful for pups with *1712*

concomitant upper respiratory tract problems. Oxygen administration can help overcome hypoxia, and artificial ventilation may be useful for reversing acidosis and encouraging the production of lung surfactant.

Table • 256-1 Normal Hematologic and Biochemical Values for Neonatal Pups (Birth to 8 Weeks Old)

PARAMETER	0 TO 2 WEEKS	2 TO 4 WEEKS	4 TO 8 WEEKS
RBC ($\times 10^6$/uL)	3.4–6	3.5–4.8	4.5–6.8
Hb (g/dL)	9–12.6	8.5–8.9	8.4–9.5
PCV (%)	32–50	25–30	26–40
MCV (fL)	65–90	50–80	65–75
MCH (pg)	21–30	16–25	20–30
MCHC (%)	32–35	32–35	30–33
WBC ($\times 10^3$/uL)	9–25	8–16.5	10–18.9
ALT (IU/L)	20–300	10–30	10–50
AST (IU/L)	20–250	10–50	15–30
ALP (IU/L)	200–10,000	150–500	100–150
TP (g/dL)	3.5–5.5	3.5–4.5	4–5
Alb (g/dL)	1.5–3	1–2	2–3
Glucose (mg/dL)	50–150	60–150	60–250

RBC, Red blood cell concentration; *Hb,* hemoglobin concentration; *PCV,* packed cell volume; *MCV,* mean corpuscular volume; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *WBC,* total white blood cell concentration; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *ALP,* alkaline phosphatase; *TP,* total protein; *Alb,* albumin.

Pups with pale mucous membranes and a slow capillary refill time (greater than 2.0 seconds) usually are at least 10% dehydrated. This fluid deficit must be replaced, in addition to the ongoing maintenance requirement. Fluid requirements for general maintenance are approximately 60 to 180 mL/kg/day. In a small number of neonates, fluid may be replaced by oral administration of electrolytes; however, in most pups, fluids must be provided by intravenous, intraperitoneal, or intraosseus administration.

256.3.5.2.1 Intravenous catheter placement may be difficult in a dehydrated neonate.

An over-the-needle catheter should be used whenever possible, because this is the easiest type to keep in position for long periods. However, human neonatal scalp catheters may be technically easier to place in small vessels. It is always worthwhile to spend some time ensuring adequate venous access, and although surgical cut down onto a vein initially may seem to lengthen the procedure, in the long-term it often is the most sensible option. The cephalic vein is most often catheterized, although because of the short length of the neonate's leg, kinking of the catheter is common. Catheterization of the jugular vein is better. With catheter placement, care must be taken to perform appropriate sterile preparation of the site to avoid introducing organisms or providing a focus of infection.

In the consideration of which fluids are most suitable for administration, it is sensible in most cases to assume that acidosis is a factor. The safest fluid replacement, therefore, is lactated Ringer's solution (although the neonate has reduced hepatic function and may be unable to metabolize lactate into bicarbonate), which is given with added maintenance potassium (20 mmol/L). Ideally the acid-base and electrolyte status should be established, although this may be difficult. If the acidosis is likely to be severe, bicarbonate may be given; administration of 2 mmol/kg over 2 to 4 hours is recommended if specific acid-base data are not available.

Once the ideal fluid has been selected, it is important that ongoing maintenance and current deficits be estimated. Normal principles of the estimation of fluid deficit apply; as a rough guide for immediate replacement, 1.5 mL can be administered per 50 g of body weight. In many neonates the total fluid volume to be administered is small, and it may be useful to consider administration via a syringe pump to avoid overhydration. Intraperitoneal administration may be used if venous access is difficult or if ongoing monitoring to ensure successful intravenous administration is likely to be inadequate. The most appropriate intraperitoneal dosing scheme is to provide fluids in three boluses at approximately 8-hour intervals. The risk of accidental puncture of viscera is relatively small, although repeated needle placement poses a risk of sepsis. Despite the relative merits of this technique, intraperitoneal fluids may be relatively slowly absorbed, especially in hypovolemic neonates. In reality, it is preferable to ensure adequate venous access.

If access to a vein is not possible, fluids may be administered by the intraosseus route.[8] In the neonate, access normally is provided via the trochanteric fossa of the proximal femur or the flat medial aspect of the proximal tibia (distal to the tibial tuberosity). The hair should be clipped and the site prepared aseptically. A standard 18-to 20-gauge needle (size and length vary, depending on the pup's size) is used to push longitudinally into medullary cavity. In some cases the cortical bone is sufficiently soft to allow the use of an intravenous over-the-needle catheter. Repeated puncture is not advised, because holes in the cortical bone allow fluid leakage; however the catheter may be left in position for up to 72 hours. Thereafter a new catheter should be placed in a different bone. Fluid and drugs can be administered via the needle at rates similar to those for intravenous infusion.

In some neonates hypovolemia may be complicated by sepsis, and the resultant combination of problems can be catastrophic. Although the use of corticosteroids in neonates with hypovolemic and septic shock remains controversial, short-acting intravenous agents (e.g., methylprednisolone sodium succinate) are the drugs of choice. Septic shock may result in further depletion of glycogen reserves, increased peripheral use of glucose, and decreased gluconeogenesis, resulting in hypoglycemia. In such animals, additional bolus glucose therapy can be provided by using a 5% dextrose solution mixed 50:50 with the lactated Ringer's solution or by giving 1 to 2 mL of 10% glucose intravenously.[9]

In certain circumstances, specific drug therapy may be considered, including administration of vitamin K_1 for pups with signs of hemorrhage, or administration of doxapram hydrochloride for pups with poor respiratory effort (or in an attempt to increase surfactant production). In human neonates, it is common to administer a surfactant (phospholipids, neutral lipids, and hydrophobic surfactant–associated proteins B and C from calf lungs) via the intratracheal route in an attempt to modify alveolar surface tension and thus stabilize the alveoli.[10] This treatment is combined with conventional mechanical ventilation or high-frequency oscillatory ventilation. Because in dogs with true fading puppy syndrome there appears to be an abnormality of lung surfactant composition, a similar treatment may be useful but currently is untested.

Broad-spectrum antimicrobials frequently are administered to neonates with significant illness. In these cases it is not appropriate to wait for culture and sensitivity results; however, it is sensible to collect bacteriologic samples prior to drug administration to allow concomitant processing, which may result in a change in the selected antimicrobial once the results have been obtained. Culture of whole blood is recommended. When drug administration is considered, confusion often arises over products that are given to the dam and excreted in milk. A drug's concentration in milk depends on its lipid solubility,

blood protein binding capacity, and pKa; however, in general less than 5% of the maternal dose reaches the milk.

256.4 INVESTIGATION OF NEONATAL LOSS

It is important to ensure an accurate diagnosis of neonatal loss. All stillborn pups and those that die shortly after birth should undergo a detailed postmortem examination that includes appropriate bacteriologic, virologic, and histologic testing. The bodies should be chilled rather than frozen and then transported to an appropriate pathology facility.

256.5 PREVENTIVE HEALTH CARE PROGRAMS

A preventive health care program should be planned for the differing circumstances of each breeder.[11] In principle, this program should include broad-spectrum anthelmintic therapy, which commences at 3 weeks of age and is repeated 2 weeks later. Fecal examination to determine the parasite burden can modify the subsequent treatment regimen. Immunization of puppies with appropriate vaccines (canine distemper, parvovirus, adenovirus type II, and parainfluenza) should be initiated at 6 to 9 weeks of age. The precise choice of vaccine depends on the preference of the veterinarian and the particular circumstances of the client.

256.6 CONCLUSION

Acquiring an understanding of the common challenges facing the neonate may help the veterinarian and breeder to reduce perinatal loss. In the absence of detailed research work into the physiology of birth adaptation, generic management strategies should be followed to ensure the health of the bitch during pregnancy and the care of the neonate during parturition and the first few weeks of life. When neonatal problems occur, rapid and aggressive supportive therapy is mandatory, as is proper investigation of all cases of neonatal mortality.

257 CHAPTER • 257 Renal Disease: Clinical Approach and Laboratory Evaluation

Stephen P. DiBartola

257.1 DEFINITIONS

Azotemia is defined as an increased concentration of nonprotein nitrogenous compounds in the blood, usually urea and creatinine. *Prerenal azotemia* is a consequence of reduced renal perfusion (e.g., severe dehydration, heart failure), and *postrenal azotemia* results from interference with excretion of urine from the body (e.g., obstruction, uroabdomen). *Primary renal azotemia* is caused by parenchymal renal disease. The term *renal failure* refers to the clinical syndrome that occurs when the kidneys are no longer able to maintain their regulatory, excretory, and endocrine functions, resulting in retention of nitrogenous solutes and derangements of fluid, electrolyte, and acid-base balance. Renal failure occurs when 75% or more of the nephron population is nonfunctional. The term *uremia* refers to the constellation of clinical signs and biochemical abnormalities associated with a critical loss of functional nephrons, including the extrarenal manifestations of renal failure (e.g., uremic gastroenteritis, hyperparathyroidism). The term *renal disease* refers to the presence of morphologic or functional lesions in one or both kidneys regardless of extent.

257.2 CLINICAL APPROACH

The clinician should try to answer the following questions:

- Is renal disease present?
- Is the disease glomerular, tubular, interstitial, or some combination of these?
- What is the extent of the renal disease?
- Is the disease acute or chronic, reversible or irreversible, progressive or nonprogressive?
- What is the current status of the animal's renal function?
- Can the disease be treated?
- What nonurinary complicating factors are present and require treatment (e.g., infection, electrolyte and acid-base disturbances, dehydration, obstruction)?
- What is the prognosis?

The diagnosis of renal disease begins with a careful evaluation of the history and physical examination findings.

257.2.1 History

A complete history should be taken, including signalment (age, breed, sex), presenting complaint, husbandry, and review of body systems. The history of the presenting complaint should include information about the onset (acute or gradual), progression (improving, unchanging, or worsening), and response to previous therapy. Information about husbandry includes the animal's immediate environment (indoor or outdoor), use

(pet, breeding, show, or working animal), geographic origin and travel history, exposure to other animals, vaccination status, diet, and information about previous trauma, illness, or surgery.

Questions relating to the urinary tract include those about changes in water intake and the frequency and volume of urination. The owner should be questioned about pollakiuria, dysuria, or hematuria. Care must be taken to distinguish dysuria and pollakiuria from polyuria and to differentiate polyuria from urinary incontinence. The distinction between pollakiuria and polyuria is important, because polyuria may be a sign of upper urinary tract disease, whereas pollakiuria and dysuria usually are indicative of lower urinary tract disease. Nocturia may be an early sign of polyuria but also can occur as a result of dysuria. Normal urine output ranges from 20–40 mL/kg/day in dogs and cats.

Information about the initiation of urination and the diameter of the urine stream may be helpful, because animals with partial urethral obstruction may have difficulty initiating urination or may have an abnormal urine stream. If hematuria is present, the owner should be questioned about its timing. Blood at the beginning of urination may indicate a disease process in the urethra or genital tract. Blood at the end of or throughout urination may signify a problem in either the bladder or the upper urinary tract (kidneys or ureters).

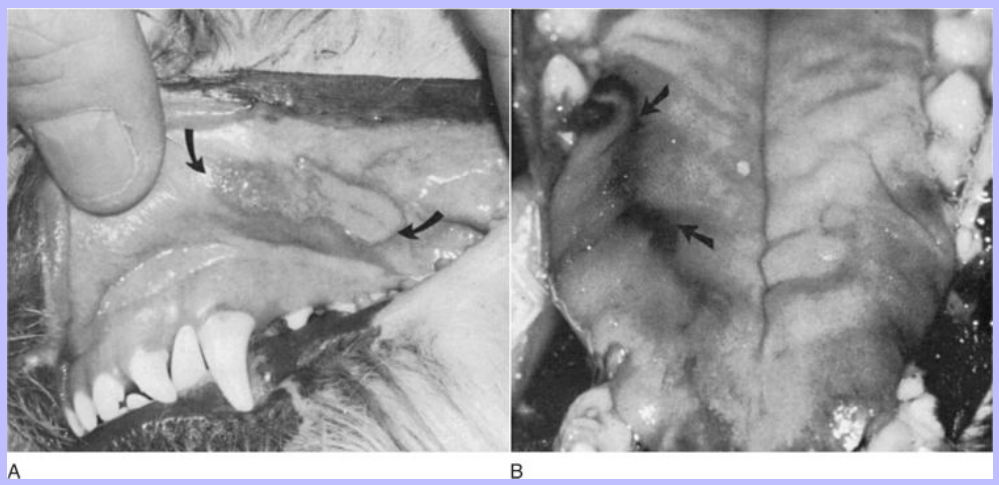
Polydipsia usually is more easily detected by owners than polyuria. Water intake should not exceed 60–80 mL/kg/day in dogs and 40 mL/kg/day in cats. It is helpful to describe amounts in quantitative terms familiar to the owner, such as cups (approximately 250 mL) or quarts (approximately 1 liter). The owner should be questioned about exposure of the animal to nephrotoxins, such as ethylene glycol in antifreeze, Easter lily (cats only), aminoglycosides (e.g., gentamicin), and nonsteroidal anti-inflammatory drugs (e.g., flunixin meglumine, ibuprofen). Also, it should be determined whether the animal has received any drugs that could cause polydipsia and polyuria (e.g., glucocorticoids, diuretics).

257.2.2 Physical Examination

A complete physical examination (including fundic and rectal examinations) should be performed. Careful attention should be paid to hydration status and to whether ascites or subcutaneous edema is present, because these may accompany nephrotic syndrome (i.e., glomerular disease). The oral cavity should be examined for ulcers, tongue tip necrosis, and pallor of the mucous membranes (Figure 257-1). The presence of retinal edema, detachment, or hemorrhage or of vascular tortuosity should be noted during fundic examination. Occasionally, severe hypertension secondary to renal disease results in acute onset of blindness due to retinal detachment. Young, growing animals with renal failure may develop marked fibrous osteodystrophy, characterized by enlargement and deformity of the maxilla and mandible (so-called rubber jaw), but this is rare in older dogs with renal failure.

Both kidneys can be palpated in most cats and the left kidney in some dogs. Kidneys should be evaluated for size, shape, consistency, pain, and location. Unless empty, the bladder can be palpated in most dogs and cats. The bladder should be evaluated for degree of distension, pain, wall thickness, and presence of masses, both intramural (e.g., tumors) and intraluminal (e.g., calculi, clots). In the absence of obstruction, a distended bladder in a dehydrated animal suggests abnormal renal function or administration of drugs that impair urinary concentrating ability (e.g., glucocorticoids, diuretics). The prostate gland and pelvic urethra are evaluated by rectal examination. The penis should be exteriorized and examined and the testes palpated. A vaginal examination is performed to evaluate for abnormal discharge and masses and to assess the appearance of the urethral orifice.

Figure 257-1 **A,** Buccal ulcer. Uremic ulcers often are found in tissue overlying teeth *(arrows)*. Oral ulceration is most commonly observed in dogs with primary (intrinsic) renal azotemia. **B,** Tongue margin necrosis. This lesion may occur in dogs with acute or chronic azotemia.



257.2.3 Differentiation of Acute from Chronic Renal Failure

Acute renal failure (ARF) sometimes can be difficult to distinguish from chronic renal failure (CRF). However, differentiation is crucial, because ARF potentially is reversible, whereas CRF is not. The history, physical examination findings, renal size, and hematocrit can be helpful in making this distinction. The kidneys are small (but can be normal sized and occasionally even enlarged) in CRF but are normal sized (or slightly enlarged) in ARF. A history of previous polyuria and polydipsia is often (but not always) found in patients with CRF. Physical examination findings such as weight loss and poor haircoat suggest CRF but are not always present. Likewise, nonregenerative anemia often but not always is found in patients with CRF.

Due to the development of renal secondary hyperparathyroidism in CRF, ultrasonography of the parathyroid glands may be helpful in the differentiation of CRF from ARF. In one study, the parathyroid glands of normal dogs and of dogs with ARF and CRF were evaluated using a 10 MHz linear-array, high-resolution transducer.[1] As expected, the maximal measured length of the parathyroid glands in dogs with CRF (3.9 to 8.1 mm) was greater than that for normal dogs (2 to 4.6 mm) and dogs with ARF (2.4 to 4 mm). Although measurements overlapped somewhat among groups, parathyroid gland ultrasonography may be helpful in the differentiation of ARF and CRF. Parathyroid gland size appeared to be related to the body weight of the dog.

Urea can dissociate into isocyanic acid, which in turn can react nonenzymatically with the terminal valine residue of hemoglobin to form carbamylated hemoglobin. The amount of carbamylated hemoglobin present is related to the severity and duration of azotemia. Carbamylated hemoglobin concentrations are higher in dogs with renal failure than in control dogs and higher in dogs with CRF than in those with ARF.[2,3]

257.3 LABORATORY EVALUATION OF RENAL FUNCTION

257.3.1 Glomerular Function

Evaluation of glomerular function is an essential part of the diagnostic approach in dogs and cats suspected of having renal disease, because the glomerular filtration rate (GFR) is directly related to functional renal mass. Determinations of the serum creatinine and blood urea nitrogen (BUN) concentrations are commonly used screening tests; the creatinine clearance test is useful in pets suspected of having renal disease that have normal BUN and serum creatinine concentrations. Plasma clearance of radioisotopes and renal scintigraphy are sophisticated techniques that may be used to determine the GFR and obtain information about kidney function but that do not require urine collection. Evaluation of urinary protein excretion allows assessment of primary glomerular disease (e.g., glomerulonephritis, glomerular amyloidosis).

257.3.1.1 Blood Urea Nitrogen

Urea is synthesized in the liver via the ornithine cycle from ammonia derived from amino acid catabolism. The amino acids used in the production of urea arise from the catabolism of exogenous (i.e., dietary) and endogenous proteins. Renal excretion of urea occurs by glomerular filtration, and the BUN concentration is inversely proportional to the GFR. Urea is subject to passive resorption in the tubules, and this occurs to a greater extent at slower tubular flow rates, which occur during dehydration and volume depletion. Thus urea clearance is not a reliable estimate of the GFR. With significant vascular volume depletion, decreased urea clearance may occur without a decrease in the GFR.

1717

1718

The production and excretion of urea do not proceed at a constant rate. These two processes increase after a high-protein meal, therefore an 8-to 12-hour fast is recommended before measurement of the BUN concentration to avoid the effect of feeding on urea production. Gastrointestinal bleeding can increase the BUN concentration, because blood represents an endogenous protein load. In 52 dogs with hematemesis, melena, or both, the BUN concentrations and BUN to creatinine ratios were significantly higher than in age-matched control dogs; this suggests that gastrointestinal hemorrhage contributes to an increased BUN concentration in dogs as a consequence of increased gastrointestinal absorption of nitrogenous compounds.[4] Clinical conditions characterized by increased catabolism (e.g., starvation, infection, fever) also can increase the BUN concentration. Some drugs may increase the BUN concentration by increasing tissue catabolism (e.g., glucocorticoids, azathioprine) or by decreasing protein synthesis (e.g., tetracyclines), but these effects likely are minimal. On the other hand, the BUN concentration can be decreased by low-protein diets, anabolic steroids, severe hepatic insufficiency, or portosystemic shunting. These nonrenal variables limit the usefulness of the BUN concentration as an indicator of the GFR. The normal BUN concentrations are 8 to 25 mg/dL in the dog and 15 to 35 mg/dL in the cat.

257.3.1.2 Serum Creatinine

Creatinine is a nonenzymatic breakdown product of phosphocreatine in muscle, and daily production of creatinine in the body is determined largely by the muscle mass of the individual. Young animals have lower concentrations, whereas males and well-muscled individuals have higher concentrations. The serum creatinine concentration is not appreciably affected by diet. Creatinine is not metabolized and is excreted by the kidneys almost entirely by glomerular filtration. Its rate of excretion is relatively constant in the steady

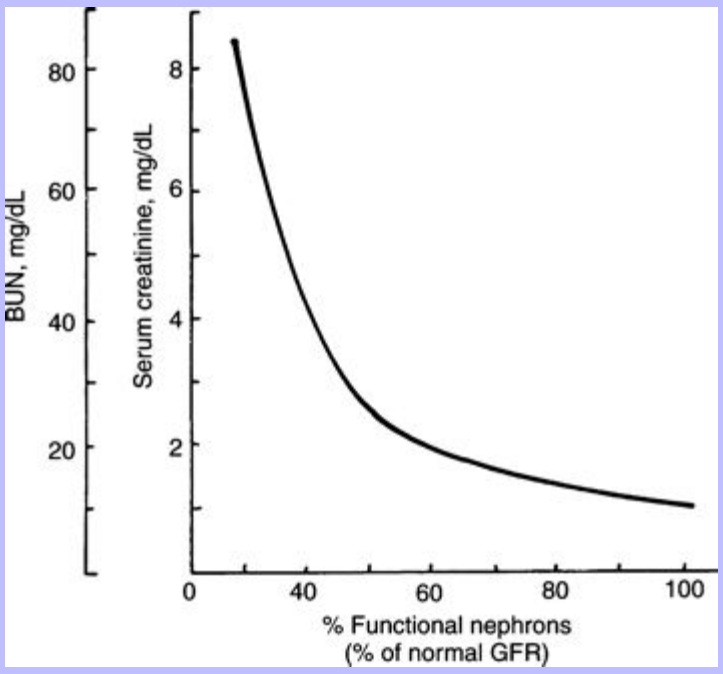
state, and the serum creatinine concentration varies inversely with the GFR. Thus *determination of creatinine clearance provides an estimate of the GFR*.

Creatinine is measured by the alkaline picrate reaction, which is not entirely specific for creatinine and which measures another group of substances collectively known as noncreatinine chromagens. These substances are found in plasma, in which they may constitute up to 50% of the measured creatinine at normal serum concentrations, but they normally do not appear in urine. As the serum creatinine concentration increases as a result of progression of renal disease and a declining GFR, the amount of noncreatinine chromagens remains unchanged and contributes progressively less to the total measured serum creatinine concentration. The normal serum creatinine concentrations are 0.3 to 1.3 mg/dL in the dog and 0.8 to 1.8 mg/dL in the cat.

The relationship of the BUN or serum creatinine concentration to the GFR is a rectangular hyperbola. The slope of the curve is small when the GFR is mildly or moderately decreased but large when the GRF is severely reduced (Figure 257-2). Therefore large changes in the GFR early in the course of renal disease cause small increases in the BUN or serum creatinine concentration, which may be difficult to appreciate clinically; on the other hand, small changes in the GFR in advanced renal disease cause large changes in the BUN or serum creatinine concentration. The inverse relationship between the serum creatinine concentration and the GFR is valid only in the steady state.

When nonrenal variables have been eliminated from consideration, an increase in the BUN or serum creatinine concentration above normal implies that at least 75% of the nephrons are not functioning (see Figure 257-2). Neither the cause nor the reversibility of this malfunction can be predicted from the increase in the BUN or serum creatinine concentration. Also, the increase in the BUN or serum creatinine concentration cannot be used to predict whether azotemia is prerenal, primary renal, or postrenal in origin, or to distinguish between acute and chronic, reversible and irreversible, and progressive and nonprogressive processes. The BUN/creatinine ratio in prerenal and postrenal azotemia may be increased as a result either of increased tubular resorption of urea at lower tubular flow rates or of easier absorption of urea than creatinine across peritoneal membranes in animals with uroabdomen. A decrease in the BUN/creatinine ratio often follows fluid therapy, reflecting a decrease in tubular resorption of urea rather than an increase in the GFR.

Figure 257-2 Relationship of blood urea nitrogen (BUN) or serum creatinine concentration to percentage of functional nephrons. (From Chew DJ, DiBartola SP: Manual of Small Animal Nephrology and Urology. New York, Churchill Livingstone, 1986.)



257.3.1.3 Cystatin C

Cystatin C is a small polypeptide protease inhibitor that is freely filtered by the glomeruli. It does not undergo tubular secretion, and filtered cystatin C is almost completely resorbed by the proximal tubular cells and catabolized to its constituent amino acids. Cystatin C is produced at a constant rate in all tissues, and its excretion is not dependent on age, gender, or diet. As a result, the serum concentration of cystatin C may serve as a useful marker of the GFR. Some concern exists that the serum cystatin C concentration may be affected by the presence of inflammation or neoplasia.

Recently, two studies evaluated normal dogs and dogs with renal failure using an immunoturbidometric assay designed to measure the serum concentration of human cystatin C.[5,6] The serum concentration of cystatin C in normal dogs was found to be approximately 1 mg/dL.

257.3.1.4 Creatinine Clearance

The renal clearance of a substance is that volume of plasma that would have to be filtered by the glomeruli each minute to account for the amount of that substance appearing in the urine each minute. The renal clearance of a substance that is neither resorbed nor secreted by the tubules is equal to the GFR. For such a

substance in a steady state, the amount filtered equals the amount excreted. Thus: GFR × P_x = U_x × V. Dividing both sides of the equation by P_x gives the familiar clearance formula (U_xV/P_x), which in this case is equal to the GFR.

Creatinine is produced endogenously and excreted by the body largely by glomerular filtration, and its clearance can be used to estimate the GFR in the steady state. Numerous studies in the dog and cat have shown that *endogenous* creatinine clearance in these species is 2 to 5 mL/min/kg. Values for glomerular function tests in the dog and cat are presented in Table 257-1.

In chronic progressive renal disease, urinary concentrating ability is impaired after two thirds of the nephron population have become nonfunctional, whereas azotemia does not develop until three fourths of the nephrons have become nonfunctional. Thus the main indication for determination of *endogenous* creatinine clearance is the clinical suspicion of renal disease in a pet with polyuria and polydipsia that has normal BUN and serum creatinine concentrations. The only requirements for determination of *endogenous* creatinine clearance are accurately timed urine collection (usually 12 or 24 hours), determination of body weight, and an assessment of the serum and urine creatinine concentrations. Failure to collect all urine produced erroneously reduces the calculated clearance value.

To eliminate the inaccuracy caused by noncreatinine chromagens, some investigators have advocated use of *exogenous* creatinine clearance. In this procedure, creatinine is administered subcutaneously or intravenously to increase the serum creatinine concentration approximately tenfold and to reduce the relative effect of noncreatinine chromagens. *Exogenous* creatinine clearance values exceed endogenous creatinine clearance values and closely approximate inulin clearance in the dog. In one study, the inulin and *exogenous* creatinine clearances were nearly identical in dogs. The creatinine/inulin clearance ratio was not altered by ablation of 50% to 94% of renal mass and was not affected by gender, dietary protein intake, or duration of time after renal ablation.[7] *Endogenous* creatinine clearance is a reliable estimate of the GFR only when methodology specific for true creatinine is used.[8] In cats, *exogenous* creatinine clearance may be slightly lower than inulin clearance.

257.3.1.5 Single Injection Methods for Estimating the Glomerular Filtration Rate

Single injection plasma clearance methods using inulin, iohexol, or creatinine have been used in dogs and cats with normal and reduced renal mass to estimate the GFR.[9–14] With these methods, the plasma clearance of a substance that is not bound to plasma proteins and is excreted only by glomerular filtration (e.g., inulin, iohexol, creatinine) is calculated as the quotient of the administered dose divided by the area under the plasma concentration versus time curve. This technique has the advantage of not requiring collection of urine, but its accuracy depends on the pharmacokinetic model used to calculate the area under the curve and the timing and number of samples used to make the calculation. The advantages and limitations of single injection plasma clearance methods for evaluation of the GFR were recently reviewed.[15]

Table • 257-1 Tests of Glomerular Function in Dogs and Cats

PARAMETER	DOG	CAT
Blood urea nitrogen (mg/dL)	8–25	15–35
Serum creatinine (mg/dL)	0.3–1.3	0.8–1.8
Serum cystatin C (mg/dL)	0.5–1.5	Not available
Endogenous creatinine clearance (mL/min/kg)	2–5	2–5
Exogenous creatinine clearance (mL/min/kg)	3–5	2–4
24-Hour urine protein excretion (mg/kg/day)	<20	<20
Urine protein to urine creatinine ratio (U_{Pr}/U_{Cr})	<0.4	<0.4

257.3.1.6 Radioisotopes

Radioisotopes (e.g., ^{125}I-iothalamate or ^{131}I-iothalamate, ^{51}Cr-ethylenediaminetetraacetic acid [EDTA], ^{99m}Tc-diethylenetriamine penta-acetic acid [DTPA]) also have been used to estimate the GFR in dogs and cats using both plasma clearance and dynamic renal scintigraphic methods. The plasma clearance approach has the same advantages and limitations as described above for iohexol or exogenously administered creatinine; procedures involving radioisotopes require technical expertise and equipment available primarily at referral institutions. Methods using ^{99m}Tc-DTPA to estimate the GFR are clinically useful because the short half-life of ^{99m}Tc (6 hours) allows the animal to be released within 24 to 48 hours after the procedure.

The percentage of an injected dose of ^{99m}Tc-DTPA extracted by the kidneys over a finite period correlates well with inulin clearance (the gold standard for estimation of the GFR). A major advantage of dynamic renal scintigraphy is that it provides information about individual kidney function; however, in dogs with renal disease, this method correlates less well with inulin clearance than does the plasma clearance method.[16] Renal scintigraphy is less accurate than plasma clearance methods for several reasons. A brief sampling period (usually 1 to 3 minutes after injection) is used in dynamic renal scintigraphy to avoid loss of radioactivity as urine is excreted from the kidneys into the ureters and bladder. In a recent study, the ideal time for counting radioactivity during ^{99m}Tc-DTPA renal scintigraphy in normal dogs was found to be 30 seconds to 2 minutes after injection.[17] Data acquired over such a short period may not accurately reflect the animal's steady state GFR. Other factors that contribute to potential inaccuracy include characteristics of the gamma camera itself (e.g., field uniformity, linearity, spatial resolution), the selection of renal and background regions of interest, and renal depth correction.[18] Partial obstruction can delay excretion of the tracer from the kidneys and lead to overestimation of the GFR. Despite these limitations, dynamic renal scintigraphy is helpful in clinical situations when information about individual renal function is important. Nuclear imaging with ^{99m}Tc-DTPA has been used to determine the GFR in normal dogs[19] and dogs with renal disease[20] and in normal cats and cats with renal dysfunction.[21,22]

Quantitative renal scintigraphy[23] and determination of plasma disappearance after single injection[24] using ^{99m}Tc-mercaptoacetyltriglycine have been used to estimate renal plasma flow in dogs. Hepatic uptake of ^{99m}Tc-mercaptoacetyltriglycine in cats may limit the value of this tracer for evaluation of renal plasma flow in this species.[25]

257.3.1.7 Urine Protein to Creatinine Ratio

In animals with persistent proteinuria on routine urinalysis, the severity of the proteinuria may be assessed by measuring 24-hour urine protein excretion or by performing a urine protein to urine creatinine ratio (U_{Pr}/U_{Cr}). A normal value for 24-hour urine protein excretion in dogs and cats is less than 20 mg/kg/day. 1719
Dogs with primary glomerular disease (e.g., glomerulonephritis, glomerular amyloidosis) often have markedly increased 24-hour urine protein excretion values, and those with amyloidosis generally have the highest 24-hour urine protein excretion values.[26,27] 1720

Determination of the U_{Pr}/U_{Cr} eliminates the necessity of a 24-hour urine collection and has been shown to correlate closely with 24-hour urine protein excretion in dogs[28] and cats.[29] Its value lies in the fact that, whereas both the urine creatinine and urine protein concentrations are affected by the total urine solute concentration, their ratio is not. The normal U_{Pr}/U_{Cr} in dogs and cats is less than 0.4. In dogs, U_{Pr}/U_{Cr} results are not affected by differences in gender, the method of urine collection, fasted versus fed states, or the time of day of collection.[30,31] Pyuria and marked blood contamination of urine samples can result in an abnormal U_{Pr}/U_{Cr} in the absence of glomerular disease.[32] Consequently, both the urine protein concentration and the U_{Pr}/U_{Cr} must be evaluated in conjunction with urinary sediment findings. Feeding of a high-protein diet or induction of renal failure increased 24-hour urine protein excretion and the U_{Pr}/U_{Cr} in cats,[33] and administration of prednisone to normal dogs increased the U_{Pr}/U_{Cr} from normal to a mean of 1.2 at 30 days and 0.9 at 42 days.[34] Values for 24-hour urine protein excretion and the U_{Pr}/U_{Cr} are presented in Table 257-1.

Dogs with proteinuria on screening urinalysis have been shown to have an increased U_{Pr}/U_{Cr}.[26,28,31,35] A high degree of overlap is found between dogs with glomerulonephritis and those with amyloidosis with regard to 24-hour urine protein excretion and the U_{Pr}/U_{Cr}.[26,27] Therefore renal biopsy remains the only reliable way to differentiate these two diseases.

257.3.1.8 Microalbuminuria

In humans, microalbuminuria is defined as excretion of 30 to 300 mg of albumin in urine per day, and its presence may be an early indicator of vascular endothelial damage.[36] Microalbuminuria is an established risk factor for progression of renal disease in humans with type 1 or type 2 diabetes mellitus.[37] Whether microalbuminuria is predictive of progressive renal disease in humans with essential hypertension is less certain, but it is associated with adverse cardiovascular events in this population.[38,39] Microalbuminuria in dogs has been defined as a urine albumin concentration of greater than 1 mg/dL but less than 30 mg/dL. Urine albumin concentrations in this range can be detected by an antigen-capture enzyme-linked immunosorbent assay (ELISA) (i.e., ERD-Screen Urine Test; Heska Corp., Fort Collins, Colorado).[40] In recent studies, the prevalence of microalbuminuria in normal healthy dogs was 19%, and the prevalence in a hospital population of dogs was 36%. Microalbuminuria has been detected in heartworm-infected dogs and in those with familial renal disease (e.g., soft-coated wheaten terriers with glomerular disease, male dogs with X-linked hereditary nephritis). The effect of pyuria on detection of microalbuminuria was found to be variable. It remains to be determined whether seemingly normal dogs with microalbuminuria are at

increased risk for the development of progressive renal disease. Sequential monitoring of dogs with documented microalbuminuria probably is warranted until this factor's prognostic value in otherwise normal dogs can be determined.

257.3.1.9 Bladder Tumor Antigen Test

The first-generation Bard bladder tumor antigen (BTA) test (i.e., V-BTA Test; Polymedco, Cortlandt Manor, New York) is a qualitative latex agglutination dipstick test run on voided urine that detects a glycoprotein antigen complex associated with bladder neoplasia in humans. In a prospective study of 65 dogs with transitional cell carcinoma and other urinary tract disorders, the Bard V-BTA Test had a sensitivity of 90% and a specificity of 78%.[41] False positives occurred in urine samples with marked proteinuria or glucosuria and in those with pyuria or hematuria. The high sensitivity of the test and its less reliable performance in the presence of pyuria and hematuria suggest that it would be most appropriately used as a routine screening test in geriatric dogs at risk for the development of transitional cell carcinoma.

In another study, the V-BTA Test reliably differentiated dogs with lower urinary tract neoplasia from normal dogs but did not reliably differentiate dogs with neoplasia from dogs with other abnormalities of the lower urinary tract.[42] The V-BTA Test is commercially available for veterinary use.

Second-and third-generation Bard BTA tests (BTA Stat and Bard Trak, respectively), as well as other tests that use monoclonal antibodies against human bladder tumor antigens, give false-negative results in dogs and should not be used.[41]

257.3.2 Tubular Function

The kidney is an organ of water conservation. Depending on the needs of the animal, the kidney can produce urine that is highly concentrated or quite dilute. Normal urinary concentrating ability depends on the ability of the hypothalamic osmoreceptors to respond to changes in plasma osmolality, the release of antidiuretic hormone (ADH) from the neurohypophysis, and the response of the distal nephron to ADH. In addition, medullary hypertonicity must be generated and maintained by the countercurrent multiplier and exchanger systems of the kidney, and an adequate number of functional nephrons must be present to generate the appropriate response to ADH. Laboratory tests of tubular function are summarized in Table 257-2.

257.3.2.1 Urine Specific Gravity and Osmolality

The total urine solute concentration is measured either by the urine specific gravity (USG) or the urine osmolality (U_{Osm}). The latter depends only on the number of osmotically active particles, regardless of their size. The *urine specific gravity* is defined as the weight of a solution compared with an equal volume of distilled water. It depends on both the number and molecular weight of the solute particles but has the advantage of requiring only simple, inexpensive equipment for measurement.

Table • 257-2 Tests of Renal Tubular Function in Dogs and Cats

TEST	DOG	CAT
Random urine specific gravity	1.001–1.070	1.001–1.080
Urine specific gravity after 5% dehydration	1.050–1.076	1.047–1.087
Urine osmolality after 5% dehydration (mOsm/kg)	1787–2791	1581–2984
Urine to plasma osmolality ratio after 5% dehydration	5.7–8.9	Not available
Fractional electrolyte clearance (%)		
Sodium	<1	<1
Potassium	<20	<24
Chloride	<1	<1.3
Phosphate	<39	<73

Modified from DiBartola SP: Clinical Evaluation of Renal Function. 16th Annual Waltham/OSU Symposium for the Treatment of Small Animal Disease. Vernon, California, Kal Kan Foods, 1992, p 10.

1720

1721

Normally, urine is composed of solutes of relatively low molecular weight (e.g., urea, electrolytes), and a roughly linear relationship exists between the urine osmolality and the urine specific gravity. The range of urine osmolality that corresponds to a given USG, however, may be relatively wide. If the urine contains appreciable amounts of larger molecular weight solutes (e.g., glucose, mannitol, radiographic contrast agents), these substances have a proportionally greater effect on specific gravity than on osmolality.

The term *isosthenuria* (USG of 1.007–1.015, U_{Osm} of 300 mOsm/kg) refers to urine of the same total solute concentration as unaltered glomerular filtrate. The term *hyposthenuria* (USG less than 1.007, U_{Osm} less than 300 mOsm/kg) refers to urine of lower total solute concentration than glomerular filtrate. Although rarely used clinically, the term *hypersthenuria (baruria)* (USG greater than 1.015, U_{Osm} greater than 300 mOsm/kg) refers to urine of higher total solute concentration than glomerular filtrate. The normal range of the total urine solute concentration for dogs and cats is wide (USG of 1.001 to 1.080). In a study of normal pet dogs, USG values were found to vary widely (from 1.006 to greater than 1.050).[43] Samples obtained in the morning had higher USG values than those obtained in the evening, and urine concentration decreased with age, but no effect of gender on the USG was detected.

257.3.2.2 Water Deprivation Test

The water deprivation test (WDT) is a useful test of tubular function and is indicated in the evaluation of animals with confirmed polydipsia and polyuria for which the cause remains undetermined after initial diagnostic evaluation. An expedient safe alternative to the WDT is DDAVP (synthetic ADH) trial therapy. Please see Chapter 28 for a discussion on this approach.

The water deprivation test usually is performed in animals with hyposthenuria (USG less than 1.007) that are suspected of having central or nephrogenic diabetes insipidus or psychogenic polydipsia. A dehydrated animal that has dilute urine has already failed the test and should not be subjected to water deprivation. In such an animal, failure to concentrate urine likely is due to structural or functional renal dysfunction or to the administration of drugs that interfere with urinary concentrating ability (e.g., glucocorticoids, diuretics). The water deprivation test also is contraindicated in animals that are azotemic. It should be performed with extreme caution in animals with severe polyuria, because such pets may rapidly become dehydrated during water deprivation if they have defective urinary concentrating ability.

At the beginning of the water deprivation test, the bladder must be emptied and baseline data collected (e.g., body weight, hematocrit, plasma proteins, skin turgor, serum osmolality, urine osmolality, USG). Water then is withheld, and these parameters are monitored every 2 to 4 hours. The urine and serum osmolalities are the best tests to follow, but osmolality results often are not immediately available to the clinician. Thus the USG and body weight assume the greatest importance for decision making during performance of the test. An increase in the total plasma protein concentration is a relatively reliable indicator of progressive dehydration, but increases in the hematocrit and changes in skin turgor are not reliable. The serum creatinine and BUN concentrations should not increase during a properly conducted water deprivation test.

Maximal stimulation of ADH release occurs after the loss of 3% to 5% of body weight. The test is concluded when the dog or cat either demonstrates adequate concentrating ability or becomes dehydrated, as evidenced by loss of 3% to 5% or more of its original body weight. It is important when weighing the animal to use the same scale each time and to empty the bladder at each evaluation.

The time required for dehydration to develop during water deprivation varies. Dehydration usually becomes evident within 48 hours in normal dogs and cats but in rare cases may require a longer time. Dogs with diabetes insipidus and psychogenic polydipsia usually become dehydrated after a much shorter period of water deprivation (less than 12 hours and usually less than 6 hours). By the time dehydration is evident, the USG usually exceeds 1.045 in normal dogs and cats. Failure to achieve maximal urinary solute concentration does not localize the level of the malfunction, and a structural or functional defect may be present anywhere along the hypothalamic-pituitary-renal axis. Furthermore, animals with medullary solute washout may have impaired concentrating ability regardless of the underlying cause of polyuria and polydipsia.

If urine osmolality has increased less than 5% or the USG has changed less than 10% for three consecutive determinations, or if the animal has lost 3% to 5% or more of its original weight, 0.1 to 0.2 U/lb of aqueous vasopressin (Pitressin) (up to a total dose of 5 U) or 5 μg of DDAVP may be given subcutaneously and the parameters of urinary concentrating ability monitored 2 to 4 hours after ADH injection. A further increase in urine osmolality after administration of ADH should not exceed 5% to 10% in normal dogs and cats.

257.3.2.3 Gradual Water Deprivation

Gradual water deprivation can be performed to eliminate diagnostic confusion caused by medullary solute washout. The owner can be instructed to restrict water consumption to 120 mL/kg/day 72 hours before, 90 mL/kg/day 48 hours before, and 60 mL/kg/day 24 hours before the scheduled water deprivation test. In dogs with psychogenic polydipsia, this promotes endogenous release of ADH, increased permeability of the inner medullary collecting ducts to urea, and restoration of the normal gradient of medullary hypertonicity. An alternate approach is to instruct the owner to reduce water consumption by approximately 10% per day over a 3-to 5-day period (but not to less than 60 mL/kg/day). This approach should be used only for animals that are otherwise healthy on initial clinical evaluation, and the owner should provide dry food *ad libitum* and weigh the dog daily to monitor for loss of body weight.

257.3.2.4 Fractional Clearance of Electrolytes

The extent to which electrolytes appear in the urine is the net result of tubular resorption and secretion. The fractional clearance of electrolytes can be used to evaluate tubular function and is defined as the ratio of the clearance of the electrolyte in question to that of creatinine:

$$FC_x = (U_xV/P_x)/(U_{Cr}V/P_{Cr}) = (U_xP_{Cr})/(U_{Cr}P_x)$$

where FC_x = fractional clearance of X; U_x = urine concentration of X; P_x = plasma concentration of X; U_{cr} = urine concentration of creatinine; P_{cr} = plasma concentration of creatinine; V = urine flow rate.

This ratio usually is multiplied by 100, and the fractional clearance value is expressed as a percentage. The advantage of this measurement is that a timed urine collection is not necessary. In normal animals, the fractional clearances of all electrolytes are much less than 1 (100%), implying net conservation, but values are higher for potassium and phosphorus than for sodium and chloride. Unfortunately, fractional excretion values calculated from "spot" urine samples are variable and do not correlate well with values calculated using 72-hour urine samples.[44]

The fractional clearance of sodium may be useful in the differentiation of prerenal and primary renal azotemia. In animals with prerenal azotemia and volume depletion, sodium conservation should be avid and the fractional clearance of sodium low (less than 1%). In animals with azotemia caused by primary parenchymal renal disease, the fractional clearance of sodium is higher than normal (greater than 1%). 1721 1722

Values for fractional electrolyte clearances have been reported for normal dogs,[45] dogs with CRF,[46] normal cats,[47,48] and cats with experimentally induced CRF.[49] Normal values for urinary fractional clearance of electrolytes are summarized in Table 257-2.

257.4 ROUTINE URINALYSIS

Urine for urinalysis may be collected by voiding (midstream sample), catheterization, or cystocentesis. Cystocentesis is preferred because it prevents contamination of the sample by the urethra or genital tract, it is simple to perform when the bladder is palpable, the risk of introducing infection is negligible, and it is well-tolerated by both dogs and cats. In animals to be evaluated for hematuria, however, it may be helpful first to evaluate a sample collected by voiding, because other methods of urine collection may add red blood cells to the sample as a result of trauma.

For urinalysis, fresh urine should be examined whenever possible. Refrigerated urine should be warmed to room temperature before the urinalysis is performed. The technique used to collect the sample should be noted, because this may influence the interpretation. Urinalysis is divided into three parts: physical properties, chemical properties, and sediment evaluation.

257.4.1 Physical Properties

257.4.1.1 Appearance

Normal urine is yellow as a result of the presence of urochrome pigment. Concentrated urine may be deep amber, and dilute urine may be almost colorless. A red or reddish brown color usually is due to red blood

cells, hemoglobin, or myoglobin; a yellow-brown to yellow-green color may be due to bilirubin. Normal urine usually is clear. Cloudy urine often contains increased cellular elements, crystals, or mucus. The most common abnormal odor is ammoniac and is due to the release of ammonia by urease-producing bacteria.

257.4.1.2 Specific Gravity

As mentioned before, the USG reflects the total solute concentration of the urine, and the amount of any substance in urine must be interpreted in light of the specific gravity. For example, 4+ protein in 1.010 urine represents more severe proteinuria than 4+ protein in 1.045 urine. The USG should be obtained before any treatment is given, because fluids, diuretics, or glucocorticoids may alter the specific gravity.

257.4.2 Chemical Properties

257.4.2.1 pH

Urine pH varies with diet and acid-base balance. The normal pH of urine in dogs and cats is 5.0 to 7.5. Causes of an acidic urine pH include a meat protein–based diet, administration of acidifying agents, metabolic acidosis, respiratory acidosis, paradoxical aciduria in metabolic alkalosis, and protein catabolic states. Causes of an alkaline urine pH include urinary tract infection by urease-positive bacteria, a plant protein–based diet, urine allowed to stand exposed to air at room temperature, postprandial alkaline tide, administration of alkalinizing agents, metabolic alkalosis, respiratory alkalosis, and distal renal tubular acidosis.

257.4.2.2 Protein

Randomly obtained urine samples from normal dogs contain small amounts of protein (up to 50 mg/dL). Commonly used dipstick methods for protein determination are much more sensitive to albumin than globulin. In the evaluation of proteinuria, it is critical to localize the origin of the protein loss by means of the history, physical examination, and critical evaluation of the urine sediment. Persistent, moderate to heavy proteinuria in the absence of urine sediment abnormalities is highly suggestive of glomerular disease (e.g., glomerulonephritis, glomerular amyloidosis). If the sediment is active and proteinuria is mild to moderate, the possibility of inflammatory renal disease or disease of the lower urinary or genital tract should be considered.

257.4.2.3 Glucose

Glucose in the glomerular filtrate is almost completely resorbed in the proximal tubules and is not normally present in the urine of dogs and cats. Glucose appears in the urine *(glucosuria)* if the blood glucose concentration exceeds the renal threshold (approximately 175 to 225 mg/dL in the dog and 250 to 350 mg/dL in the cat). Most dipstick tests use a colorimetric test based on an enzymatic reaction (glucose oxidase) specific for glucose. Causes of glucosuria include diabetes mellitus, stress or excitement in cats, administration of glucose-containing fluids, and renal tubular diseases, such as primary renal glucosuria and Fanconi syndrome. Glucosuria also may be observed occasionally in dogs and cats with chronic renal disease, those with tubular injury caused by nephrotoxins, and in some dogs with familial renal disease.

257.4.2.4 Ketones

Beta hydroxybutyrate, acetoacetate, and acetone are ketones, the products of exaggerated and incomplete oxidation of fatty acids. They are not normally present in the urine of dogs and cats. The nitroprusside reagent present in dipstick tests reacts with acetone and acetoacetate but is much more reactive with acetoacetate. It does not react with beta hydroxybutyrate. Causes of ketonuria include diabetic ketoacidosis, starvation or prolonged fasting, glycogen storage disease, a low-carbohydrate diet, persistent fever, and persistent hypoglycemia. Ketonuria occurs more readily in young animals, and of the causes listed above, diabetic ketoacidosis is the most important cause in adult dogs and cats.

257.4.2.5 Occult Blood

Dipstick tests for blood are sensitive but do not differentiate erythrocytes, hemoglobin, and myoglobin. These tests are more sensitive to hemoglobin than to intact erythrocytes; the former causes a diffuse color change, whereas the latter causes spotting of the reagent pad. A positive test result must be interpreted in light of the urine sediment findings (i.e., presence or absence of red blood cells). Free hemoglobin (secondary to hemolysis) is the most common abnormal pigment found in urine. Potential causes of hemolysis include transfusion reaction, autoimmune hemolytic anemia, disseminated intravascular coagulation, postcaval syndrome of dirofilariasis, splenic torsion, and heat stroke. Myoglobinuria is less common but may be present if severe rhabdomyolysis occurs (e.g., status epilepticus, crushing injury). For proper interpretation, the occult blood reaction must be considered together with the urine sediment findings (e.g., hematuria).

257.4.2.6 Bilirubin

Bilirubin is derived from the breakdown of heme by the reticuloendothelial system. It is transported to the liver, where it is conjugated with glucuronide and excreted in the bile. Only direct-reacting or conjugated bilirubin appears in the urine. The canine kidney can degrade hemoglobin to bilirubin, and the renal threshold for bilirubin is low in dogs. Thus in dogs with liver disease, bilirubin may be detected in the urine before its serum concentration is increased. It is not unusual to find small amounts of bilirubin in concentrated urine samples from normal dogs, especially males. Bilirubin is absent from normal feline urine. The causes of bilirubinuria are hemolysis (e.g., autoimmune hemolytic anemia), liver disease, extrahepatic biliary obstruction, fever, and starvation.

1722 1723

257.4.2.7 Leukocyte Esterase Reaction

Indoxyl released by esterases from intact or lysed leukocytes reacts with a diazonium salt and is detected as a blue color reaction after oxidation by atmospheric oxygen. This test is specific for pyuria in canine urine samples but has low sensitivity (produces many false-negative results).[50] In cats, the leukocyte esterase test was found to be moderately sensitive but highly nonspecific (produced many false-positive results) for the detection of pyuria.[51]

257.4.3 Urinary Sediment Examination

Depending on the criteria used for data analysis, as few as 3% or as many as 16% of dogs and cats with normal findings on physical and chemical evaluation of urine may have important urinary sediment

abnormalities (e.g., pyuria, bacteriuria, microscopic hematuria).[52] The sediment examination should be performed on fresh urine samples, because casts and cellular elements degenerate rapidly at room temperature. Urine should be centrifuged at 1000 to 1500 rpm for 5 minutes and the sediment then stained with Sedi-Stain (Becton Dickinson, Franklin Lakes, New Jersey) or examined unstained, depending on individual preference. In the evaluation of urine sediment, the method of urine collection must be kept in mind, because it influences the interpretation. The USG must also be kept in mind, because it influences the relative numbers of formed elements. The number of casts is recorded per low power field (lpf), and the numbers of red blood cells, white blood cells, and epithelial cells are recorded per high power field (hpf).

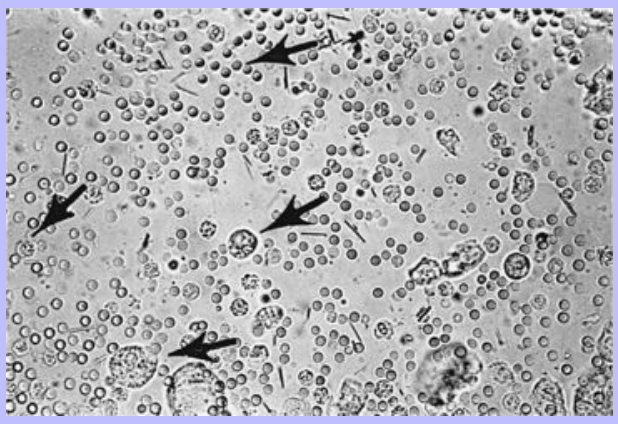
257.4.3.1 Red Blood Cells

Occasional red blood cells are considered normal in the urine sediment. Normal values are: voided sample, 0 to 8/hpf; catheterized sample, 0 to 5/hpf; and cystocentesis sample, 0 to 3/hpf. The presence of an excessive number of red blood cells in the urine is called *hematuria* (Figure 257-3), which may be microscopic or macroscopic. The causes of hematuria are summarized in Box 257-1.

257.4.3.2 White Blood Cells

Occasional white blood cells are considered normal in the urine sediment. Normal values are: voided sample, 0 to 8/hpf; catheterized sample, 0 to 5/hpf; and cystocentesis sample, 0 to 3/hpf. The presence of an increased number of white blood cells in the urine sediment is called *pyuria* (Figure 257-4) and, in an appropriately collected urine sample, is indicative of inflammation somewhere in the urinary tract. The presence of white blood cells does not help localize the lesion unless white cell casts are present, indicating renal origin. Urinary tract infection is the most common cause of pyuria, but genital tract contamination also may cause pyuria in voided or catheterized samples (Box 257-2).

Figure 257-3 Photomicrograph of an abnormal urine sample. Arrow at top indicates red blood cells (RBCs), arrow at left indicates a white blood cell (WBC), and central and bottom arrows indicate two different sizes of transitional epithelial cells. RBCs in urine may resemble those in blood or may shrink or swell in response to variations in urine osmolality.



257.4.3.2.1

Box • 257-1 Causes of Hematuria in Dogs and Cats

257.4.3.2.1.1

Urinary Tract Origin (Kidneys, Ureters, Bladder, Urethra)

Trauma

- Traumatic collection (e.g., catheter, cystocentesis)
- Renal biopsy
- Blunt trauma (e.g., automobile accident)

Urolithiasis

Neoplasia

Inflammatory disease

- Urinary tract infection
- Feline urologic syndrome (idiopathic feline lower urinary tract disease)
- Chemically induced inflammation (e.g., cyclophosphamide-induced cystitis)

Parasites

- *Dioctophyma renale*
- *Capillaria plica*

Coagulopathy

- Warfarin intoxication
- Disseminated intravascular coagulation
- Thrombocytopenia

Renal infarction

Renal pelvic hematoma

Vascular malformation

Renal telangiectasia (Welsh corgi)

Idiopathic renal hematuria

257.4.3.2.1.2 Genital Tract Contamination (Prostate, Prepuce, Vagina)

Estrus

Inflammatory, neoplastic, and traumatic lesions of the genital tract

257.4.3.3 Epithelial Cells

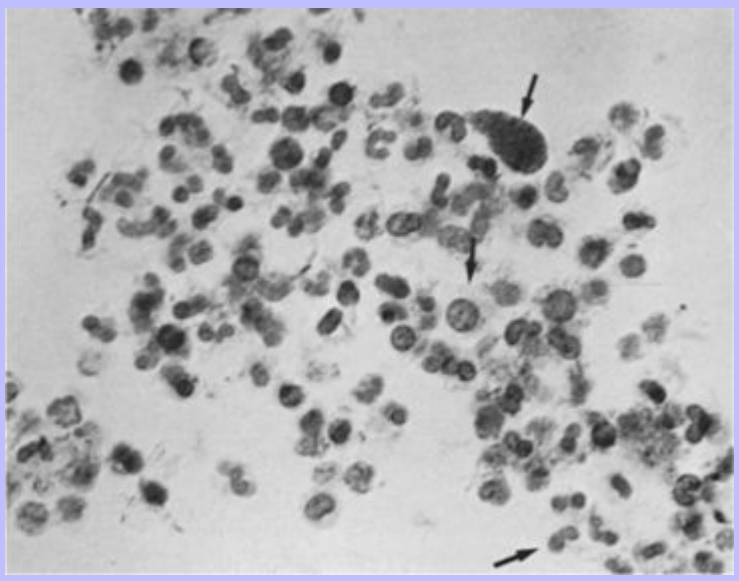
Both squamous and transitional epithelial cells may be found in the urine sediment, but they are often of little diagnostic significance. Squamous cells are large, polygonal cells with small round nuclei (Figure 257-5). They are common in voided or catheterized samples because of urethral or vaginal contamination. Occasional squamous cells are normal, and increased numbers may be present during estrus.

Transitional epithelial cells are variable-sized cells derived from the urothelium from the renal pelvis to the urethra (Figure 257-6). Although their size generally increases from the renal pelvis to the urethra, the finding of small transitional cells in the urine sediment does not have localizing value. Caudate cells are transitional cells with tapered ends thought to originate from the renal pelvis (Figure 257-7). Occasional transitional cells are normal, and increased numbers may be present with infection, irritation, or neoplasia of the urinary tract. Renal cells are small epithelial cells from the renal tubules, but their renal origin can be determined only if they are observed in cellular casts. Neoplastic epithelial cells are best identified using conventional blood cell stains (e.g., Wright-Giemsa).

1723

1724

Figure 257-4 Photomicrograph of an abnormal urine sample. White blood cells (WBCs) in urine are subject to degenerative changes that may complicate their identification. They may shrink in concentrated urine or swell in dilute urine. WBCs usually are one and one half to two times the size of red blood cells. Clumps of WBCs often are associated with infection. Occasional transitional epithelial cells also are present in this field. The arrow at bottom right indicates a neutrophil with a swollen cytoplasm and easily identifiable polymorphonuclear nucleus. Occasional transitional epithelial cells also are present *(top arrow)*.



257.4.3.4 Casts

Casts are cylindric molds of the renal tubules composed of aggregated proteins or cells. They form in the ascending limb of Henle's loop and the distal tubule because of the maximal acidity, highest solute concentration, and lowest flow rate in this area. The presence of casts in the urinary sediment indicates activity in the kidney itself and thus is of localizing value. Occasional hyaline (Figure 257-8) and granular (Figure 257-9) casts per low power field are considered normal. No cellular casts should be observed in sediment from normal urine. Excretion of an abnormal number of casts in the urine is called *cylindruria*.

1724

1725

257.4.3.4.1 Box • 257-2 Causes of Pyuria

257.4.3.4.1.1 Urinary Tract Origin (Kidneys, Ureters, Bladder, Urethra)

Infectious

- Urinary tract infection (e.g., pyelonephritis, cystitis, urethritis)

Noninfectious

- Urolithiasis
- Neoplasia
- Trauma
- Chemically induced (e.g., cyclophosphamide)

257.4.3.4.1.2 Genital Tract Contamination (Prostate, Prepuce, Vagina)

Figure 257-5 Photomicrograph of a squamous epithelial cell in the urine. Note the small nucleus, irregular cell shape, and folding of the cytoplasmic margins in some areas.

Figure 257-6 Photomicrograph of a raft of transitional epithelial cells in the urine.

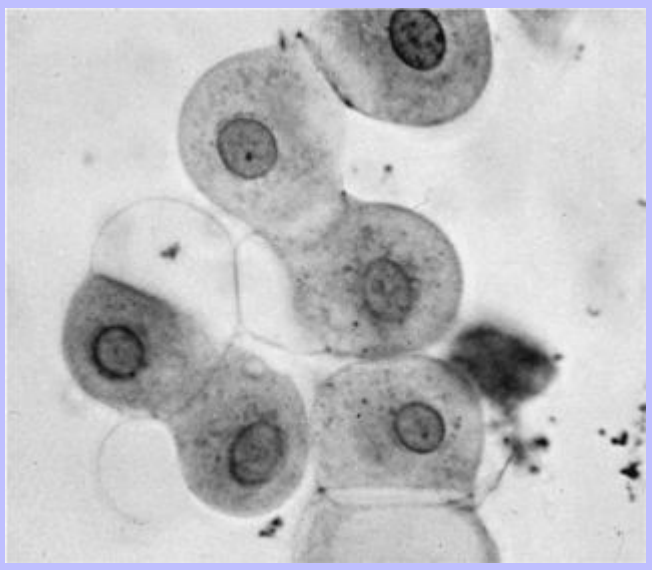


Figure 257-7 Photomicrograph of caudate epithelial cells in urine. The tails on these small epithelial cells suggest that they originated in the renal pelvis.

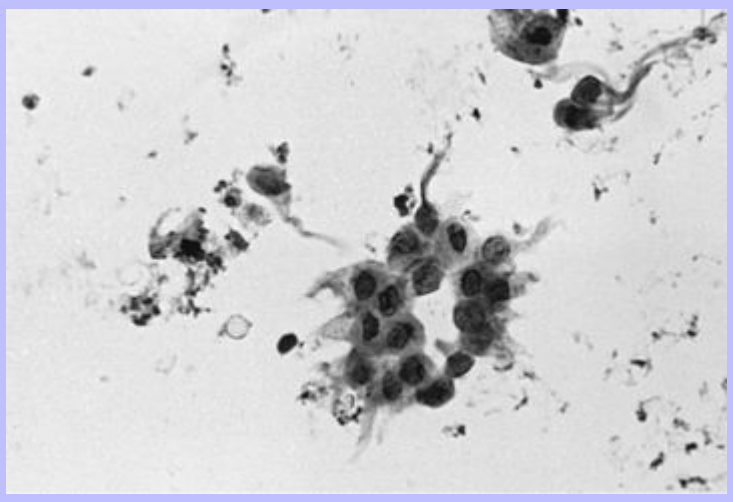

Figure 257-8 Photomicrograph of hyaline casts in urine. Note the transparent nature of these casts *(between arrows)*. The casts are easily missed because their optical density is very low, necessitating low illumination for optimal visualization. The darker cast in the center of the field is a waxy cast. Many lipid droplets are present in the background.

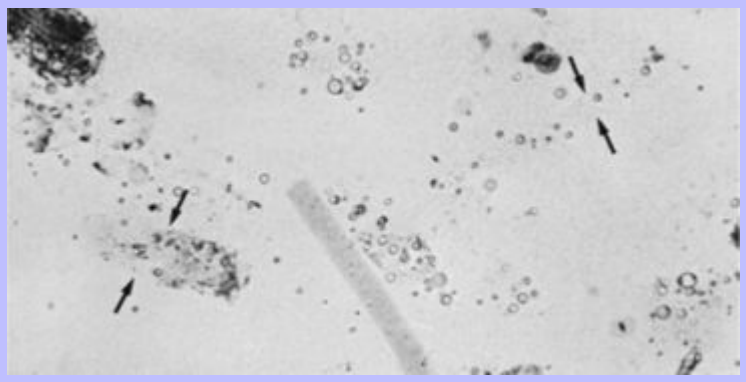

Casts observed in the urine sediment are categorized as hyaline, granular, cellular, or waxy. Hyaline casts are pure protein precipitates (Tamm-Horsfall mucoprotein and albumin). They are difficult to see and dissolve rapidly in dilute or alkaline urine. Small numbers of hyaline casts may be observed with fever or exercise. They are commonly seen in renal diseases associated with proteinuria (e.g., glomerulonephritis, glomerular amyloidosis).

Coarsely (Figure 257-10) and finely (see Figure 257-9) granular casts represent the degeneration of cells in other casts or precipitation of filtered plasma proteins and are suggestive of ischemic or nephrotoxic renal tubular injury. Fatty casts, a type of coarsely granular cast that contains lipid granules, may be seen in nephrotic syndrome or diabetes mellitus. Cellular casts include white cell or pus casts (suggestive of pyelonephritis) (Figure 257-11), red cell casts (fragile and rarely observed in dogs and cats), and renal epithelial cell casts (Figure 257-12) (suggestive of acute tubular necrosis or pyelonephritis). Waxy casts represent the final stage of degeneration of granular casts; they are relatively stable, and their presence suggests intrarenal stasis (Figure 257-13). They often are very convoluted and have cracks and blunt ends.

1725

1726

Figure 257-9 Photomicrograph of a finely granular cast in urine.

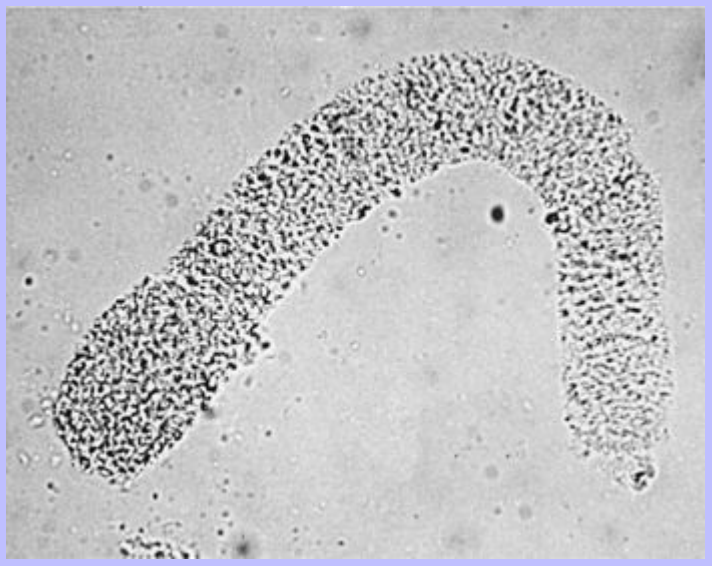

Figure 257-10 Photomicrograph of coarsely granular casts in urine. A "shower" of casts is seen in this field. The cast at the left contains coarse granules; the one on the far right is a cellular cast undergoing degeneration.

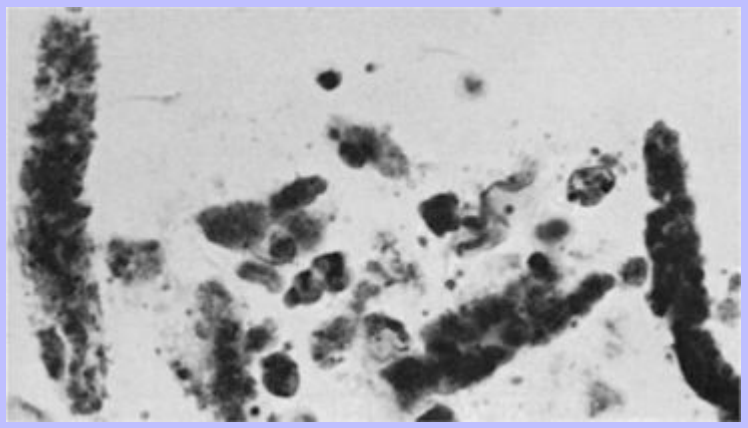

Figure 257-11 Photomicrograph of a white blood cell cast in urine. Neutrophils can be seen within this cast, and their presence suggests renal bacterial infection (i.e., pyelonephritis).

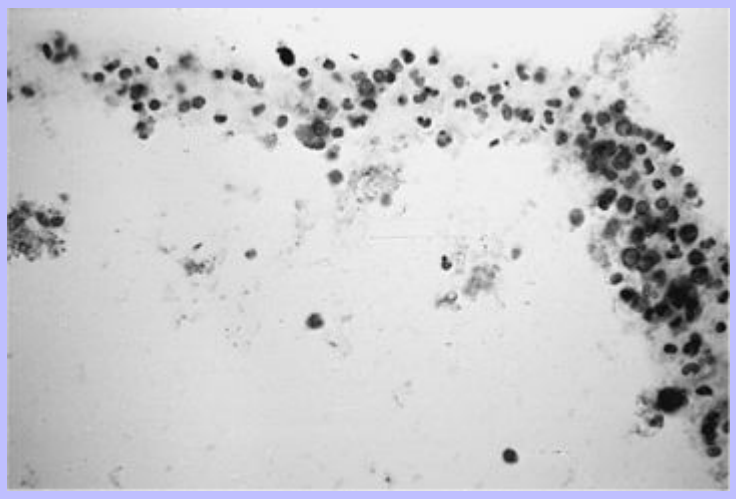

Figure 257-12 Photomicrograph of an epithelial cell cast in urine. Small renal epithelial cells can be identified in this cast *(white arrows)*. (Courtesy Nancy Facklam, nancy.facklam@gov.ab.ca)

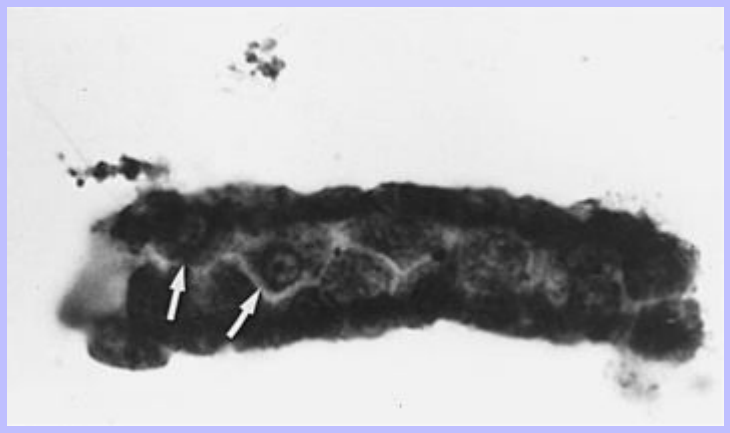

Figure 257-13 Photomicrograph of a urine sample containing waxy and granular casts. The cast at the left is waxy, whereas the others are granular. Note that the waxy cast is translucent, and the hyaline casts are transparent. Waxy casts are brittle and often have cracks or sharply broken ends.

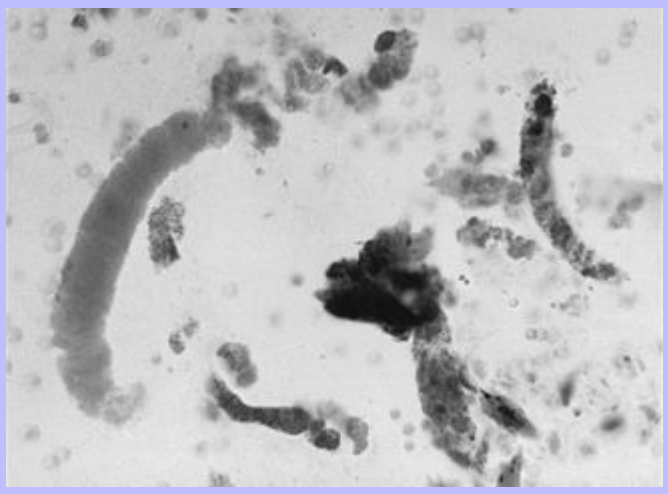

257.4.3.5 Organisms

Normal bladder urine is sterile. The distal urethra and genital tract harbor bacteria, and voided or catheterized urine samples may be contaminated with bacteria from the distal urethra, genital tract, or skin. Contamination from the urethra in voided or catheterized specimens usually does not result in large enough numbers of bacteria to be visualized microscopically in the urine sediment. If allowed to incubate at room temperature, however, these contaminants may proliferate. For these organisms to be readily apparent microscopically, there must be more than 10,000 rods or more than 100,000 cocci per milliliter of urine. The presence of large numbers of bacteria in urine collected by catheterization or cystocentesis suggests a urinary tract infection (Figure 257-14). Usually accompanying pyuria is seen. Particulate debris in the sediment may be confused with bacteria and cause false-positive results. Also, the bottle of stain may be contaminated with bacteria. Microscopic absence of bacteria in the sediment does not rule out urinary tract infection. Yeast and fungal hyphae in the sediment usually are contaminants.

Figure 257-14 Photomicrograph of a urine sample containing bacteria. Chains of bacterial rods are present in this field, as are red blood cells *(arrows)* and a large struvite crystal. Bacteria are most readily identified in urine when they are rods; they often are observed in association with clumped white blood cells or within white blood cells.

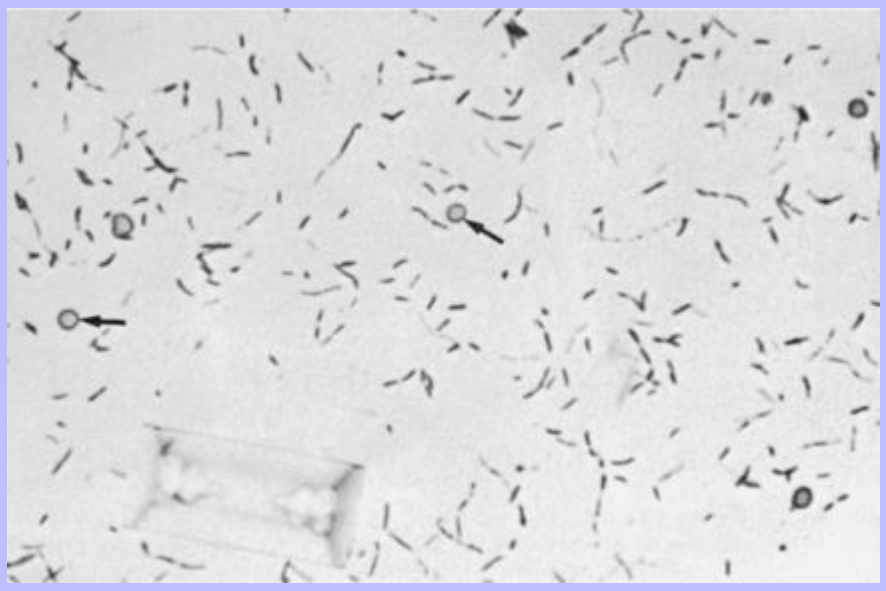

Figure 257-15 Photomicrograph of a urine sample containing ammonium biurate crystals. These crystals may be observed in normal Dalmatian dogs and in dogs with liver disease or portosystemic shunts.

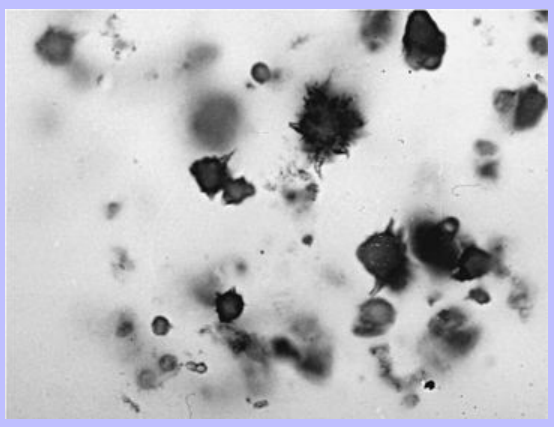
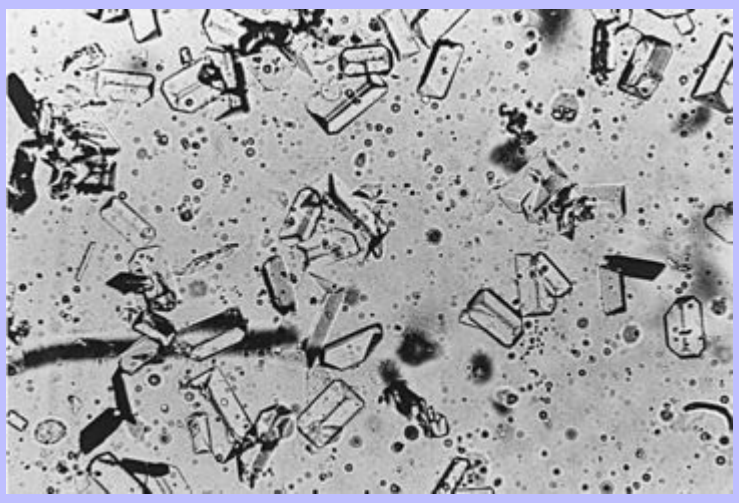


257.4.3.6 Crystals

The solubility of crystals depends on the urine pH, temperature, and specific gravity. Crystals commonly are present in the urine of dogs and cats and often are of little diagnostic significance. Struvite, amorphous phosphates, and oxalates are examples of crystals that may be found in normal urine samples. Uric acid, calcium oxalate, and cystine typically are found in acidic urine, whereas struvite ($MgNH_4PO_4 \cdot 6H_2O$, or so-called triple phosphate), calcium phosphate, calcium carbonate, amorphous phosphate, and ammonium biurate typically are found in alkaline urine. Characteristic crystals also may be found in the urine sediment of animals receiving specific drugs, especially sulfonamides. Bilirubin crystals may be found in concentrated samples of normal dog urine. Urates are commonly observed in the urine of Dalmatians and may be seen in the urine of animals with liver disease or portosystemic shunts (Figure 257-15). Struvite crystals may be observed in the urine of cats with idiopathic lower urinary tract disease, in dogs and cats with struvite urolithiasis, or in the urine of normal animals (Figure 257-16). In oliguric ARF, the presence of calcium oxalate crystals (Figures 257-17 and 257-18) is highly suggestive of ethylene glycol intoxication. The presence of cystine crystals in the urine of dogs and cats is abnormal and suggestive of cystinuria (Figure 257-19).

1726
1727

Figure 257-16 Photomicrograph of a urine sample containing struvite crystals. These crystals may be observed in the urine of normal dogs and cats and are common in alkaline urine.



257.4.3.7 Miscellaneous Findings

Sperm commonly are found in urine samples from normal intact male dogs. Rarely, parasite ova of *Dioctophyma renale* or *Capillaria plica* or microfilaria of *Dirofilaria immitis* may be observed in the urine sediment. Refractile lipid droplets may be seen with diabetes mellitus or nephrotic syndrome. They also may be observed in cats as a result of degeneration of lipid-laden tubular cells.

257.5 MICROBIOLOGY

Clinical signs and urinalysis findings provide supportive evidence, but microbiology is required to diagnose urinary tract infection (UTI) conclusively. The kidneys, ureters, bladder, and proximal urethra of normal dogs and cats are sterile, whereas a resident bacterial flora populates the distal urethra, prepuce, and vagina. Urinary tract infection occurs when bacteria colonize areas of the urinary tract that normally are sterile. Aerobic gram-negative bacteria account for most UTIs in dogs and cats, and the remainder are caused by gram-positive organisms. *Escherichia coli* is the organism most commonly implicated in urinary tract infections in dogs and cats. Other organisms isolated include *Proteus* spp., coagulase-positive staphylococci, and streptococci. *Pasteurella multocida* occasionally is isolated from cats with UTI. *Enterobacter* sp., *Klebsiella* sp., and *Pseudomonas aeruginosa* are observed less commonly in dogs and rarely in cats.

Figure 257-17 Photomicrograph of a urine sample containing calcium oxalate dihydrate crystals. These crystals may be observed in the urine of normal dogs as well as in those with calcium oxalate urolithiasis or acute renal failure caused by ethylene glycol ingestion. Note the typical “Maltese cross” appearance within a rhomboidal structure. These crystals can vary markedly in size.

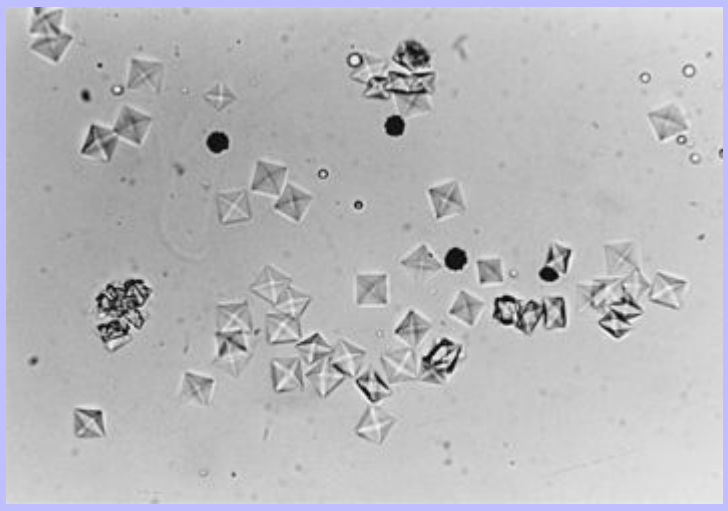


Figure 257-18 Photomicrograph of a urine sample containing calcium oxalate monohydrate crystals. Previously misnamed hippurate, these "picket fence"–and "dumbbell"–shaped crystals may be found in the urine of dogs with acute renal failure caused by ethylene glycol ingestion.

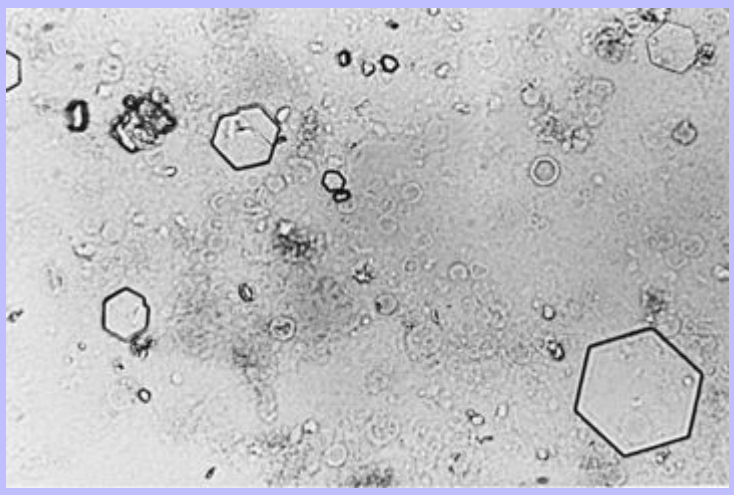
Results obtained with bacterial culture of urine depend on the method of urine collection. Voided urine has the greatest potential for bacterial contamination, and catheterization may inoculate the bladder with bacteria from the distal urethra. Urine collected by cystocentesis should be sterile in normal animals. Quantitative bacterial culture of urine allows determination of the number of bacterial colonies (colony-forming units [cfu]) that grow from 1 mL of urine (cfu/mL). Ideally, urine should be submitted for culture within 30 minutes of collection. If this is not possible, the sample may be refrigerated for up to 6 hours without significant loss of bacterial growth. Chemical preservation with a solution of boric acid, glycerol, and sodium formate, in combination with refrigeration, effectively maintained bacterial viability in canine urine samples for up to 72 hours.[53]

1727

1728

Figure 257-19 Photomicrograph of a urine sample containing cystine crystals. These crystals usually are found in acidic urine and are not present in normal animals. Their presence suggests cystinuria with or without cystine urolithiasis.



Bacterial culture of midstream-voided urine samples from normal dogs and cats often results in the growth of less than 1000 to greater than or equal to 100,000 cfu/mL. Therefore culture of voided urine is not recommended in evaluation of patients for UTI. If, however, no growth is obtained from a voided urine sample, UTI can be excluded as a diagnosis. Bacterial growth of greater than or equal to 100,000 cfu/mL may result from culture of urine obtained from catheterization in 20% of normal female dogs. Thus using a measurement of 100,000 cfu/mL as an indicator of UTI in female dogs results in a substantial number of false-positive results. Also, the urethral catheterization procedure itself may cause UTI in 20% of normal female dogs. Consequently, collection of urine by cystocentesis is recommended for establishing a diagnosis of UTI in female dogs. Isolation of bacteria from urine collected by catheterization from male dogs is uncommon, and a measurement of greater than 1000 cfu/mL is recommended for establishing a diagnosis of UTI using these urine samples. In both male and female cats, growth of greater than 1000 cfu/mL in samples collected by catheterization is considered compatible with a diagnosis of UTI.

Urine samples obtained by cystocentesis from normal dogs and cats should yield no growth, because this procedure bypasses the normal bacterial flora of the urethra and genital tract. Consequently, results obtained by cystocentesis are the standard against which results obtained using voided or catheterized samples are compared. A small number of organisms from the skin or environment occasionally contaminate samples obtained by cystocentesis, and growth of less than 1000 cfu/mL may be considered suggestive of contamination. Isolation of bacteria from urinary tissues obtained during surgery indicates UTI regardless of the number. Colony counts used to establish a diagnosis of UTI for different methods of urine collection are summarized in Table 257-3.

Microscopic examination of gram-stained urine smears also may be helpful in the diagnosis of UTI. In one study, one drop of uncentrifuged urine was allowed to dry, gram-stained, and examined under oil immersion. The presence of more than 2 organisms per field correlated with bacterial counts of greater than 1000 cfu/mL, whereas no organisms were visible in specimens with less than 1000 cfu/mL.[53]

257.6 RADIOLOGY

Radiography provides precise information about renal size that frequently cannot be obtained from the physical examination. To correct for variation in patient size and radiographic magnification, renal size is evaluated in reference to surrounding anatomic landmarks, usually the second lumbar vertebra (L2) on the ventrodorsal view. The left kidney normally is well visualized in the dog, but the right kidney often cannot be seen as well, especially its cranial pole. In the dog, the left kidney (near vertebra L2 to L5) is located caudal to the right kidney (near vertebra T13 to L3). In the cat, the kidneys lie near vertebra L3, with the right kidney positioned slightly cranial to the left. Renal size in dogs and cats can be assessed radiographically and compared to the length of vertebra L2. On the ventrodorsal view, the kidney to L2 ratio is 2.5 to 3.5 in dogs and 2.4 to 3 in cats.

Excretory urography is performed by taking sequential abdominal radiographs after intravenous administration of an iodinated organic compound. The contrast medium is filtered and excreted by the kidneys, and the quality of the study partly depends on the patient's GFR. Radiographs should be taken at appropriate intervals (e.g., less than 1 minute, 5 minutes, 20 minutes, and 40 minutes) to obtain maximum information about the renal parenchyma and collecting system. Excretory urography is useful for the evaluation of a number of abnormalities, including renal size, shape, or location; filling defects in the renal pelvis or ureters; certain congenital defects (e.g., unilateral agenesis); renomegaly; acute pyelonephritis; and rupture of the upper urinary tract. Excretory urography should not be performed in dehydrated patients or in those with known hypersensitivity to contrast media. Although excretory urography normally is a safe procedure, a decrease in the GFR may persist for several days after intravenous administration of contrast agents to normal dogs, and ARF has been reported in a dog after excretory urography.[54] The general technique and interpretation of excretory urography in dogs and cats have been reviewed elsewhere.[55] Ultrasound-guided percutaneous antegrade pyelography has been used to localize ureteral obstruction in dogs and cats.[56]

Table • 257-3 Assessment of Quantitative Urine Culture Results in Dogs and Cats

METHOD OF COLLECTION	SPECIES	SEX	COLONY COUNT INDICATIVE OF URINARY TRACT INFECTION (UTI)
Cystocentesis*	Dog	Male	$>10^2$ cfu/mL
		Female	$>10^2$ cfu/mL
	Cat	Male	$>10^2$ cfu/mL
		Female	$>10^2$ cfu/mL
Catheterization	Dog	Male	$>10^3$ cfu/mL
		Female	$>10^5$ cfu/mL†
	Cat	Male	$>10^3$ cfu/mL
		Female	$>10^3$ cfu/mL
Midstream voided	Dog	Male	Unreliable‡
		Female	Unreliable‡
	Cat	Male	Unreliable‡
		Female	Unreliable‡

* Growth of small numbers of a single organism ($\leq 10^2$ cfu/mL) from urine samples collected by cystocentesis is suggestive of skin contamination during collection. Growth of large numbers ($>10^3$

cfu/mL) of multiple organism from urine samples collected by cystocentesis is suggestive of needle puncture of bowel and contamination by intestinal flora.

† This guideline may result in erroneous diagnosis of UTI because $>10^5$ cfu/mL may be obtained from urine samples collected by catherization in 20% of normal female dogs. Also, the procedure of urethral catheterization itself may cause UTI in 20% of normal female dogs. Collection of urine by cystocentesis is recommended for establishing a diagnosis of UTI in female dogs.

‡ Culture of midstream-voided urine samples from normal dogs and cats may result in growth of $\geq 10^5$ cfu/mL. In the absence of prior antimicrobial therapy, a negative result on a voided sample excludes a diagnosis of UTI.

257.6.1 Ultrasonography

Renal ultrasonography is a noninvasive imaging technique that does not depend on renal function, has no known adverse effects on the patient, and allows characterization of internal renal architecture. The major advantage of ultrasonography is the ability to discriminate among the renal capsule, cortex, and medulla, the pelvic diverticula, and the renal sinus.[57–60] Normally, the kidney is less echogenic than the liver or spleen. Collagen and fat provide highly reflective acoustic interfaces and account for the observation that the renal capsule, diverticula, and sinus are the most echogenic structures in the kidney. The renal medulla normally is less echogenic than the renal cortex because of its higher water content and fewer acoustic interfaces.[59] The hyperechogenicity of the renal cortex relative to the medulla varies among normal cats and has been attributed to variations in the amount of fat in the proximal tubular cells.[61]

1728

1729

Renal length and volume, as determined by ultrasonography, are linearly related to body weight in dogs.[62,63] In cats, renal length as determined by ultrasonography ranges between 3 and 4.3 cm.[64] Measurements of renal size determined by excretory urography exceed those obtained by ultrasonography.[57,64] This difference is due to osmotic diuresis and radiographic magnification effects during excretory urography and to indistinct renal margins and inaccurate choice of scanning planes during ultrasonography.[62,64]

Renal ultrasonography is useful for differentiating solid from fluid-filled lesions and for determining the distribution of lesions in the kidney (i.e., focal, multifocal, diffuse).[65] A pattern of multiple, anechoic cavitations is highly suggestive of polycystic kidney disease.[66,67] Cysts are smooth, sharply demarcated, anechoic lesions that demonstrate through transmission.[58] The renal pelvis is dilated with anechoic fluid in hydronephrosis, and the kidney is surrounded by an accumulation of anechoic fluid in cats with perinephric pseudocysts.[68,69] Organized hematomas, abscesses, and necrotic nodules present a pattern of mixed echogenicity. Focal or diffuse lesions of mixed echogenicity that disrupt normal anatomy often are tumors.[65] Poorly vascular tumors of homogenous cell type (e.g., lymphosarcoma) may produce hypoechoic lesions that occasionally may be misinterpreted as cysts.[65,66] Diffuse parenchymal renal diseases characterized by cellular infiltration with preservation of normal renal architecture (e.g., chronic tubulointerstitial nephritis) may produce diffuse hyperechogenicity but occasionally have a normal ultrasonographic appearance. Consequently, normal renal ultrasonographic results do not eliminate the possibility of renal disease.

Ethylene glycol intoxication also causes renal hyperechogenicity. Within 4 hours of ethylene glycol ingestion, renal cortical echogenicity exceeds that of the liver and approaches that of the spleen.[70,71] Medullary echogenicity increases to a lesser extent. Increased cortical and medullary echogenicity, with relative

hypoechogenicity of the corticomedullary junction and inner medulla, results in a “halo” sign that correlates with the onset of anuria. Renal hyperechogenicity in ethylene glycol intoxication is attributed to deposition of calcium oxalate crystals in the kidneys.

An echogenic line in the outer zone of the medulla and paralleling the corticomedullary junction (so-called medullary rim sign) has been observed in ethylene glycol intoxication but also in acute tubular necrosis, hypercalcemic nephropathy, granulomatous nephritis caused by feline infectious peritonitis, and chronic tubulointerstitial nephritis.[72,73] This lesion also has been observed in normal cats[61] and has been associated with mineralization of tubular basement membranes. In a study of 32 dogs with medullary rim sign, most of the dogs in which this feature was the sole ultrasonographic finding had no evidence of renal dysfunction, whereas those with other ultrasonographic abnormalities (e.g., reduced renal size, increased medullary echogenicity, pyelectasia) had clinical evidence of renal dysfunction.[74]

Intrarenal resistance to blood flow may be assessed during duplex Doppler ultrasonography and evaluated by calculation of the resistive index. The normal value for the renal resistive index in healthy, unsedated dogs is approximately 0.6.[75] Somewhat lower values have been reported in normal, sedated dogs[76] and cats.[77] Other studies have suggested an upper limit of 0.7 for the resistive index in normal, unsedated cats.[78,79] Higher than normal values for the resistive index have been reported in some renal diseases of dogs and cats[80] but not in experimentally induced aminoglycoside nephrotoxicosis.[81]

Renal ultrasonography also has been used to monitor the status of renal allografts in dogs[82] and renal autografts in cats.[78] A rapid increase in renal volume in the immediate postoperative period may signify rejection, but some enlargement normally occurs as a consequence of edema and renal hypertrophy. The renal volume and cross-sectional area, as monitored by ultrasonography, increased by 103% and 83%, respectively, as a result of hypertrophy and rejection by 17 days after allograft transplantation in dogs.[82] Changes in renal width were greater than changes in height or length, which suggests that the cross-sectional area measurement may be a useful parameter to monitor. In cats, renal autografts increased 50% in the cross-sectional area by 13 days after transplantation as a result of postoperative edema and hypertrophy, but no changes were seen in the resistive index.[78]

257.7 RENAL BIOPSY

Renal biopsy allows the clinician to establish a histologic diagnosis and should be considered when the information obtained is likely to alter patient management. Examples of such situations include differentiation of protein-losing glomerular diseases, differentiation of ARF from CRF, determination of the status of the tubular basement membranes in ARF, and determination of the patient's response to therapy or the progression of previously documented renal disease. A renal biopsy should not be performed until a thorough clinical evaluation of the patient has been completed.

Before renal biopsy, an intravenous catheter should be placed, and the animal's clotting ability should be evaluated by measurement of the buccal mucosal bleeding time and estimation of platelet numbers. The patient's hematocrit and plasma proteins should be determined before biopsy but after adequate rehydration with parenteral fluids. The hematocrit and plasma proteins may be monitored after biopsy to detect hemorrhage.

Several techniques can be used for renal biopsy, including blind percutaneous, laparoscopic, keyhole, open, and ultrasound-guided approaches. The choice of technique depends largely on the experience and technical skill of

the operator, the species to be biopsied, and the sample size required. The blind percutaneous technique works well in cats, because their kidneys can be readily palpated and immobilized. Laparoscopy allows direct visualization of the kidney and detection of hemorrhage but requires special equipment and expertise. The keyhole approach occasionally is used in dogs but is useful only if the operator is experienced with the technique. In one study of renal biopsy techniques in dogs, modifications of the keyhole technique and the use of laparoscopy did not improve the quality of the biopsy specimen obtained or reduce the complication rate.[83]

If the operator is relatively inexperienced with renal biopsy or if a larger sample is required, wedge biopsy by means of laparotomy is recommended. Laparotomy offers the operator the advantages of being able to inspect the kidneys and other abdominal organs visually, to choose the specific biopsy site, to take an adequately sized sample, and to observe the kidney for hemorrhage. Some techniques require general anesthesia for adequate patient restraint and analgesia, but needle biopsy specimens of the kidney can be obtained from dogs and cats under ultrasound guidance using one of several sedation protocols. In one study, the GFR (estimated by ^{99m}Tc-DTPA) was similar in dogs sedated with butorphanol and diazepam, acepromazine and butorphanol, and diazepam and ketamine, and the GFR of sedated dogs was not significantly different from that of awake dogs.[84]

1729

1730

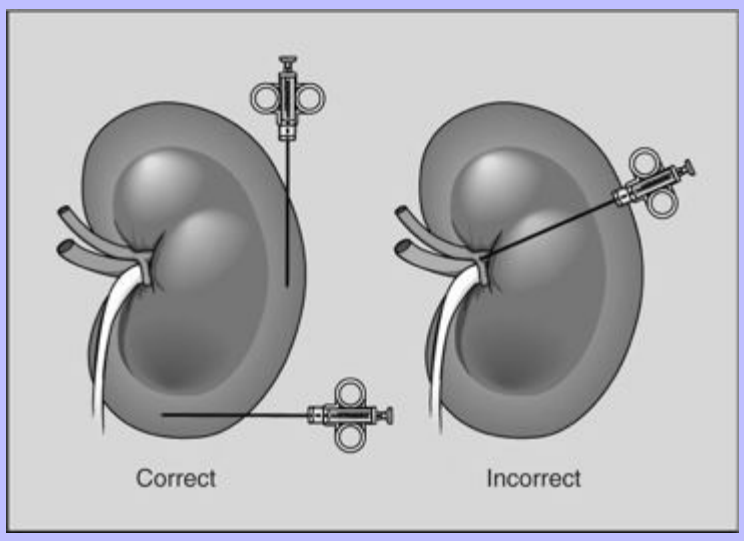
At our hospital, renal biopsy in dogs and cats currently is performed under ultrasound guidance using the Bard® Biopty biopsy instrument (Bard Biopty biopsy system; C.R. Bard, Covington, Georgia) and with the animal sedated with a combination of medetomidine, butorphanol, and atropine. This combination of drugs recently was evaluated for renal biopsy in dogs (using ^{99m}Tc-DTPA renal scintigraphy as an estimate of the GFR) and was found to have effects on the GFR similar to those observed with saline alone.[85] In another study, needle biopsy of the kidney in normal cats sedated with ketamine and acepromazine had minimal effect on the GFR as evaluated by ^{99m}Tc-DTPA renal scintigraphy.[25] Occasionally, the tissue architecture is less important (e.g., in renal lymphosarcoma and feline infectious peritonitis), and aspiration of the kidney using a 23-or 25-gauge needle may provide useful material for cytology.

The most commonly used biopsy instruments are the Franklin-modified Vim Silverman needle and the Tru-Cut biopsy needle. Excessive penetration of the kidney with the outer cannula of the Franklin-modified Vim Silverman instrument should be avoided to prevent retrieval of an insufficient amount of renal cortex. Care should be taken in directing the angle of the biopsy instrument to avoid the renal hilus and major vessels. Samples containing large amounts of medulla are more likely to contain large vessels and to lead to infarction of renal tissue. It therefore is recommended that the biopsy needle be directed along the long axis of the kidney, solely through cortical tissue (Figure 257-20). In cats, because of the small size of feline kidneys, it is common to obtain relatively large amounts of medullary tissue, and this has been associated with infarction and fibrosis.

After biopsy using the open approach or keyhole technique, the kidney should be digitally compressed for 5 minutes, and after release the abdomen inspected for hemorrhage. The sample may be dislodged from the biopsy instrument with a stream of sterile saline from a syringe or, alternatively, the biopsy instrument may be immersed directly in fixative. For routine histopathology, the sample should be fixed in buffered 10% formalin for at least 3 to 4 hours. For immunofluorescence studies, the sample can be preserved in Michel's transport medium. Immunopathology studies also may be performed by a peroxidase-antiperoxidase method using formalin-fixed samples, without the need for special preservation of the sample.

After renal biopsy, a brisk fluid diuresis should be initiated to prevent clot formation in the renal pelvis. The patient's hematocrit and plasma proteins should be monitored at appropriate intervals over the next 12 to 24 hours to detect serious hemorrhage.

Figure 257-20 Demonstration of renal biopsy technique showing correct and incorrect placement of the biopsy instrument in the kidney. (Drawing courtesy Dr. Shelly Vaden, North Carolina State University, Raleigh.)



The most common complication of renal biopsy is hemorrhage. Subcapsular hemorrhage commonly occurs at the site of biopsy, and many patients experience microscopic hematuria during the first 48 hours after biopsy. Macroscopic hematuria is less common. Severe hemorrhage into the peritoneal cavity is rare and usually is associated with improper technique. Such hemorrhage must be treated aggressively by compression bandage of the abdomen, fresh whole blood transfusion, and exploratory surgery if necessary.

Linear infarcts in the path of the biopsy needle are commonly observed after renal biopsy in both dogs and cats. These are small and superficial when the biopsy is limited to the renal cortex. However, if an arcuate artery is damaged by passage of the biopsy needle through the corticomedullary junction, a wedge-shaped infarct may occur. This complication is more common in cats because of the small size of the kidneys in relation to the length of the biopsy needle.

Hydronephrosis occasionally complicates renal biopsy. If the renal pelvis is penetrated by the biopsy needle, bleeding may occur, and clot formation can lead to obstruction of the kidney and hydronephrosis. This complication should be considered if the biopsy report indicates the presence of transitional epithelium at one end of the biopsy or if progressive renal enlargement is detected after renal biopsy. The risk of this complication can be minimized by limiting the biopsy site to the renal cortex and instituting a fluid diuresis afterward.

258 CHAPTER • 258 Acute Uremia

Larry D. Cowgill

Thierry Francey

Acute uremia is a clinical condition in which the kidneys suddenly and often catastrophically fail to meet the excretory, metabolic, and endocrine demands of the body. This abnormality is induced by rapid hemodynamic, filtration, tubulointerstitial, or excretory injury to the kidneys or outflow system (or both), which results in accumulation of solutes (uremia toxins), metabolic dysfunction, and dysregulation of fluid, electrolyte, and acid-base balance. Acute uremia is, conceptually, a quickly developing disease to intrinsically normal kidneys. However, some animals have prerenal, renal parenchymal, or postrenal events superimposed on a pre-existing chronic renal injury that causes a similar clinical condition.

The term *acute renal failure* (ARF) does not standardize the classification of acute uremia relative to its severity, clinical course, response to therapy, or prognosis for recovery.[1,2] To date no specific biologic markers provide these distinctions. Numerous definitions of acute uremia exist that are based on changes in glomerular filtration rate (GFR), degree of azotemia, or urine production in humans. These criteria, however, are rarely applied to animals because the abruptness of their disease and changes in azotemia or volume of urine production are usually not known. Acute uremia in animals is generally a disease recognized later than in humans and with varying abruptness and azotemia. The diagnosis of ARF is established with high specificity but low sensitivity. Affected animals have a spectrum of functional and clinical deficiencies that should be considered in its classification, management, and outcome.

Acute uremia is associated with a rapid (hours to days) and progressive increase in serum concentrations of urea, creatinine, and phosphate. There may also be variable degrees of hyperkalemia, metabolic acidosis, or both. Progression of azotemia may not be recognized in animals being evaluated for the first time that are already in a late stage of disease or in those without previously obtained serial blood chemistry determinations. After azotemia is demonstrated, the acute condition must be differentiated from functional disturbances (prerenal azotemia) or chronic renal failure (CRF). Oliguria and anuria are characteristic of severe forms of acute uremia, but this feature is unpredictable. Nonoliguric forms of acute uremia are common and must be differentiated from polyuria associated with CRF. In contrast to CRF, acute uremia is potentially reversible if the animal survives until the underlying conditions resolve and natural recovery (repair) of the renal injury takes place. Throughout its progression, therapeutic opportunities exist to alter the outcome of the disease. If the diagnosis is missed or if the injury is too severe, the kidney will be incapable of morphologic repair. Thus delays in initiating therapy or failure to provide appropriate supportive therapy may result in irreversible renal damage and death.

The incidence of acute uremia is lower than that of CRF in both dogs and cats. The clinical signs associated with acute and CRF may be similar, and clinicians must distinguish between these conditions to administer appropriate therapy and render an accurate prognosis. Acute uremia frequently complicates other surgical or medical diseases and must be recognized as a serious complication of any condition.

258.1 CAUSE OF ACUTE UREMIA

Acute uremia can be categorized as prerenal azotemia, intrinsic ARF, postrenal azotemia, or some combination of these conditions.

258.1.1 Prerenal Azotemia

Prerenal azotemia is a hemodynamically mediated decline in GFR resulting from decreased renal blood flow, perfusion pressure, or increased renal vascular resistance. It represents a functional alteration in GFR that is completely reversible without morphologic consequences to renal parenchyma. Prerenal azotemia develops as a coordinated neural and humoral response to hemodynamic deficiencies in an attempt to preserve perfusion to vital organs. Filtration failure ensues when the renal perfusion pressure falls below the threshold for renal autoregulation (usually a mean arterial pressure [MAP] < 80 mm Hg).[3,4] As renal compensatory mechanisms are activated in response to hemodynamic failure (cardiogenic, septic, hypovolemic shock) or to decreased functional renal mass, even small additional impairments in renal perfusion or glomerular hemodynamics (nonsteroidal anti-inflammatory drugs [NSAIDs], angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers) can precipitate severe filtration failure.[5,6] Activation of the sympathetic nervous system (SNS), the renin-angiotensin-aldosterone system, and the release of antidiuretic hormone (ADH) in response to these hemodynamic events promote via salt and water conservation, urine concentration, and oliguria in an attempt to restore blood volume.

Mild azotemia (serum creatinine concentrations < 4 mg/dL, and blood urea nitrogen [BUN] concentrations < 80 mg/dL), increased urine specific gravity [USG], and decreased urine sodium excretion (urine sodium concentration < 20 mEq/L; fractional excretion of sodium < 1%) are hallmarks of prerenal azotemia. These parameters may be masked by the use of diuretics or by underlying conditions (CRF, adrenal insufficiency, hepatic failure, diabetes insipidus) that impair renal concentrating ability. Tubular reabsorption of urea can be increased disproportionately to creatinine at these low urine flow rates, causing variable increases in BUN/creatinine ratio.[7,8] A prerenal component is often superimposed on intrinsic renal failure, causing severe uremia. Prolonged renal hypoperfusion can result in structural alterations secondary to ischemic cellular injury that may induce intrinsic ARF. Vasculitis, pancreatitis, hypoproteinemia, heat stroke, liver failure, and gastric torsion are examples of disease states inducing hemodynamic disturbances with the propensity to cause progressive prerenal azotemia leading to intrinsic ARF.[9]

1731 1732

258.1.2 Intrinsic Acute Renal Failure

Intrinsic ARF is the result of parenchymal damage to the kidney and can be categorized according to the initial site of injury as *primary vascular*, *glomerular, tubular*, or *interstitial*. This anatomic classification is arbitrary due to multiple interactions between these structures but may be helpful in understanding the pathophysiology of lesions observed in individual dogs and cats (Box 258-1). For clinical purposes, ARF may be categorized based on cause. With this classification, ARF can develop as a continuation of prerenal events, local ischemia (ischemic nephrosis), or as a consequence of exogenous or endogenous nephrotoxins (toxic nephrosis). Using a causative classification, primary renal diseases (pyelonephritis, toxic nephrosis) and systemic diseases with renal manifestations (pancreatitis, ischemic nephrosis) can induce ARF with mixed anatomic involvement.

Ischemia due to prolonged hypotension, hypovolemia, circulatory collapse, or excessive renal vasoconstriction predisposes a dog or cat to filtration failure and acute uremia as an extension of prerenal azotemia. Renal ischemia may also develop after renal arterial thrombosis, disseminated intravascular coagulation (DIC), or septic thrombi.

258.1.2.1 Box • 258-1 Causes of Intrinsic Acute Renal Failure

258.1.2.1.1 Renal Ischemia

Progression of prerenal azotemia

Renal vascular disease (avulsion, thrombosis, stenosis)

258.1.2.1.2 Nephrotoxicity

Exogenous toxins

Endogenous toxins

Drugs

258.1.2.1.3 Primary Renal Diseases

Infections: pyelonephritis, leptospirosis, infectious canine hepatitis

Immune-mediated disease: acute glomerulonephritis, systemic lupus erythematosus (SLE), renal transplant rejection

Neoplasia: lymphoma

Miscellaneous: "Alabama rot"[26]

258.1.2.1.4 Systemic Diseases with Renal Manifestation

Infections: Feline infectious peritonitis (FIP), borreliosis, babesiosis, leishmaniasis, bacterial endocarditis

Pancreatitis

Systemic inflammatory response syndrome, sepsis, multiple organ failure, disseminated intravascular coagulopathy (DIC)

Heart failure

SLE

Hepatorenal syndrome

Malignant hypertension

Hyperviscosity syndrome: polycythemia, multiple myeloma

Nephrotoxins are the primary cause of ARF in dogs. They can be of exogenous or endogenous origin and of diverse chemical classes including organic compounds and solvents, antimicrobials, vasoactive drugs, and miscellaneous therapeutics (Box 258-2).[10–12]

NSAIDs inhibit cyclooxygenase (COX)-dependent synthesis of vasodilatory prostaglandins that regulate renal blood flow when renal perfusion is compromised. Nonselective COX-1/COX-2 inhibitors (flunixin meglumine, ibuprofen, aspirin),[13] promote loss of counter-regulatory vasodilation to an ischemic insult, which intensifies vascular resistance and furthers hypoperfusion of the kidney.[14] Although species differences exist, newer NSAIDs with selective COX-2 inhibition (meloxicam, carprofen, deracoxib) also have the potential to be nephrotoxic.

The principal toxicity associated with NSAIDs use in animals is a nonoliguric ischemic nephrosis. Idiosyncratic tubulointerstitial nephritis, nephrotic syndrome, renal papillary necrosis, and hyporeninemic-hypoaldosteronism have also been described in humans.[15] The nephrotoxicity of NSAIDs is exacerbated in animals with congestive heart failure (CHF), nephrotic syndrome, renal insufficiency, hypertension, cirrhosis, and those undergoing anesthesia in which renal perfusion is compromised and renal vascular tone is increased.[14] Because of the ischemic nature of this nephrotoxicity, the lesions are generally reversible.

ACE inhibitors may induce ARF through alterations in glomerular hemodynamics, renal hypoperfusion, and tubular ischemia. Sodium depletion, diuretic abuse, and CHF may increase the nephrotoxic potential of these drugs. The risks of toxicity are magnified in animals with pre-existing CRF because basal GFR is dependent on increased postglomerular resistance mediated by angiotensin II.[6,16,17] ACE inhibitors with mixed renal and hepatic elimination may prove less toxic in animals with CRF when compared with ACE inhibitors that are excreted only through the kidneys.[18]

Clinicians may prevent ARF induced by NSAIDs or ACE inhibitors with judicious monitoring of serum creatinine concentrations before mitigating treatment, together with early (3 to 5 days) and frequent (biweekly) monitoring of serum creatinine concentrations after the start of therapy. If increased concentrations of serum creatinine are documented, treatment should be stopped or doses reduced. Special precautions should be taken when administering diuretics, ACE inhibitors, NSAIDs, or a combination of these medications concurrently due to their additive hemodynamic effects.

Ethylene glycol toxicosis is one of the most common causes of ARF and one of the most common toxicoses recognized in companion animals.[19] Automobile antifreeze is the usual source of exposure, and the toxicity develops by the direct actions of its metabolites on the tubular epithelium and deposition of calcium oxalate crystals in the tubular lumens and interstitium.

Plant-related intoxications represent a new category of acute uremia in dogs and cats with severe nephrosis. Exposure and ingestion of lilies has been reported to cause severe acute ARF in cats.[20,21] Similarly, ingestion of grapes or raisins has been recently associated with ARF in dogs.[22,23]

Aminoglycosides (gentamicin, amikacin, tobramycin, netilmicin, and neomycin) are potent nephrotoxins causing direct tubular injury or tubular dysfunction associated with wasting of filtered solutes.[24] Further, nearly all antimicrobials (including penicillins, cephalosporins, carbapenems, fluoroquinolones, macrolides,

tetracyclines, and sulfonamides) can cause tubular injury, tubular dysfunction, or intratubular obstruction.[15,24,25]

Amphotericin B is a polyene antifungal that complexes with sterol moieties of cell membranes forming pores that disrupt cellular integrity and increase membrane permeability.[26] Nephrotoxicity is the dose-limiting factor associated with use of this drug, and renal function should be closely monitored throughout its administration. The advent of lipid formulations, and particularly of liposome encapsulated amphotericin B, has markedly decreased the nephrotoxicity associated with amphotericin use and has allowed more aggressive application of this drug.[27–30]

Diphosphonates

Mushrooms

Grapes/raisins

Calcium antagonists

Snake venom

Bee venom

Lily

Illicit drugs

258.1.2.2.3 Endogenous Toxins

Pigment nephrosis

Hemoglobin

Myoglobin

Cisplatin is an alkylating antineoplastic agent concentrated within and excreted primarily by the kidney. Its administration leads to a dose-dependent, progressive, and irreversible nonoliguric ARF. Carboplatin, an analogue of cisplatin, is less nephrotoxic and has largely replaced cisplatin in clinical practice.[15]

1733
1734

Primary renal diseases include infectious, immune-mediated, neoplastic, or degenerative conditions with primary expression in the kidney. When peracute or extensive, primary renal diseases produce an acute uremia that must be differentia-ted from traditional ischemic or nephrotoxic causes. Acute pyelonephritis develops from ureteral reflux of bacteria in the urine of animals with lower urinary tract (LUT) infection. It is an important cause of acute uremia in both dogs and cats.[11,31] The azotemia may be moderate or severe and associated with variable urine output. Suppurative nephritis is an infection arising from hematogenous dissemination of bacteria or septic embolization of the kidneys in animals with bacteremia or septicemia. Predisposing conditions include bacterial endocarditis, discospondylitis, and pyometra.

Leptospirosis is a specific infectious zoonosis of dogs with predominantly hepatorenal manifestation.[32–38] It was a well-characterized syndrome of acute hemorrhagic diathesis, subacute icterus, or subacute uremia caused by *Leptospira interrogans* serogroups *canicola* and *icterohaemorrhagiae*. Widespread use of a bivalent vaccine against these serogroups led to near extinction of leptospirosis in the canine population, until recently.[32,33,35,38] Retrospective studies in the United States and Canada have documented a regional re-emergence of the disease since the 1990s and a change in its epidemiology with *L. pomona, L. bratislava, L. grippotyphosa,* and *L. autumnalis* as the most commonly identified serogroups. The associated clinical syndrome has also changed, with ARF rather than hepatorenal or coagulation manifestations.[32,33,36,39] Possible explanations for the recently recognized re-emergence and clustering of leptospirosis could include urbanization of the canine population and encroachment of dogs into environments harboring reservoirs of the host species.[32,34,37] New, multivalent vaccines have emerged in response to these epidemiologic trends, but it remains to be seen whether vaccination will change the prevalence or biology of this disease. Because of its growing prevalence as a cause of acute uremia in dogs, leptospirosis should be included routinely in the differential diagnosis of all dogs with ARF, regardless of vaccination status.

A rapidly progressive form of ARF with severe azotemia, proteinuria, peripheral edema, and body cavity effusion has been associated with positive serology for *Borrelia burgdorferi*. This form of the disease is recognized routinely in dogs from endemic areas and, despite aggressive therapy, is invariably fatal.[40]

Systemic diseases including pancreatitis, sepsis, and hemolytic anemia (see Box 258-1) promote intrinsic ARF through secondary mechanisms associated with renal hemodynamics, systemic inflammatory responses, or drug toxicities associated with the underlying disease or diseases (see Pathophysiology, following). The ensuing ARF can exacerbate the course of the primary disease or dominate the clinical presentation of affected animals.

258.1.3 Postrenal Azotemia

Postrenal azotemia occurs with obstruction or diversion of urine and consequent retention of excretory products within the body. The most common causes of postrenal azotemia include partial or complete obstruction of the urethra or bladder by uroliths, mucous plugs, blood clots, or intra-or extraluminal mass lesions. Bilateral ureteral dilation should raise suspicion of a common outflow obstruction at the ureterovesical junction caused by a transitional cell carcinoma in the bladder neck or inadvertent ligation of the ureters during ovariohysterectomy. Bilateral ureteral obstruction or unilateral obstruction in a dog or cat with only one functioning kidney can be caused by calcium oxalate uroliths, solidified blood clots, mucous plugs, inflammatory debris, or stricture. These problems are being recognized with increased frequency as a leading cause acute uremia in cats.[41,42] Rupture of the urinary outflow tract diverts urine into the retroperitoneal space (ureteral), peritoneal cavity (ureteral, bladder, or proximal urethra), or pelvic canal (urethra), with consequent

development of oligoanuria and uremia. Correction of the outflow obstruction or rupture may represent a surgical challenge, but if successful it will resolve azotemia without the presence of permanent structural damage to the kidneys.

Protracted outflow obstruction for more than 7 days can result in renal parenchymal damage and intrinsic ARF. At this stage, recovery of renal function is unpredictable and influenced by the severity and duration of the obstruction, completeness of the surgical correction, postobstructive medical complications, and pre-existing renal disease. Intuitively, a successful outcome will be less likely and the animal will be subjected to greater structural damage or death from uremia if correction of the outflow impairment is delayed or incomplete.

258.2 PATHOPHYSIOLOGY OF ACUTE UREMIA

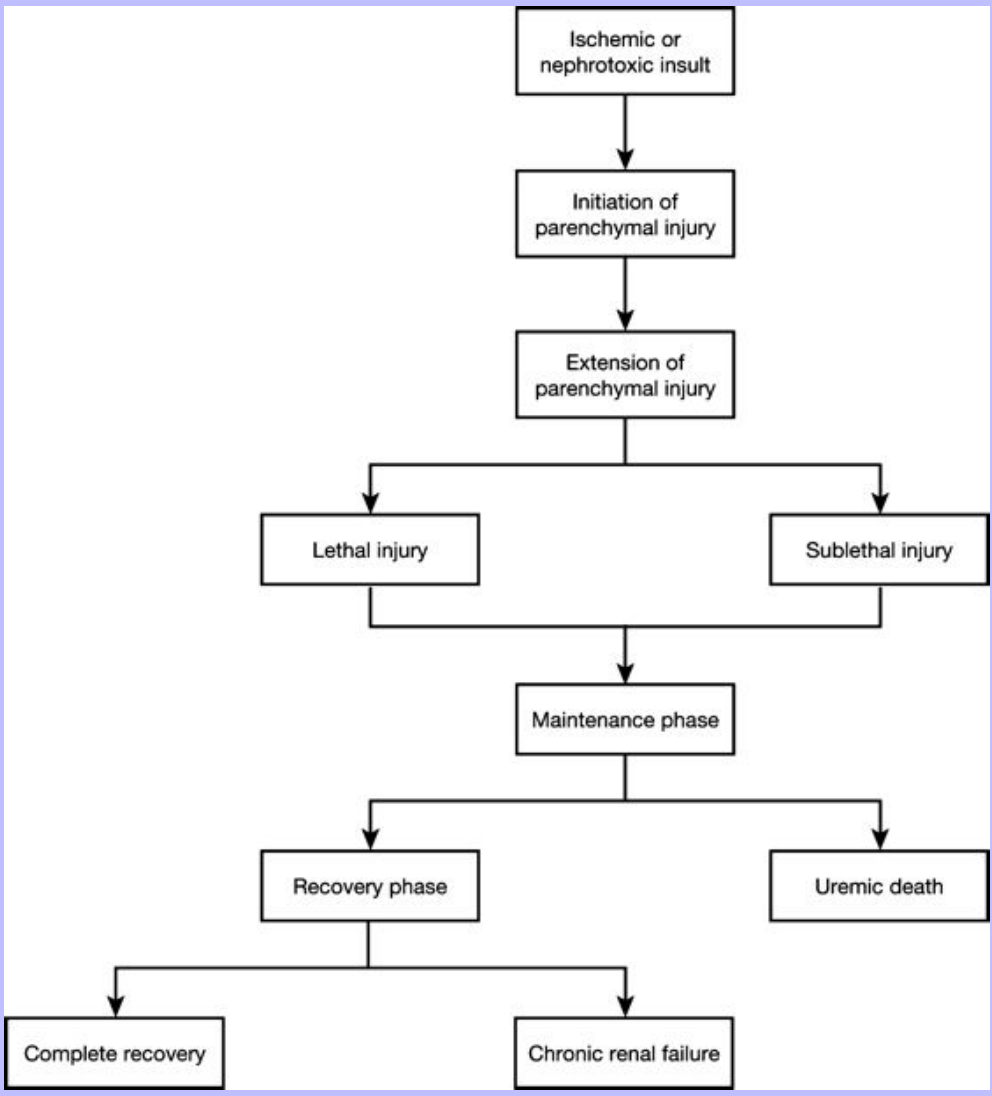
Ischemic and toxic insults to the kidney cause a state of acute tubular injury (ATI). At the cellular level, ATI can vary from sublethal cell damage to cellular necrosis or apoptosis. The term *ATI* is often equated with the older term, *acute tubular necrosis,* used to denote ARF; however, the two terms should be distinguished in the pathophysiologic description of the syndrome. The histopathologic changes in some kidneys are more subtle than necrosis, and the tubular injury may be sublethal, making ATI a more appropriate descriptor and providing better correlation between observed structural alterations and clinical correlates of renal dysfunction.[43] With ischemic and nephrotoxic ARF, the tubular injury is characterized by degenerative and less commonly necrotic foci of tubular epithelium distributed heterogeneously throughout the kidneys with minimal evidence of interstitial inflammatory infiltrates. The straight portion of the proximal tubule (S3 segment) shows the most severe degenerative changes after an insult and maximal mitotic activity during recovery. The convoluted proximal tubule (S1 and S2 segments), the segments in the inner medulla, the medullary thick ascending limb, and the collecting tubules are least severely affected or completely spared by ischemic or toxic damage.[43,44]

258.2.1 Phases of Intrinsic Acute Renal Failure

ARF classically proceeds through three clinical phases: (1) initiation, (2) maintenance, and (3) recovery.[45] The late stage of the initiation phase is now recognized as pathophysiologically distinct and this classical progression has been modified recently to include the *extension phase* as indicated in Figure 258-1.[2,46] The initiation phase is the period during which the animal is subjected to the renal insult. At this phase, parenchymal injury evolves, and the tubular epithelium undergoes sublethal but potentially reversible injury.[2,47] Early intervention during the initiation phase will often prevent progression to more severe injury.

During the extension phase the kidney is subjected to alterations in renal perfusion, continued hypoxia, secondary inflammation, and ongoing epithelial and endothelial injury. As a result of these sustained or cumulative insults, the cellular injury progresses to cell death by necrosis or apoptosis. The functional consequences are a progressive decline in glomerular filtration, loss of urine-concentrating ability, and development of oligoanuria (or nonoliguria) and azotemia. At this critical phase in the pathogenesis, clinical manifestations may not be apparent, but the injury may be unresponsive to therapeutic intervention. The combined initiation and extension phases may last from hours to days but remain unrecognized because the changes in GFR and USG are not clinically apparent.

Figure 258-1 Clinical phases of acute renal failure (ARF). In the initiation and extension phases, renal damage and sublethal cellular injury evolve, but renal failure is not evident. In the maintenance phase, the inciting events have ceased, cellular damage is established, and signs of uremia become apparent. The recovery phase involves tubular regeneration and repair and the partial or complete return of renal function.



The maintenance phase ensues after a critical amount of irreversible epithelial damage has occurred. GFR is decreased, the regulation of regional blood flow is altered, urine volume may decrease, and the complications

of uremia develop. Elimination of inciting factors at this phase will not alter existing damage or rate of recovery.[17,48] The maintenance phase lasts from days to weeks and when prolonged portends a slower rate of recovery and a likelihood of permanent renal impairment.

The recovery phase is the period where renal tissue undergoes regeneration and repair with restoration of renal function. Recovery may be associated with an increase in urine output and progressive resolution of the azotemia; however, molecular evidence of regeneration may be detected before these signs are apparent.[48] An increase in urine production at this phase may not correspond to meaningful improvement in GFR, so changes in the azotemia may lag behind evidence of tubular repair. Diuresis is a physiologic response to accumulated water, salt, and osmotically active solutes, immature tubular function, or diuretic therapy. Functional repair follows cellular recovery of the sublethally injured epithelium, removal of intratubular debris, and re-epithelialization of the tubule.[49] The renal injury induces growth factor production and alters gene expression to enable remnants of surviving epithelium to dedifferentiate, re-enter the cell cycle, replicate, repopulate the denuded tubule, and redifferentiate into a functionally mature tubular epithelium. These events are orchestrated by mitogens (stimulate cell proliferation), motogens (stimulate cell mobility), and morphogens (induce changes in multicellular architecture) including insulin-like growth factor-1 (IGF-1), epidermal growth factor (EGF), transforming growth factor (TGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), nerve growth factor (NGF), hepatocyte growth factor (HGF), and vascular endothelial growth factor (VEGF).[50] These same repair factors may also contribute to fibrosis and other deleterious aspects of the pathogenesis and progression of renal damage. The recovery phase may last from weeks to months. With renal repair, some animals recover adequate or even normal renal function after weeks or even months of anuria that follows a severe renal injury like ethylene glycol intoxication.

1735

1736

258.2.2 Outflow Obstruction

Acute urinary outflow obstruction transmits increased hydrostatic pressure to the renal pelvis, the tubular system, and Bowman space. Within glomerular capillaries, the ultrafiltration pressure is dissipated, causing a progressive decline in GFR. The heightened pressure in Bowman capsule and tubular lumen is counterbalanced by ongoing sodium and water reabsorption along the nephron, but this compensation is inadequate to prevent filtration failure. Renal blood flow is progressively altered with initial increases and subsequent decreases due to local vasodilation and increased interstitial hydrostatic pressure, respectively.

258.2.3 Pathogenesis of Acute Renal Failure

Four functional and pathologic alterations have been shown to participate to variable degrees in the initiation, extension, and maintenance phases of ARF on the basis of animal models of ischemic and nephrotoxic ARF: (1) reduction of the glomerular capillary ultrafiltration coefficient (K_f) and permeability, (2) intratubular obstruction, (3) back leak of filtrate across disrupted tubular epithelium, and (4) intrarenal vasoconstriction and renal medullary hypoxia.[45,49,51]

Decreased ultrafiltration coefficient (K_f) reduces GFR by either a decrease in hydraulic conductivity or effective surface area of glomerular capillaries. Transmission and scanning electron microscopy in animal models of ARF demonstrated both loss and fusion of normal foot processes and marked disruption of podocyte architecture.[52] Vasoconstriction initiated by angiotensin II and other vasoactive agents or contraction of the mesangium by ischemia, toxins, thromboxane A_2, endothelin, and platelet activating factor alter K_f by

reducing effective glomerular surface area. It is likely that conductivity and surface area are affected by both ischemic and toxic insults.[52–54]

Intratubular obstruction occurs when tubular casts produced by desquamated epithelial cells or cellular debris combine with intratubular proteins.[55,56] Tubular obstruction can also occur by precipitation of filtered heme pigments, crystal deposition (calcium oxalate, sulfonamides), or by extratubular compression (interstitial edema, inflammation). The impediment to tubular fluid flow increases intratubular hydrostatic pressure, decreases net ultrafiltration pressure, and halts single nephron glomerular filtration.

Back leak of tubular fluid across the disrupted epithelium further decreases urine formation and consequently the apparent ultrafiltration rate.[57,58]

Intrarenal vasoconstriction is a common participant in the pathogenesis of either hemodynamic or nephrotoxic injury. The resulting decrease in renal blood flow is transient and may occur in either the initiation or the extension phases. At the same time renal blood flow will be redirected preferentially to the cortex to maximize GFR and solute reabsorption at the expense of perfusion to the outer medulla. The redistribution creates profound hypoxia at the site of this oxygen-demanding segment.[3,51,59,60] Vasoconstriction is induced by altered regulation of competing dilatory and constrictive vasoactive processes that regulate and balance vascular resistance. Up-regulation of the renin-angiotensin system, impairment of renal autoregulatory capacity, enhanced adrenergic activity, and systemic or local release of vasoactive agents (thromboxane A2, leukotrienes C4 and D4, endothelin-1, adenosine, and endothelium-derived prostaglandin E_2) promote enhanced vasoconstrictive forces. The vasoconstriction frenzy is further exacerbated by vascular endothelial dysfunction to cause decreased production and release of vasodilator substances, including nitric oxide and prostaglandins.

258.2.4 Cellular Biology of Intrinsic Acute Renal Failure

Discovery of the cellular responses to ischemic and nephrotoxic injuries have improved our understanding of the clinical course of ARF. An extensive discussion of these mechanisms is beyond the scope of this review but are summarized in Figure 258-2 and reviewed in-depth elsewhere.[17,43,61]

Hypoxia secondary to poor perfusion of the outer medulla causes depletion of energy-dependent mechanisms within cells. Energy depletion alters cytosolic ionic concentrations (Na+, Ca++), loss of cellular polarity and vectorial cellular transport, disruption of tight junctions and the brush border membrane, and detachment of tubular cells from the basement membrane. In addition to these degenerative events, release of inflammatory cytokines (IL-l, TNF-), chemokines, heat shock proteins, nitric oxide, and reactive oxygen species induce a proinflammatory state that further compromises cellular oxygenation. Recognition of these hypoxic and inflammatory interactions provides opportunity for new therapeutic strategies to alter the course of ARF.

The kidney is exposed to high concentrations of endogenous and exogenous toxins, including drugs and their metabolites. This is intensified by regional hemodynamic, reabsorptive, and concentrating processes. In contrast to NSAIDs and ACE inhibitors, which induce ischemic lesions through alterations in blood flow in the glomerulus and the interstitium, other nephrotoxins, like aminoglycosides and ethylene glycol, cause direct epithelial injury and cellular damage (see discussion of cause ARF)[15,19]

258.3 CLINICAL CONSEQUENCES OF ACUTE UREMIA

The clinical consequences of acute uremia are the collective result of the excretory (water, potassium, phosphorus, nitrogenous waste products, medications), regulatory (fluid volume, electrolytes, acid-base, divalent cations, blood pressure), and endocrine (calcitriol and parathyroid hormone [PTH], erythropoietin) failure of the kidney. The clinical manifestations of acute uremia are the result of the multisystemic basis of the syndrome. Recent observations in dogs indicate that usually four or more organ systems are affected at presentation and in early stages of management. Ranking of organ system involvement (in percent of uremic dogs) revealed the following: gastrointestinal (GI) (93%), cardiovascular (80%), respiratory (52%), hematologic (40%), and neurologic (36%).[62] The multisystemic features of uremia per se become interspersed with the discrete symptomatology induced by the underlying cause, concurrent diseases, and therapy. An awareness and understanding of these collective manifestations of uremia is necessary to properly direct the therapeutic approach.

258.3.1 Disorders of Fluid Balance

At initial examination most animals are hypovolemic and dehydrated due to GI fluid losses, hemorrhage, and inadequate fluid intake. Dehydration at this stage of disease fosters renal hypoperfusion and leads to a prerenal azotemia. Extended hypovolemia promotes further impairment of renal perfusion, worsens the azotemia, and predisposes the kidneys to additional ischemia injury. Overaggressive fluid therapy predictably leads to hypervolemia and overhydration, causing peripheral and pulmonary edema, pleural effusion, systemic hypertension, and CHF. In dogs referred for severe ARF, nearly 70% were overhydrated when they arrived at the authors' hospital, some in excess of 25% of their body weight.

1736

1737

Serial measurements of body weight and critical assessment of hydration at presentation and at regular intervals during therapy are essential to avoid this iatrogenic complication.

258.3.2 Inadequate Urine Production

Oliguria or anuria is both a hallmark and a critical feature of acute uremia. Whereas anuria constitutes essentially no urine production, no consensus exists on the exact definition of oliguria. Urine production less than 0.27 mL/kg/hr,[63] less than 0.48 mL/kg/hr[64,65] and less than 1 to 2 mL/kg/hr[66] have all been described. The authors interpret urine production less than 1 mL/kg/hr in a rehydrated, euvolemic, or hypervolemic dog or cat on intravenous fluids or receiving diuretics as pathologically oliguric. The concept of pathologic oliguria seems justified by the fact that animals with normal renal function would be expected to produce more than the lower limit of normal urine output under similar clinical conditions. Pathologic oliguria should be differentiated from physiologically appropriate oliguric states associated with prerenal disorders that are responsive to fluid administration.

Approximately one third of dogs with severe ARF are anuric, one third are oliguric, and one third are nonoliguric.[62] Severe renal injuries associated with nephrotoxins have a higher incidence of anuria. Solute retention, overhydration, hyperkalemia, and metabolic acidosis are exacerbated in oligoanuric animals compared with those with nonoliguric disease. Persistent oligoanuria prevents administration of essential therapies associated with large fluid volumes (enteral and parenteral medications, blood products, and nutrition). The conversion from an oliguric to a nonoliguric state may facilitate delivery of these therapies without concurrent improvement in GFR.

258.3.3 Electrolyte and Acid-Base Disturbances

Impaired excretory function of the diseased kidney leads to an array of electrolyte and acid-base disturbances. The most prominent disturbance is hyperkalemia, which can be further aggravated by inappropriate potassium administration in enteral or parenteral fluids and by metabolic acidosis. Hyperkalemia decreases the transmembrane potassium gradient, depolarizes cell membranes, and impairs excitation and conduction. When expressed at the sinus node and on myocardial cells, these perturbations cause classic electrocardiographic abnormalities associated with the severity of hyperkalemia. The cardiac effects lead progressively to bradycardia, atrial standstill, and cardiac arrest as the hyperkalemia worsens. These same electrophysiologic disturbances affecting skeletal muscle, smooth muscle, and peripheral nerves can cause profound weakness, flaccid paralysis, respiratory failure, GI hypomotility, and hyporeflexia. Hyperkalemia is a leading cause of death, failure of conventional therapies, and a specific indication for dialysis.

Abnormalities in serum sodium are frequently iatrogenic and induced by inappropriate fluid therapy and excessive use of sodium bicarbonate. Hyponatremia is an indication of excessive free water administration associated with hyponatric solutions (5% dextrose, TPN, or enteral formulations). Transient dilutional hyponatremia is seen after the administration of mannitol, hypertonic dextrose, or synthetic colloid solutions as free water shifts from the intracellular to the extracellular space. It may also be recognized with excessive losses of sodium associated with vomiting, pancreatitis, adrenal insufficiency, or diuretic administration.

Hypernatremia may be documented at initial examination and indicates excessive free water loss. In hospitalized animals, it is a common complication of isonatric crystalloid administration for maintenance fluid requirements. Hypernatremia is a complication of excessive administration of hypertonic saline or sodium bicarbonate.

Metabolic acidosis is a predictable feature of acute uremia due to the impaired acid excretion, decreased bicarbonate reabsorption, and decreased ammonia generation. Metabolic acidosis is worsened by additional acid loads generated by the underlying disorder (ethylene glycol, salicylate intoxication), decreased perfusion (lactic acidosis), hypercatabolism, and concurrent diseases (diabetic ketoacidosis). These abnormalities are attended by an increased anion gap, decreased serum bicarbonate, acidemia, and hyperkalemia. Severe metabolic acidosis produces tachypnea, Kussmaul's respiration, decreased cardiac contractility, cardiac arrhythmias, hypotension, and pulmonary congestion.[67] Neurologic sequelae include depression, lethargy, stupor, or coma due to impaired volume regulation in the brain.[68] Metabolic acidosis induces insulin resistance and increases protein catabolism, which further contributes to the azotemia and muscle wasting.[69]

Dehydration, intractable vomiting, or sodium bicarbonate therapy will occasionally cause metabolic alkalosis. Mixed acid-base disturbances are common in animals with impaired ventilation (pulmonary edema or hemorrhage, pleural effusion, pneumonia) or hyperventilation (pain, pulmonary thromboembolism).

258.3.4 Uremic Intoxications

Acute filtration failure causes the rapid accumulation of a spectrum of low (< 500 D) and middle molecular weight (500 to 15,000 D) uremia toxins. Collectively, uremia toxins contribute to the multisystemic features of acute uremia in direct proportion to their accumulation in the body. Conversion of urea to ammonia, decreased mucus production, hypergastrinemia, and central effects of uremia toxins contribute collectively to the GI manifestations. The GI signs include anorexia, nausea, vomiting, fetid breath, stomatitis, oral ulcerations, lingual necrosis, xerostomia, reflux esophagitis, gastritis, GI ulcers, hematemesis, GI bleeding, diarrhea,

enterocolitis, intussusception, and ileus.[70] As a subcomponent of the collective GI involvement, as many as 10% of dogs with severe ARF develop acute pancreatitis.[11,62]

Toxin-induced bleeding tendencies are promoted by impaired platelet-vessel wall and platelet-platelet interactions. Purpura, petechia, ecchymosis, bruising, bleeding from gum margins and venipuncture sites, epistaxis, and GI blood loss are characteristic. GI bleeding contributes to anemia and on occasion causes acute blood loss. In addition, uremia toxins cause or contribute to hypothermia, uremic pneumonitis, carbohydrate intolerance, and impaired immunity.

258.3.5 Cardiovascular Complications

Volume overload, cardiomegaly, heart failure, cardiac arrhythmias, and hypertension are common cardiovascular complications. Less commonly pericarditis, pericardial effusion, and tamponade may occur.[71] Bradycardia, supraventricular and ventricular premature contractions, and paroxysmal ventricular tachycardia are expected arrhythmias with severe uremia. Approximately 80% of the dogs with severe acute uremia have systemic hypertension. The severity of the hypertension is variably volume dependent and could be exacerbated by fluid therapy. If unresolved it may cause retinal detachment, hyphema, retinal hemorrhage, encephalopathy, and cerebrovascular hemorrhage.[72,73]

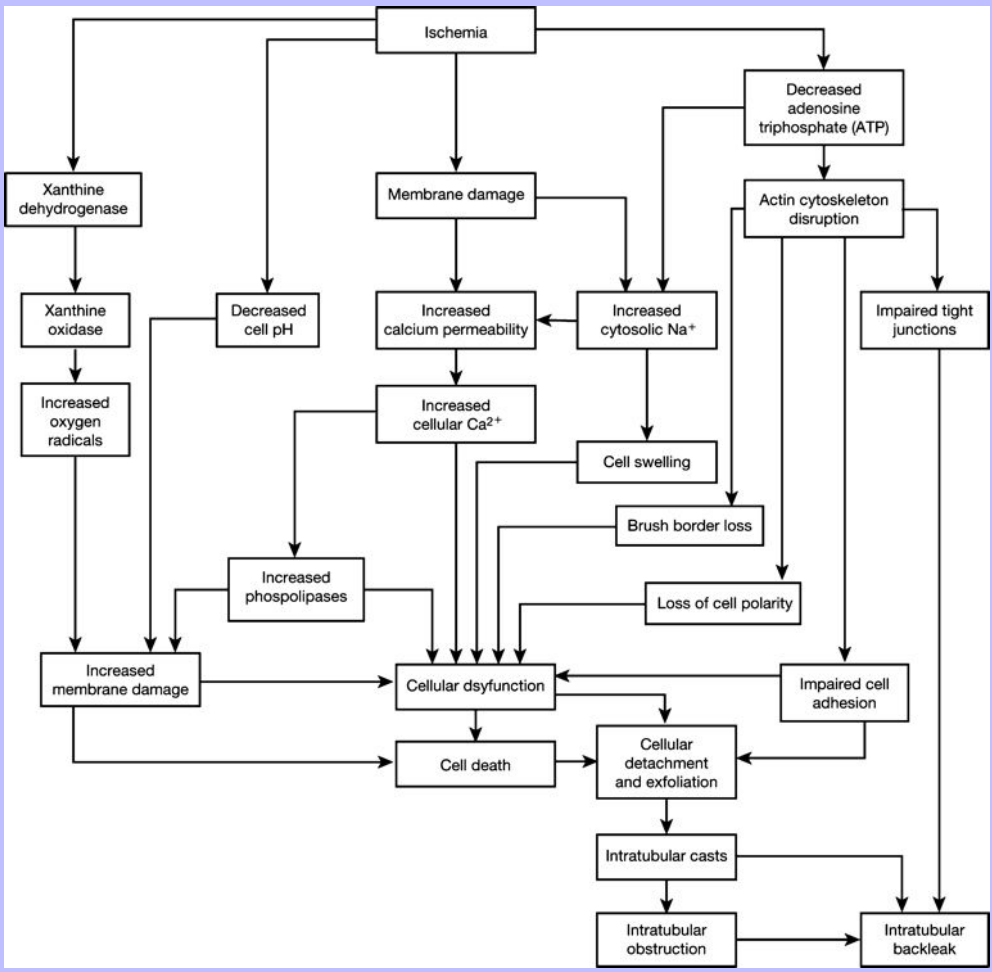
Uremic animals are at risk for cardiac arrest due to severe hyperkalemia and the collective metabolic, acid-base, and electrolyte disturbances associated with acute uremia. Bradycardia and vomiting pose additional risks for cardiac arrest secondary to increased vagal tone associated with the gastroenteritis.

258.3.6 Pulmonary Complications

Respiratory disease is seen in approximately half of dogs with severe uremia, is frequently life threatening, and is often refractory to conventional therapy. In order of frequency, pulmonary edema, pleural effusion, pneumonia, pulmonary hemorrhage, uremic pneumonitis, and pulmonary artery thromboembolism have been documented. Interstitial or alveolar edema and pleural effusion develop from excessive fluid administration and volume overload. The signs of fluid overload must be distinguished from those of CHF before appropriate therapy can be instituted. Aspiration pneumonia is a common sequelae to protracted vomiting. Severe generalized patchy interstitial to alveolar pulmonary infiltrates and associated pulmonary dysfunction is recognized in some dogs with leptospirosis.[74] Respiratory arrest may complicate all these respiratory disorders.[75]

1737 1738

Figure 258-2 Cellular events in renal tubular epithelia in response to an ischemic insult. The diagram illustrates the multifactorial interactions that result ultimately in sublethal cellular dysfunction or cell death.



258.3.7 Neuromuscular Disorders

The underlying cause for neuromuscular dysfunction is multifactorial but includes intrinsic central nervous system (CNS) pathology (cerebral hemorrhage) and secondary manifestations of the uremic state (electrolyte and acid-base imbalances, hypertension). Resulting clinical signs are diverse and include fatigue, dullness, lethargy, impaired mentation, altered behavior, confusion, stupor, tremors, seizures, coma, peripheral neuropathies, myoclonus, muscular cramps, and muscular weakness. Ethylene glycol toxicosis causes specific CNS dysfunction before the onset of or in concert with the development of overt renal failure. Rapid

correction of the azotemia with hemodialysis can induce osmotic shifts of water in the brain, resulting in cerebral edema, seizure, cerebellar and brain stem herniation, coma, and death.

CNS side effects are associated with some medications (H_2 blockers, metoclopramide) when administered at conventional doses to animals with reduced capacity to eliminate such drugs. Animals with acute renal swelling display pain on abdominal palpation due to distension of the renal capsule. Prostration, dullness, or aggressive behaviors are typical manifestations of renal pain, especially in cats.

258.4 DIAGNOSIS OF ACUTE UREMIA

The clinical signs of acute uremia vary with the underlying cause and severity of disease, previously administered therapy, and comorbid diseases predisposing or compounding renal injury. A rapid and accurate differentiation of the possible syndromes resulting in acute uremia must be made to direct the therapeutic approach. These possible syndromes are (1) prerenal azotemia, (2) prerenal azotemia complicating CRF, (3) acute (parenchymal) renal failure (ARF), (4) prerenal azotemia complicating ARF, (5) chronic end-stage renal failure, and (6) postrenal azotemia. Each of these disparate azotemic conditions may appear quite similar. Because no specific biologic markers are available to predict the existence, severity, or recovery of renal parenchymal injury, the diagnosis of acute uremia is established from a comprehensive data base (which includes history, physical examination, laboratory testing, diagnostic imaging, histopathology, and special testing).

258.4.1 History

Acute uremia is characterized by a sudden onset of illness of less than 1 week's duration; however, animals with acute uremia secondary to underlying urinary or systemic diseases may have a longer duration of documented illness. Historical signs include listlessness, depression, anorexia, vomiting, diarrhea, and weakness. Less commonly, seizures, syncope, ataxia, and dyspnea may be reported. Potential exposure to nephrotoxic chemicals or plants (lily,[21] grapes or raisins[22,23]), new environmental conditions, ill animals, or traumatic events should be ascertained in the history. Recent surgery, diagnostic testing, travel, newly prescribed medications, or blood loss are potential risk factors for renal injury. Oliguria or anuria are consistent features of acute uremia, but a history of normal or increased urine production does not exclude its consideration. Historical weight loss, polyuria, polydipsia, nocturia or isosthenuria, or laboratory evidence of pre-existing renal insufficiency suggests underlying chronic renal disease. Renal function in animals with asymptomatic chronic renal insufficiency may decompensate suddenly after subtle insults including, fever, concomitant disease, vomiting, diarrhea, CHF, and drug administration, and they may develop a uremic crisis that is seemingly acute.

258.4.2 Physical Examination

Physical examination is an essential component of the diagnostic approach and may define the location and cause of the uremic state. Due to the acute nature of this condition, most animals in ARF have good body and coat condition. They have variable degrees of hydration. Depression, hypothermia, oral ulceration, “uremic breath,” bile-stained fur, scleral injection, cutaneous bruising, discoloration or necrosis of the tongue, tachycardia or bradycardia, tachypnea, muscle fasciculations, and seizures are present in proportion to the severity and duration of the azotemia. Bilaterally enlarged, firm, slightly resilient, or painful kidneys noted on abdominal palpation is indicative of acute nephritis or nephrosis or bilateral ureteral obstruction. Enlarged and firm kidneys on palpation are more suggestive of renal neoplasia, amyloidosis, or polycystic kidney disease. Asymmetry in kidney size is being recognized more frequency in cats with acute uremia due to the increasing

incidence of unilateral ureteral obstruction (Figure 258-3). The obstructed kidney is enlarged, and the contralaterally smaller kidney is frequently end-stage and nonfunctional. The size of the urinary bladder is variable on abdominal palpation, depending on the quantity of urine formation and the integrity of the outflow tract. An undetectable urinary bladder indicates profound oliguria or anuria or complete ureteral obstruction. An enlarged, firm, and painful bladder predicts outflow obstruction of the bladder.

In the absence of hemorrhage or hemolysis, mucous membranes are usually pink in dogs and cats with ARF. This is in contrast to the pale mucous membranes observed in animals with CRF. Most animals with ARF have evidence of dehydration when first evaluated, which may underscore prerenal causes or contributions. Prolonged capillary refill time, dry mucous membranes, decreased skin turgor, sunken eyes, tachycardia, poor pulse quality, and hypotension are consistent with the presence of dehydration and hypovolemia. Animals that have been given parenteral fluids may demonstrate signs of overhydration (wet mucous membranes, serous nasal discharge, increased skin turgor, peripheral edema, tachypnea, dyspnea, muffled heart sounds, hypertension, and ascites).

ARF is frequently layered secondarily on other diseases or even CRF. Manifestations of these other conditions may dominate findings of the physical examination and mask its characteristic features. Lameness, icterus, fever, discolored urine, back or flank pain, petechia, and dysuria are associated with some disorders. Uremic animals typically are hypothermic in proportion to the severity of the azotemia. The presence of a normal or slightly elevated body temperature is inappropriate for uremic animals and is consistent with fever associated with an underlying infectious or inflammatory state.

258.4.3 Laboratory Assessment

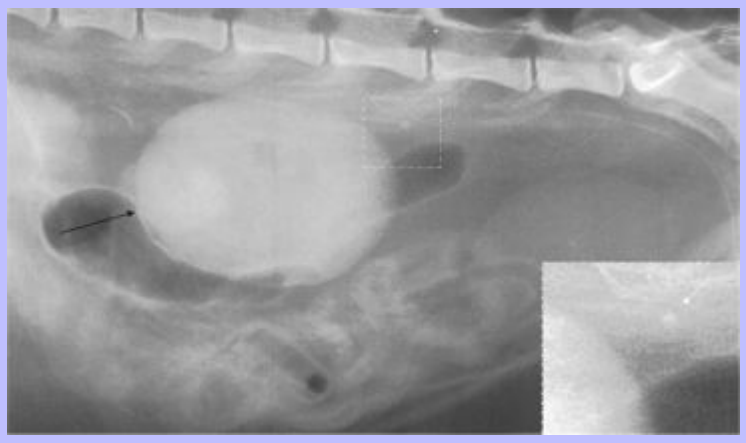
The initial diagnostic assessment should include a complete blood count (CBC), comprehensive biochemical profile (serum creatinine, urea, phosphate, calcium, bicarbonate, sodium, potassium, chloride, glucose, albumin, globulin, hepatic transaminases, and bilirubin) (Figure 258-4), urinalysis with sediment examination, and urine culture.

CBC results may reflect primary or comorbid conditions of diagnostic relevance. Normal or increased red blood cell (RBC) count, hematocrit, and hemoglobin concentrations are consistent with prerenal azotemia or acute uremia, whereas a nonregenerative anemia suggests CRF. The hemogram may be significantly influenced by the hydration status of the animal and may overestimate the actual RBC mass with dehydration and underestimate red cell mass with over hydration.

Progressive azotemia is part of the definition for acute uremia (Figure 258-4). In humans, the diagnosis is predicated on subtle daily increases in serum creatinine, but this feature is observed rarely in animals. Animals are usually evaluated when the azotemia is well established, and clinical signs are clearly apparent. Both serum creatinine and urea nitrogen will increase in direct proportion to the severity of the renal impairment or completeness of the outflow obstruction. The degree of functional impairment can be broadly categorized based on steady-state serum creatinine concentration given the inverse relationship between serum creatinine and renal function (GFR).[76] From this projection, the renal dysfunction can be staged as mild in animals with a serum creatinine concentration less than 2.5 mg/dL (>40% of normal function), moderate for those with a serum creatinine concentration between 2.5 mg/dL and 5.0 mg/dL (between 40% and 20% of normal function), severe for those with a serum creatinine concentration between 5 mg/dL and 10 mg/dL (between 20% and 10% of normal function), and extreme if the serum creatinine concentration is greater than 10 mg/dL (<10% of normal function). Reductions in lean body mass and overhydration can lower the serum creatinine concentration and cause overestimation of true renal function.

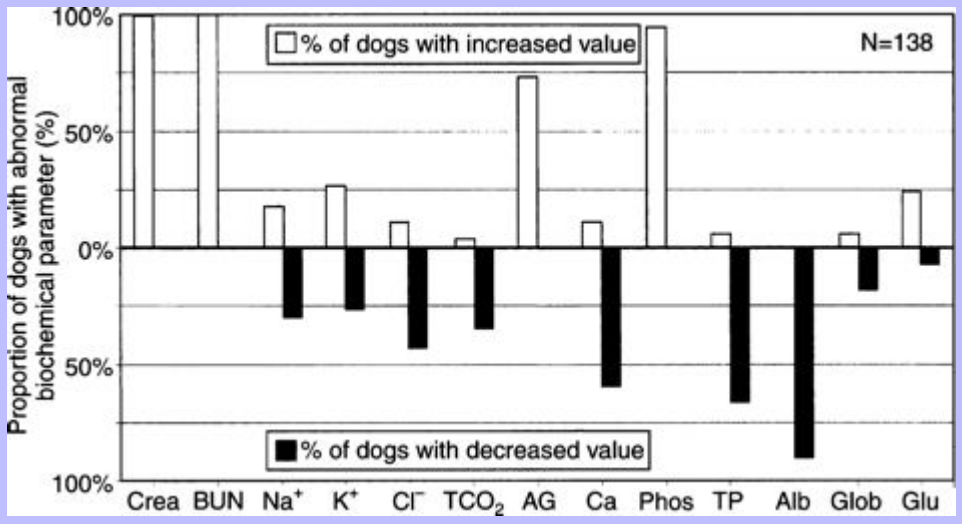
1739
1740

Figure 258-3 Lateral radiographic image of a cat abdomen illustrating extreme asymmetry in renal size characteristic of the "big kidney-little kidney" syndrome associated with ureteral obstruction. The right end-stage kidney *(black arrow)* is superimposed on the enlarged left kidney. The dashed box and insert highlight a radiodense calcium oxalate urolith in the left ureter *(white arrow)*.



Serum urea nitrogen (SUN) concentration also increases inversely with reductions in GFR and contributes to the developing azotemia. Unlike creatinine, urea is influenced by numerous extra renal parameters that make its concentration less specific as a marker of renal function. Urea appearance is closely linked with exogenous and endogenous nitrogen metabolism, hydration status, urine production, and diuretic therapy that make it a useful predictor of the clinical severity of the uremic state. Urea is also used as a surrogate for the production and removal of low molecular weight uremia toxins during dialysis.[77]

Figure 258-4 Incidence of serum biochemical changes in 138 dogs with severe ARF at the time of referral. The proportions of dogs with abnormally high (above zero line) and abnormally low (below zero line) values are shown for the following parameters: creatinine (Crea), BUN, sodium (Na^+), potassium (K^+), chloride (Cl^-), total CO_2 (TCO_2), anion gap (AG), calcium (Ca), phosphorus (Phos), total protein (TP), albumin (Alb), globulins (Glob), and glucose (Glu).



For comparable azotemia, animals with acute uremia usually have more profound alterations of serum mineral, electrolytes, and bicarbonate concentrations reflected on the biochemistry profile than animals with CRF (see Figure 258-4). In acute uremia, serum phosphate concentration generally exceeds that of creatinine and may be associated with mild to moderate hypocalcemia. Serum calcium concentration may be less than 5.0 mg/dL in animals with acute antifreeze intoxication. In contrast, serum calcium is usually normal or moderately elevated in proportion to serum creatinine and phosphate in animals with CRF.[78,79] Serum potassium concentration varies with the severity and cause of the uremia, extent of vomiting, and fluid and diuretic administration (see Figure 258-4). Serum potassium typically is increased (between 5.5 mEq/L and 9.0 mEq/L) in proportion to the degree of azotemia. It tends to be higher in animals with anuric ARF or urinary outflow obstruction. Serum bicarbonate concentration decreases with the severity of the renal failure such that bicarbonate deficits of 5, 10, and 15 mmol/L are associated with mild, moderate, and severe degrees of acute uremia, respectively.[80] Profuse vomiting or previous bicarbonate administration may cause metabolic alkalosis that is not consistent for the degree of azotemia.

Distinguishing animals with prerenal azotemia from those with intrinsic ARF can often be made from results of history, clinical findings, and USG. The presence of mild or moderate azotemia, clinical dehydration, hypovolemia or hypotension, and oliguria in conjunction with a concentrated USG or urine osmolality confirms the diagnosis of prerenal azotemia. Therapeutic confirmation of the diagnosis can be made by a rapid

resolution of the azotemia and oliguria with restoration of fluid balance and normalization of systemic hemodynamics. Numerous laboratory parameters including BUN/creatinine ratio, urine/plasma sodium (U/P_{Na}), and fractional sodium excretion (FE_{Na}) have also been used to distinguish oliguric animals with a prerenal condition from those with ARF. The discrimination is achieved by the increased reabsorption of urea and sodium in prerenal states compared with ARF. The utility of these tests becomes problematic in animals with coexisting diseases that impair concentration of the urine or after diuretic administration that increases urinary sodium excretion. Additionally, BUN/creatinine ratio has been shown to provide no localizing value in dogs with renal disease but may be more predictive of heightened catabolism or intestinal bleeding.[8,81] More recently, the fractional excretion of urea (FE_{urea}) has been shown to be highly sensitive for identification of humans with prerenal azotemia from those with prerenal azotemia and concurrent diuretic administration or others with intrinsic ARF (similar testing may be useful in animals).[82]

1740

1741

The tubular epithelial enzymes, gamma-glutamyl transpeptidase (GGT) and N-acetyl-beta-D-glucosaminidase (NAG), can be measured in urine to predict cellular leakage as an early marker of tubular injury or necrosis.[83–87] Urinary enzymes have shown good sensitivity for early recognition of renal injury, but they have not been adopted widely in veterinary or human diagnostics. Carbamylated hemoglobin is a nonenzymatic and nonreversible reaction product of the urea metabolite, cyanate, with hemoglobin. The concentration of carbamylated hemoglobin reflects time exposure of blood to the azotemia and has been shown to differentiate dogs with acute azotemia from those with CRF.[88,89] Testing for carbamylated hemoglobin is becoming more readily available in human hospitals and is likely to find increased utility in uremic animals.

A complete urinalysis should be performed on every dog or cat with obtainable urine at initial examination prior to instituting therapy. Both renal concentrating and diluting capabilities become impaired in the early phases of intrinsic ARF resulting in a USG that is fixed in the range between 1.008 and 1.018. A USG greater than 1.030 for dogs or greater than 1.035 for cats in the presence of azotemia indicates prerenal filtration failure.[90] A USG between 1.012 and 1.029 (dogs) or 1.012 and 1.034 (cats) associated with azotemia is consistent with a prerenal component superimposed on intrinsic renal insufficiency (*prerenal-on-acute* or *prerenal-on-chronic* disease) or an underlying urine-concentrating defect. Glucosuria in the absence of hyperglycemia is present in 50% of dogs with severe ARF and is an important sign of proximal tubular dysfunction.[62] It predicts tubular necrosis and is a useful discriminator between intrinsic ARF and other types of acute or chronic uremia.[11] Qualitative (dipstick) proteinuria is detected in most uremic animals but has little discriminatory importance.[11] Overt proteinuria associated with a urine protein/creatinine ratio greater than six should alert the possibility of primary glomerular injury.

The urine sediment examination may demonstrate RBCs, white blood cells (WBCs), casts, crystals, yeast, fungi, or bacteria that aid the differential diagnosis and cause of the uremia and should be performed routinely on freshly obtained urine. The presence of granular and hyaline casts document active renal pathology with tubular epithelial shedding or necrosis and glomerular protein leakage. Casts are detected in approximately 30% to 40% of dogs with ARF, but their absence does not exclude a diagnosis of acute parenchymal injury.[11] Calcium oxalate crystalluria is indicative of hyperoxaluria associated with ethylene glycol intoxication and oxalate nephrosis (cats).[19,90–93]

Imaging of the urinary tract with survey radiography and ultrasonography is indicated in the evaluation of all animals with acute uremia. Ultrasonography is complementary to diagnostic radiography and is the preferred imaging modality for urinary disease. Ultrasonography is rapid, noninvasive, and provides greater delineation

of renal geometry, intrarenal architecture, parenchymal consistency, and outflow integrity. It provides a more definitive assessment of renal and abdominal pathology, including nephritis and nephrosis, pyelonephritis, urolithiasis, hydronephrosis, outflow obstruction, pancreatitis, abdominal neoplasia, prostatitis, and ascites. Ultrasonic imaging facilitates collection of diagnostic specimens for biochemical analysis, cytology, culture, and histology by incorporation of guided percutaneous needle aspiration or biopsy techniques.[94] Duplex Doppler sonography can be used to verify segmental blood flow in the kidney and to predict changes in vascular impedance associated with induction and resolution of some forms of renal injury and outflow obstruction.[95,96] The sonographic appearance of the kidneys can provide immediate verification for conditions like antifreeze poisoning, ureteral obstruction, and end-stage renal disease. Ethylene glycol intoxication, for example, is characterized by marked to intense increases in cortical echogenicity with variable degrees of hypoechoic intensity at the cortical medullary junction (halo sign)(Figure 258-5). However, the increased availability and utility of ultrasonography has curtailed the routine use of survey radiography to image the urinary tract. For the diagnosis of ureteral obstruction in cats, survey radiographs may be more sensitive and predictive than ultrasonography, if careful scrutiny is directed to barely perceptible radiodensities in the retroperitoneal space, and they are justified in all cats with acute uremia (see Figure 258-3).

Excretory urography, renal scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI) may have specific indications in selected animals, but these imaging modalities are not routinely available. Antegrade pyelography incorporating ultrasound-guided pyelocentesis has become increasingly useful to confirm the presence, degree, and location of ureteral obstruction in cats (Figure 258-6). In 20% to 30% of cats with ureteral obstruction, no discrete calcific material is identified with either sonographic or survey radiographic techniques. For these circumstances, and for cases with multiple sites of obstruction or stenosis, antegrade pyelography remains the best aid for identification and localization for surgical intervention.

The cause and course of the acute uremia can be determined for most animals from assessment of the history, physical findings, and contemporary diagnostic testing. Where these features cannot be predicted with certainty, renal histopathology can provide a specific morphologic and potentially causative basis for the disease, its potential reversibility, and chronicity. Details of the techniques, indications, and contraindications for renal biopsy have been described recently.[97,98] Percutaneous or laparoscopic needle techniques can be performed in both dogs and cats with minimal sedation, anesthesia, or invasiveness and obviate the need for surgically obtained renal specimens. Routine biopsy of animals with acute uremia is probably unjustified when balanced against the potential for complications and lack of scientifically documented assessment of risk versus benefit. Renal biopsy should be considered if the definitive cause, extent, and chronicity of the renal injury cannot be established with noninvasive diagnostic methods or if therapeutic decisions would be predicated on this information. Discretion should be used in extrapolating acute morphologic findings from the biopsy to the potential long-term reversibility of the functional deficiencies. The advent of hemodialysis has changed the clinical understanding of reversible and irreversible renal failure. Identification of severe pathology at acute stages of disease may not correspond to an unfavorable outcome if the potential (time) for renal repair is provided with finite periods of renal replacement.

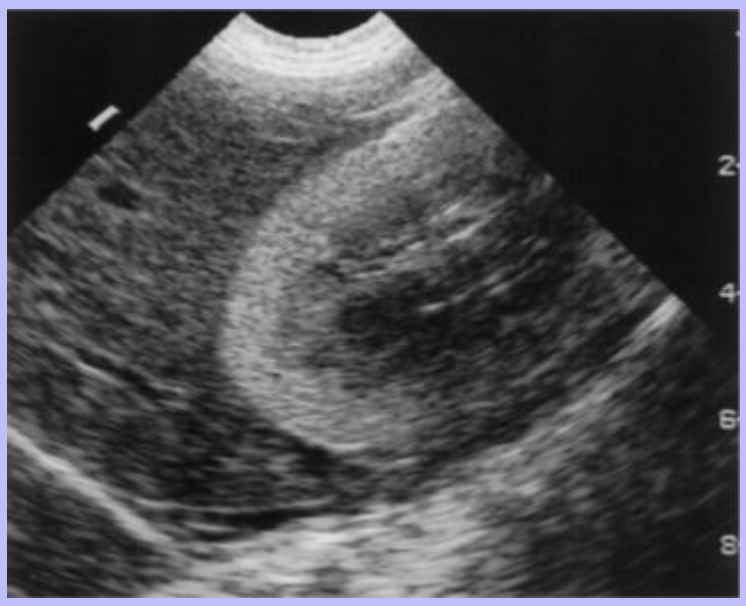
Serologic testing for leptospirosis should be performed on all dogs with acute uremia without a confirmed cause. The evaluation should be expanded to include titers to *L. pomona, L. bratislava, L. grippotyphosa, L. autumnalis,* and *L. hardjo* in addition to *L. canicola* and *L. icterohaemorrhagiae*, because the distribution of infecting serovars differ geographically.* Strict criteria for serologic conformation of an active leptospiral infection have not been established, and the recent introduction of multivalent vaccines makes interpretation more difficult. A microscopic agglutination titer greater than 1:100 indicates positive serology, and a fourfold or greater rise in titer between paired sera separated by 7 to 14 days predicts active infection.[101,102] Ambiguity in the diagnosis arises when only a single titer is available for analysis. Previous retrospective studies

1741

1742

arbitrarily established single titers of greater than 1:800 and greater than 1:3200 to nonvaccinal serovars as criteria for a positive diagnosis of leptospirosis in dogs.[33,34,36] However, laboratory variation, differences in humoral responses to individual serogroups, vaccination, and background (asymptomatic) exposure make strict serologic criteria difficult to assign. Vaccination can produce titers greater than 1:1250 to serogroups, *icterohaemorrhagiae* and *canicola,* in dogs; however, vaccination should not produce titers to nonvaccinal serovars that exceed those of vaccinal agents.[103] A recent survey of nonselected dogs identified a surprisingly high percentage of nonvaccinated dogs with positive serology to leptospirosis serogroups indicating background population exposure.[39] Shedding of leptospiral DNA has also been recognized using a sensitive polymerase chain reaction (PCR) assay in both asymptomatic and symptomatic seronegative dogs.[104] These observations suggest some dogs have delayed seroconversion or fail to seroconvert despite being actively infected. This sensitive diagnostic technique will improve clinicians' ability to diagnose active infections and understanding of renal carriage, shedding, and risks of leptospirosis in the presence and absence of vaccination. Given the limitations of current diagnostic methods, clinical guidelines for a diagnosis of active infection include a single elevated titer (≥ 1:800) to a vaccinal serogroup accompanied by clinical signs consistent with leptospirosis; a single microscopic agglutination titer 1:800 for nonvaccinal serogroups; evidence of seroconversion in paired acute and convalescent sera; and presence of typical clinical signs of leptospirosis followed by a response to appropriate antimicrobial therapy.[32]

Figure 258-5 Ultrasonographic image of the kidney from a dog acutely poisoned with antifreeze. The renal cortex is markedly hyperechoic, compared with the ultrasonic density of the adjacent spleen. This sonographic feature is a consistent finding with ethylene glycol intoxication.



A diagnosis of ethylene glycol intoxication can be made presumptively by the presence of an increased serum osmolality, osmolal gap, profound metabolic acidosis, increased anion gap, hypocalcemia, the presence of

calcium oxalate crystalluria, and sonographic appearance of the kidneys (see Figure 258-5).[19,91,93] Confirmation of the diagnosis, documentation of the degree of intoxication, and response to therapy is best performed by chemical analysis of gastric fluid, serum, or urine for the presence of ethylene glycol or its toxic metabolites by commercial laboratories. Blood ethylene glycol and glycolic acid concentrations may persist for days at toxic concentrations despite therapy with alcohol or 4-methylpyrazole in affected animals with severe oliguria or anuria.[104,105]

Figure 258-6 Nephropyelogram of a cat kidney with a proximal ureteral obstruction. The figure highlights the ultrasound-placed needle in the renal pelvis and the extensive pelvic and ureteral dilation outlined by the injected contrast. The proximal ureter is dilated, torturous, and ends abruptly *(arrow),* despite the increased pressure associated with contrast injection. These findings are consistent with a radiolucent structure producing complete ureteral obstruction.

258.5 MEDICAL MANAGEMENT OF ACUTE UREMIA

Medical management of acute uremia in animals remains founded on observations from animal models of ARF and recommendations extrapolated from human therapeutics.[4,106–108] Recommendations are prioritized to prevention of renal injury in predisposed or high-risk animals, to elimination of underlying or ongoing renal insults, and to amelioration of identified biochemical, metabolic and clinical consequences of established uremia. The mechanisms underlying the impaired glomerular hemodynamics, epithelial and vascular disruption, and

intratubular obstruction that mediate acute renal injury have been characterized in great detail in recent years (see Pathogenesis of Acute Renal Failure). Cellular energetics, vascular congestion, cytosolic calcium, oxidant stress, necrosis, apoptosis, nitric oxide, epithelial cytoskeleton, and growth promoters are but a few mediators recently recognized to participate in the pathogenesis of ARF. Novel therapies have emerged from each of these areas of discovery to counteract specific pathophysiologic events scientifically crafted in the experimental models. Despite the therapeutic promise of each of these areas of investigation to prevent or ameliorate development of ARF or to accelerate renal repair, none have become established in clinical therapeutics. This is to be expected in animals with naturally acquired disease that possess multifactorial risks and predispositions to acute uremia of diverse cause, severity, duration, and expression.

1742

1743

Thus conventional approaches to management of acute uremia remain supportive for the predicted and documented clinical consequences that develop.

258.5.1 Prevention of Acute Renal Injury

The highest priority for the management of acute uremia is to recognize those dogs or cats highly predisposed to a uremic crisis and to intervene to prevent its development. Pre-existing renal disease, advanced age, dehydration, hypovolemia, hypotension, sepsis, fever, prolonged anesthesia and surgery, trauma, systemic disease, use of vasoactive or nephrotoxic drugs, high environmental temperatures, and nephrolithiasis are predispositions that pose an increased risk.[109] Risk factors are cumulative and predispose additive potential for renal injury. When predispositions coexist with ongoing or projected therapies having a potential for renal injury, the following procedures should be reviewed. Exposure to ischemia and toxic insults should be eliminated, and the dose of nephrotoxic drugs should be modified. Hemodynamic adequacy must be established, and life-threatening fluid, electrolyte, and acid-base imbalances corrected. Decontamination procedures (induced vomiting, gastric lavage, administration of activated charcoal, and cathartics) and treatment with specific antidotes should be instituted after acute exposure to known nephrotoxins. Table 258-1 illustrates these points in the therapeutic approach to acute antifreeze poisoning. The correction of existing fluid deficits and attention to ongoing fluid balance offers the best insurance to moderate ATI. Mild to moderate ECF volume expansion with isonatric fluids is beneficial before the administration of known nephrotoxic drugs (aminoglycosides, cisplatin, amphotericin B), anesthesia, or surgical intervention. Mannitol administered (see details, following) prior to exposure to hemodynamic or nephrotoxic insults will promote urine formation and a natriuresis but has shown only limited efficacy to protect against the development of ATI. The preventative use of other therapies has consistently failed to provide any advantage over judicious fluid management.[4,110–113]

258.5.2 Conventional Management of Established Uremia

Strategy for the management of existing ARF includes elimination of known causes of renal injury (see Prevention of Acute Renal Injury) and supportive therapies directed to the life-threatening consequences of acute uremia. Systemic infections such as leptospirosis should be treated aggressively with appropriate antimicrobial therapy, and hemodynamic deficiencies must be resolved rapidly to establish euvolemia and normotension. Animals with mild renal damage may regain adequate function within 3 to 5 days of initiating treatment. This may forestall progression to life-threatening uremia. Animals with moderate or severe renal damage may require weeks to achieve repair of the injury; yet most die from uremia within 5 to 7 days. The disparity between this window for effective medical therapy and the re-establishment of renal function underlays, in part, the high mortality and unfavorable outcome associated with ARF.

258.5.3 Systemic Hemodynamics and Body Fluids

Alterations in body fluid composition are classic causes and consequences of acute uremia. Fluid therapy remains the foundation of medical management. The fluid plan must restore deficiencies in fluid volume, correct abnormalities in fluid composition, and promote urine formation. Replacement fluids should mimic as closely as possible the composition of fluid deficits. Priority is given to restoration of intravascular and interstitial volume, normalization of arterial blood pressure and renal perfusion, and compensation for ongoing fluid losses. At *initial* examination most animals with ARF are dehydrated and hypovolemic due to active fluid losses (vomiting, diarrhea, and possibly hemorrhage). The fluid deficit should be corrected with 0.9% sodium chloride or balanced crystalloid solutions (lactated Ringer's) administered intravenously to replete vascular volume. The initial replacement volume (milliliter) to correct the extracellular deficit is calculated from clinical estimates of dehydration according to the formula:

$$\text{Volume Replacement (mL)} = [\text{body weight (kg)}] \times [\text{estimated deficit (\%)}] \times 1000$$

Table • 258-1 Therapeutic Approach to Acute Antifreeze Poisoning

THERAPEUTIC PLAN	THERAPEUTIC OPTIONS
Prevent ongoing exposure (<2 hours)	1. Induce vomiting 2. Perform gastric lavage 3. Administer activated charcoal
Correct ECF fluid deficits Correct dehydration	1. Correct ECF volume deficits (saline, lactated 2. Correct metabolic acidosis (if present) 3. Correct hypocalcemia if present) 4. Initiate maintenance fluids/ongoing losses
Document urine production/promote diuresis	1. Establish urinary catheter, monitor urine output 2. Administer mannitol, furosemide, or both after rehydration
Administer antidote	1. Ethanol (20%): 5.5 mL/kg IV q4h-5 Rx, then (dogs/cats) 5.5 mL/kg IV q6h-4 Rx or 2. Ethanol (30%): 1.3 mL/kg IV bolus, then (dogs/cats) 0.42 mL/kg/hr IV for 48 hours
Eliminate toxin/metabolites	3. 4-methyl pyrazole: 20 mg/kg IV, then (dogs) 15 mg/kg IV @ 12 & 24 hours, then 5 mg/kg IV @ 36 hours 4. Hemodialysis at earliest opportunity (dogs/cats)
Manage ARF/oliguria	1. Conventional medical therapy 2. Hemodialysis

The estimated deficit is a value between 5% and 15% determined from history, physical examination, and laboratory information or computed from known deviations from historical body weight. The rate at which the deficits are corrected is predicated on the hemodynamic stability of the animal and its tolerance for fluid administration. Mild or moderate fluid deficits (5% to 8%) in hemodynamically stable animals can be replaced within 6 to 8 hours. Moderate or severe fluid deficits (>8%) associated with evidence of hypovolemia must be corrected more aggressively. The hypovolemic component of the deficit should be administered as bolus infusions within 30 minutes to restore intravascular volume and prevent prolonged hypoperfusion of kidneys. The remainder of the deficit can then be delivered over 6 to 8 hours to correct the dehydration.

1743

1744

Aggressive fluid replacement must be tempered in animals with cardiovascular disease to prevent circulatory congestion and heart failure. Serial monitoring of central venous pressure (CVP) can facilitate safe and

efficient fluid administration. An increase in CVP of 5 to 7 cm H_2O above baseline or an absolute CVP greater than 10 cm H_2O indicates an excessive rate or volume of fluid administration. Five percent dextrose in water or maintenance formulations (including half-strength saline and dextrose solutions) are not appropriate choices to replete the initial deficits and should be reserved to compensate insensible or maintenance losses later in the course of treatment.

Fluid deficits associated with profound hypovolemia and hypotension or severe blood loss must be replaced more rapidly with crystalloid solution (up to or greater than 90 mL/kg/hr) or with fluids targeted for blood volume expansion. Synthetic colloid solutions (Dextran-70 or Hetastarch) administered at 20 mL/kg will expand blood volume immediately by 17% to 24% and by approximately 35% within 60 minutes of administration.[114] Synthetic colloid solutions provide no replacement of extravascular volume necessitating concurrent administration of crystalloid solutions to replete the interstitial compartment. These solutions may be rational choices for support of vascular volume in clinical settings where oxygen-carrying capacity is less critical than volume restoration. Hypovolemia secondary to blood loss or hemorrhage may require administration of compatible whole blood, blood components, or synthetic hemoglobin products (Oxyglobin®, BioPure, Cambridge, Massachusetts).[115,116]

The production of urine at greater than 1.0 mL/kg/hr with fluid volume replacement suggests a significant prerenal contribution to the oliguria and azotemia. Failure to induce a significant diuresis after volume replacement indicates either that parenchymal damage is severe or that initial fluid deficits were underestimated. Additional fluid may be administered taking care to promote only mild volume expansion without overhydration.

After correction of the initial fluid deficits, subsequently administered fluid must reflect maintenance requirements and ongoing losses. Maintenance fluid should be limited to 5% dextrose in water to replace insensible free water losses (20 to 25 mL/kg/day) and balanced electrolyte solutions to replace measured or estimated urine, GI, and other sensible losses. Commercial maintenance formulations can be supplied if insensible and urinary losses are approximately equal. Animals that are provided only isonatric solutions (saline, lactated Ringer's) become depleted of free water and develop hypernatremia within 3 to 4 days. The severity of the hypernatremia may be amplified in animals with appreciable free water loses in the urine during the diuretic phase of ARF, post obstructive diuresis, or subsequent to treatment with osmotic diuretics like mannitol. In oliguric animals, the urinary replacement should be negligible and not prescribed at the same rate as in animals with normal urine production. Urinary losses should be measured or accurately estimated in nonoliguric animals to prevent underestimation of the urinary replacement. Nonoliguric animals in the diuretic phase of ARF or after relief of postrenal obstruction may produce greater than 10 mL/kg/hr of urine that will not be matched by estimates of normal urine production.

Supplementation of potassium in replacement or maintenance fluids must be prescribed on an individual case basis. Fluids containing supplemental potassium are generally contraindicated in oliguric animals or during rapid fluid replacement. If the supplemental load of potassium has no effective elimination route, it will quickly promote hyperkalemia. Animals in the diuretic phase of ARF may excrete excessive amounts of potassium and require supplementation to prevent potassium wasting; but potassium supplementation should always be provided cautiously and only with monitoring of daily serum potassium concentrations.

Fluids must be administered conscientiously to oliguric or anuric animals. Hypervolemia is a common complication of overzealous fluid administration or improper monitoring of fluid balance. Sixty to 70% of animals with moderate to severe acute uremia are overhydrated when referred to the authors' emergency service, or they become hypervolemic during the initial hospitalization period. Failure to induce an effective

diuresis (>1 mL/kg/hr) once the fluid deficits are replete predicts further fluid loading will be unproductive and predispose the animal to overhydration. Weight gain, tachypnea, harsh breath sounds, increased skin turgor, chemosis, serous nasal discharge, peripheral or pulmonary edema, circulatory congestion, ascites, and systemic hypertension are consistent indicators of overhydration and hypervolemia. The presence of dry oral mucous membranes in uremic animals does not reflect hydration status due to decreased salivary secretion (xerostomia). This finding may cause underestimation of true hydration and inappropriate fluid administration.

An excessive fluid load may be difficult or impossible to correct in animals with marginal urine formation. At the first evidence of overhydration, all fluid delivery should be curtailed appropriately or discontinued, and attempts should be made to induce a diuresis (see following). If the fluid burden cannot be managed successfully with diuretic administration, no medical options are available to resolve the overhydration and therapy must be directed to consequences of circulatory overload (systemic hypertension, peripheral and pulmonary edema, pleural effusion, CHF, and ascites). For life-threatening overhydration, fluid removal with hemodialysis or peritoneal dialysis is the only available therapeutic option (see Renal Replacement Therapy, following).

Cross-linked polyelectrolyte sorbents offer a promising and clinically applicable oral solution for overhydration in uremic animals. These materials can adsorb up to 50 times their intrinsic weight in GI water, providing an effective alternative for fluid elimination. At typical doses, orally administered sorbets could eliminate up to 1 L of daily fluid accumulation in a 30 kg dog. Additionally, these polymers can adsorb solutes dissolved in intestinal water, providing an alternative clearance for urea, creatinine, and potassium. Prototype materials have been used successfully in a uremic dog and are being developed for human administration.[117]

258.5.4 Inadequate Urine Production

The conversion from oligoanuric to nonoliguric renal failure has been a long-standing goal in the management of acute uremia. The routine use of diuretics and vasodilators has been advocated when fluid therapy alone is ineffective to promote diuresis.[4,110,111,118] Management benefits of an induced diuresis include (1) disclosure of less severe renal injury, (2) better regulation of fluid and electrolyte balance, (3) opportunity to provide parenteral nutrition, (4) increased toxin clearance, and (5) optimism for attending clinicians. Despite conventional endorsement of diuretic therapy in the management of ARF, this practice is losing credibility due to a lack of documented efficacy of pharmacologic agents to alter the course, morphology, or outcome of ARF. Empiric use of these drugs impose recognized risks.[4,107,110–112,118–121] A recent cohort evaluation of diuretic administration in human patients with ARF documented an increased risk of death and failure to recover renal function with diuretic use compared with its nonuse.[112,122] If delayed beyond a few hours from the initiation phase of the insult, the efficacy of diuretics becomes negligible. Their use should never supplant judicious fluid and hemodynamic support.[4,110,111,118,123]

1744

1745

Hypertonic mannitol (an osmotic diuretic) is used commonly for the prevention and management of oliguric forms of ARF. Therapeutic effects include decreased vascular resistance and cellular swelling; increased renal blood flow (RBF), GFR, and solute excretion; protection from vascular congestion and erythrocyte aggregation; increased osmotic tubular fluid flow with dispersion of tubular debris, casts and obstructions; and scavenging of toxic free radicals.[4,110,124–126] Its use to promote urine formation in the early stages of acute oliguric renal failure has been recommended in animals but lacks evidence-based justification.[9,106,127] Mannitol (20% to 25% solution) is administered to fluid replete animals as a slow intravenous bolus at 0.25 to 1.0 g/kg. If an effective diuresis results within 30 to 60 minutes, a CRI at 1.0 to 2.0 mg/kg/min or intermittent boluses of 0.25 to 0.5 g/kg intravenously, every 4 to 6 hours, can be given to continue the diuresis for 24 to 48

hours. If an adequate diuresis is not established by 60 minutes, an additional 0.25 to 0.5 g/kg intravenous bolus can be repeated cautiously, but further administration is contraindicated due to the risks of volume expansion, hemodilution, hypervolemia, and mannitol toxicity.[9,106,127–129] Mannitol should not be given to animals with severe fluid overload, pulmonary edema, or CHF. The more established the onset of uremia, the lower the expectation mannitol will promote a diuresis or influence the course of the disease.

Furosemide is less effective than mannitol at improving renal function in experimental renal injury, but these observations have not been verified in clinical trials or in dogs and cats with naturally occurring forms of disease. Furosemide inhibits active sodium and chloride reabsorption in the distal nephron causing diuresis, natriuresis, and kaliuresis. It increases tubular fluid flow and osmolar clearance, similar to the effects of mannitol. Additionally, it causes vasodilation, increased RBF, and decreased tubular oxygen consumption in hypoxia-sensitive tubular segments.[4,110,126]

Overhydration, hyperkalemia, and toxin elimination are the established indications for the use of furosemide in animals or humans with ARF.[*] Furosemide is given initially at 2 to 6 mg/kg intravenously after existing fluid deficits have been corrected. If an adequate diuresis of greater than 1 mL/kg/hr is not achieved within 30 minutes, the initial dose can be repeated. If a diuresis is achieved, the dose can be repeated every 6 to 8 hours or given as a CRI at 0.25 to 1.0 mg/kg/hr to extend the diuresis for 24 to 48 hours. Diuretics should always be administered cautiously. The animal's fluid and electrolyte balance must be monitored to prevent depletion of ECF volume that might precipitate additional prerenal insults on the existing renal injury. Like mannitol, the diuresis induced by furosemide may not improve renal morphology or change the outcome or clinical course of animals with ARF. Predictable adverse effects are development of ECF volume contraction, sodium wasting, deafness, and delay to referral.

Dopamine is a catecholamine with diuretic properties caused by PGE_2-mediated renal vasodilation, increased RBF, increased GFR, decreased tubular sodium and water reabsorption, and decreased tubular oxygen consumption. The pharmacologic effects of dopamine are dose dependent and differentially mediated through dopaminergic and adrenergic receptors. In dogs, “renal” doses of dopamine between 0.5 to 3 μg/kg/min promote these responses primarily by activating dopamine-specific D_1-like and D_2-like receptors in the kidney and postganglionic sympathetic nerves. Doses between 5 and 7 μg/kg/min activate β_1-receptors to increase cardiac output; whereas higher doses stimulate alpha receptors causing undesired vasoconstriction, tachycardia, cardiac arrhythmias and potential for myocardial, intestinal and renal ischemia.[4,110,111,118,130] At doses between 0.5 to 3 μg/kg/min, dopamine may increase urine formation and facilitate conversion from an oliguric to a nonoliguric state. Higher doses promote renal vasoconstriction, tachycardia, cardiac arrhythmias, and are contraindicated in ARF. Problems arise with overlap in dose effects, variable dopamine elimination, and individual animal sensitivity and binding affinities. These variables predispose critical animals to untoward and unpredictable effects to standard dosing.

Studies in anesthetized cats document a different spectrum of dopaminergic effects that suggest a lack of dopamine-specific receptor activity in the kidneys of this species.[130–132] Low-dose dopamine infusion (1 to 3 μg/kg/min) causes no significant changes in mean arterial blood pressure, heart rate, urine output, or sodium excretion.[131,132] Only at doses greater than 10 μg/kg/min did dopamine infusion results in dose-dependent increases in urine output and sodium excretion; however, the diuretic response was coupled with variable decreases in GFR, renal vasoconstriction, and inconsistent changes in mean arterial blood pressure and renal blood flow most consistent with α-adrenoreceptors effects.[131] These differences in the actions of dopamine predict it is conceptually inappropriate for use in cats with oligoanuric ARF. Recently, D_1 receptors with a

high affinity to fenolodopam were identified in the kidney cortex of cats, suggesting alternative drug strategies to promote diuresis.[130]

Despite the early observational benefits ascribed to dopamine that have fostered its contemporary use, essentially no documented benefits exist to support its continued use in acute uremia, except for pressor control.[4,110,111,113,119] Dopamine has no propensity to improve renal function or alter outcome and can no longer be patently endorsed.

* References 4, 9, 106, 112, 119, 121, 122, 126–128.

258.5.5 Management of Electrolyte and Acid-Base Disorders

Hyperkalemia is a common and life-threatening electrolyte disorder in animals with acute uremia. Severity of hyperkalemia and its associated cardiac and neuromuscular disturbances dictate the therapeutic approach. Options for the management of hyperkalemia are to antagonize the increased resting potential in cardiac myocytes, redistribute potassium from the extracellular to the intracellular fluid compartments, and eliminate the potassium load from the body (Table 258-2).

Severe hyperkalemia (>8 mmol/L) is associated with life-threatening cardiac arrhythmias and conduction disturbances that are accentuated by rapid increases in serum potassium and the degree of hyponatremia. To immediately resolve these threats, calcium gluconate (10 % solution) can be administered at 0.5 to 1.0 mL/kg as a slow intravenous bolus over 10 to 15 minutes to increase the threshold potential for cardiac excitation (see Table 258-2).[133–135] Calcium chloride is not an appropriate substitute because of its potency, acidifying tendency, and irritation if injected extravascularly. Rapid injection of calcium solutions may cause hypotension and cardiac arrhythmias; therefore arterial blood pressure and electrocardiogram (ECG) monitoring should be established during calcium administration. The infusion should be halted temporarily if S-T segment elevation, Q-T interval shortening, progressive bradycardia, or hypotension is observed. The effects of calcium infusion on the myocardium are rapid in onset but short lived (approximately 25 to 35 minutes), and it has no effect on serum potassium concentrations. Calcium infusion should be regarded as a *stopgap* to counteract conduction disturbances until longer-lasting controls can be initiated.

Once the cardiotoxicity has been controlled, transient lowering of serum potassium can be achieved by promoting its translocation from the extracellular to the intracellular fluid compartment with sodium bicarbonate or insulin and glucose administration. During these temporary reprieves from the hyperkalemia, additional measures must be initiated to provide long-term regulation of serum potassium. 1745 1746

Table • 258-2 Management of Hyperkalemia in Acute Renal Failure

THERAPY	MECHANISM OF ACTION
Mild Hyperkalemia (<6.0 mEq/L)	
IV fluids (0.9% saline, lactated Ringer's)	Plasma volume expansion, dilutes K+, and increases GFR and renal potassium excretion
Kayexalate 2g/kg in 3–4 divided doses PO with 20% sorbitol; may also be given as retention enema without sorbitol	Exchanges K+for Na+across the intestinal mucosa
Moderate Hyperkalemia (6.0 to 8.0 mEq/L)	
Sodium bicarbonate 1–2 mEq/kg IV slowly over 20 minutes	Translocates K+to intracellular space in exchange for H+
Dextrose (20%-50%) 1.5 g/kg IV bolus	Stimulates insulin release, which promotes transcellular entry of K+into cells
Regular insulin and dextrose (20%-50%) Insulin @ 0.1–0.25 U/kg plus Dextrose @ 1–2 g/U IV	Promotes transcellular entry of K+ into cells
Severe Hyperkalemia (>8.0 mEq/L)	
Calcium gluconate (10%) 0.5–1.0 mL/kg over 10–15 minutes; monitor the ECG during administration	Specific antagonist of the cardiotoxic effects of K+
Hemodialysis/peritoneal dialysis	Whole-body clearance of excessive potassium load

Moderate hyperkalemia (6.0 to 8.0 mmol/L) may resolve naturally after induction of diuresis. If diuresis cannot be established or serum potassium cannot be controlled with furosemide administration, all potassium-containing parenteral fluids should be replaced with solutions devoid of potassium. Sodium bicarbonate should be given to correct any existing deficit. Sodium bicarbonate can be administered empirically at 1 to 2 mmol/kg intravenously over 20 minutes in the absence of serum bicarbonate measurements (see Table 258-2). Therapeutic effects begin within 10 minutes and may persist for 1 to 2 hours.[133–135] Bicarbonate administration increases extracellular pH, which translocates potassium into cells in exchange for hydrogen ions.[133,134] Sodium bicarbonate is contraindicated in animals with metabolic alkalosis and is risky in overhydrated animals. Sodium bicarbonate administration may lower serum calcium concentration and precipitate a hypocalcemic crisis in animals with pre-existing hypocalcemia. Recent studies have shown equal efficacy for either hypertonic sodium chloride or sodium bicarbonate to reduce serum potassium and cardiac toxicity in dogs with artificially induced hyperkalemia.[136,137]

Hypertonic (20%) glucose can be administered at 0.5 to 1.5 g/kg intravenously as an alternative to sodium bicarbonate. Glucose stimulates insulin release and promotes the transcellular uptake of potassium. Alternatively, regular insulin can be given at 0.25 to 1.0 U/kg intravenously in combination with intravenous glucose at 1 to 2 g/U of administered insulin.[133,134] The effects of bicarbonate and glucose and insulin are more sustained than the effects of calcium but must be repeated as clinical circumstances dictate until the potassium load is alleviated.

Mild hyperkalemia (<6.0 mmol/L) is rarely problematic but should be monitored at 8-to 12-hour intervals. Mild hyperkalemia generally resolves with initial (potassium free) replacement fluids and routine furosemide or bicarbonate administration (or both). For long-term control in pets with refractory hyperkalemia, sodium

polystyrene sulfonate resin (Kayexalate) may be given orally at 2 g/kg in 3 to 4 divided doses as a suspension in 20% sorbitol (to prevent constipation). The resin can also be used as a retention enema suspended in water in animals unable to tolerate oral administration. The resin exchanges sodium for potassium secreted into the intestinal lumen to promote increased intestinal potassium clearance. Exchange resins are effective at controlling low-grade hyperkalemia, but have little efficacy in the management of the associated cardiotoxicity. The acceptability of these preparations is low due to persistent side effects including nausea, constipation, GI ulceration, and necrosis.

If conventional therapy fails to provide an immediate or lasting resolution for the hyperkalemia, peritoneal or hemodialysis is indicated as alternative therapies (see Renal Replacement Therapy).

1746

1747

258.5.6 Hypokalemia

Hypokalemia may develop during the diuretic stage of ARF if renal potassium losses exceed potassium intake. The use of diuretics, inadequate dietary intake, vomiting, and diarrhea contribute to its development. Hypokalemia is usually asymptomatic, but clinical signs may be noted if the serum potassium concentration is less than 2.5 mmol/L. Muscle weakness, fatigue, vomiting, anorexia, GI ileus, and cardiac arrhythmias may become apparent. Ventroflexion of the neck is observed commonly in cats.

Oral potassium supplementation at 1 to 3 mmol/kg/day is usually sufficient in animals that are able to eat. Guidelines for parenteral potassium supplementation are based on the severity of hypokalemia. Serum potassium rarely is less than 2.0 mmol/L in animals with acute uremia, and maintenance fluids containing potassium concentrations between 20 and 30 mmol/L are usually sufficient to restore normokalemia. Potassium supplementation, including that in maintenance fluids, should be provided cautiously in uremic animals. Serum potassium should be evaluated frequently to avoid hypokalemia or hyperkalemia.

258.5.7 Acid-Base Imbalances

Metabolic acidosis is the most common acid-base disorder in uremic animals. Mild metabolic acidosis (serum bicarbonate >16 mmol/L) will often resolve after fluid replacement and the onset of diuresis. Moderate to severe metabolic acidosis (serum bicarbonate <16 mmol/L) should be treated with intravenous sodium bicarbonate. Initial treatment should be directed at correcting serum pH and serum bicarbonate to approximately 7.2 and 14 to 16 mmol/L, respectively. The initial bicarbonate replacement dose (mmol) = [body weight (kg) ×0.3 × bicarbonate deficit (desired bicarbonate–measured bicarbonate)]. One half of the calculated replacement is administered intravenously over 20 to 30 minutes, and the remainder is provided with intravenous fluids over 2 to 4 hours if arterial pH is less than 7.2 after distribution (30 to 60 minutes) of the initial bolus.[108,134,138]

Full equilibration of the initial bicarbonate dose requires 2 to 4 hours, but most uremic animals have an ongoing requirement for sodium bicarbonate of approximately 80 to 90 mg/kg/day to offset production of metabolic acids. Consequently, bicarbonate should be reassessed after administration of the initial replacement dose and at least once daily to determine if therapy has been adequate or additional therapy to normalize serum bicarbonate concentration is required. Excessive sodium bicarbonate administration can promote metabolic alkalosis, volume overload, pulmonary edema, and hypertension. Serum potassium and ionized calcium concentrations may decrease precipitously with overcorrection of the acidemia causing secondary hypoventilation, hypercapnia, shift in oxyhemoglobin dissociation, reduced tissue oxygen delivery, and paradoxic cerebral acidosis after rapid increases in serum pH.[108,134,138] Alternative alkalizing agents,

including sodium acetate, sodium lactate, sodium or potassium citrate, and calcium carbonate, require hepatic metabolism to generate bicarbonate and offer no advantage to that of sodium bicarbonate.

Mild to moderate metabolic alkalosis (serum bicarbonate >26 and <35 mmol/L) resolves with administration of normal saline or balanced electrolyte solutions to correct the ECF fluid volume and chloride deficits and with the onset of diuresis. Protracted vomiting must be controlled with antiemetics to prevent persisting metabolic alkalosis. Respiratory acid-base disorders are seen in animals with concurrent pulmonary complications. Management of the respiratory component requires correction of the underlying pulmonary or pleural disease (or both) and appropriate regulation of ventilation and oxygenation. Sodium bicarbonate is not an appropriate therapy for the acidemia of respiratory origins.

258.5.8 Uremia Intoxications

Uremia toxins must be removed from the body by restoration of excretory function, intensive fluid diuresis, or dialysis to resolve the signs attributable to the azotemia. Immediate recovery of excretory function is rarely possible in advanced forms of acute uremia, and symptomatic therapies must be provided to ameliorate the uremic intoxications (Table 258-3).

258.5.8.1 Oral and Gastrointestinal Complications

Oral hygiene, uremic stomatitis, and oral ulcerations can be improved dramatically by rinsing the oral cavity every 6 to 12 hours with solutions or gels containing 0.1% to 0.2% chlorhexidine. This therapy reduces the bacterial contamination of the oral cavity, helps prevent and heal oral ulcers, and relieves the discomfort associated with the stomatitis and lingual necrosis. Pain from lingual necrosis or severe ulceration can be managed further with topical lidocaine preparations.

Antiemetic therapy is required to manage fluid and electrolyte imbalances, nutritional needs, and the discomfort associated with protracted vomiting. All oral fluids, medications, and food should be discontinued until vomiting ceases for 12 to 24 hours. H_2-receptor antagonists such as cimetidine, ranitidine, and famotidine have become mainstays for the management of gastritis, vomiting, and gastric ulceration (see Table 258-3).[70,139] They reduce gastric acid production by blocking the histamine receptor on gastric parietal cells and also reduce pepsin production, which may promote gastric ulcer formation. H_2-receptor antagonists undergo 50% to 70% renal elimination, and dosing should be reduced in proportion to the degree renal failure to prevent side effects. Omeprazole is a potent inhibitor of gastric acid secretion and acts by irreversible inactivation of H^+/K^+-ATPase activity to prevent secretion of hydrogen ions into the stomach.[139] Omeprazole reduces acid secretion in the dog for up to 24 hours; however, expense may limit its widespread application.

Oral antacids are of limited value to reduce gastric acidity due to their frequent dosing requirement. Their usefulness is limited further in animals with protracted vomiting. Sucralfate is a basic aluminum salt of sucrose octasulfate used to manage gastric ulceration. It binds tightly to exposed protein in gastric ulcers to form a protective barrier against pepsin, acid, bile, or pancreatic secretions. Sucralfate also stimulates mucus and bicarbonate secretion and mucosal prostaglandin production to improve microvascular integrity and mucosal blood flow. The efficacy of sucralfate is limited in animals that cannot tolerate oral medications. Medical therapy is typically continued for 2 to 3 weeks but may need to be extended in animals with severe gastritis after antifreeze ingestion or severe uremia. Management of the gastritis generally controls vomiting if excretory function can be restored quickly and the azotemia resolved.

Centrally acting antiemetic therapy should be considered if vomiting cannot be controlled by restricted oral intake and treatment of the gastritis (see Table 258-3). Metoclopramide is a D_2-dopaminergic antagonist that directly suppresses the chemoreceptor trigger zone.[139] It also has prokinetic effects on the stomach to promote gastric emptying, which is often delayed in uremic animals. Metoclopramide can be provided by either oral or parenteral routes and is most effective when administered as a constant intravenous infusion (see Table 258-3). Metoclopramide is excreted by the kidneys, and the dose needs modification in animals with severe uremia. Phenothiazine derivative antiemetics (chlorpromazine, prochlorperazine, acepromazine) suppress vomiting through antagonism of α-adrenergic receptors at the CRTZ and the emetic center. They are effective antiemetics in uremic animals but prone to sedative and hypotensive side effects. They should be considered for animals with intractable vomiting in which the adverse effects can be accepted. Serotonin receptor antagonists (ondansetron and dolasetron) provide central antiemetic effects at both the CRTZ and emetic center. They are highly effective for chemotherapy-induced vomiting and may be effective in acute uremia. Prokinetic agents can be used to treat delayed gastric emptying, uremic gastric paresis, and the persistent vomiting.

1747

1748

Table • 258-3 Therapeutic Agents Used in the Management of Gastrointestinal Uremic Intoxications*

AGENT	INDICATION/MECHANISM	CONVENTIONAL DOSE
Chlorhexidine (CHX-Guard®)	Stomatitis, oral ulceration Bacteriocidal agent	
Cimetidine† (Tagamet® *Smith Kline French*)	Esophagitis, gastritis, gastric ulceration/hemorrhage	5–10 mg/kg PO, IM, IV q4-6h (dog)
	H_2-receptor antagonist	5–10 mg/kg PO, IM, IV q6-8h (cat)
Ranitidine† (Zantac® *Glaxo*)	Esophagitis, gastritis, gastric ulceration/hemorrhage H_2-receptor antagonist	0.5–2.0 mg/kg PO, IV q 8-12h
Famotidine† (Pepcid® *Merck Sharp Dohme*)	Esophagitis, gastritis, gastric ulceration/hemorrhage H_2-receptor antagonist	0.5–1.0 mg/kg PO, IM, IV q 12-24h
Omeprazole (Prilosec® *Merck Sharp Dohme*)	Esophagitis, gastritis, gastric ulceration/hemorrhage H+/K+-ATPase proton pump blocker	0.5–1.0 mg/kg PO q24h
Sucralfate (Carafate® *Marion*)	Esophagitis, gastritis, gastric ulceration/hemorrhage Cytoprotective agent	0.5–1.0 g PO q6-8h (dog) 0.25–0.5 g PO q8-12h (cat)
Misoprostol (Cytotec® *Searle*)	Esophagitis, gastritis, gastric ulceration/hemorrhage Cytoprotective agents-PGE, analogue	1–5 g/kg PO q6-12h
Chlorpromazine (Thorazine ® *Smith Kline French*)	CRTZ, emetic center antiemetic α_2-adrenergic, D_2-dopaminergic, H_1-histaminergic, M_1-cholinergic antagonists	0.2–0.5 mg/kg IM, SQ q6-8h
Prochlorperazine (Compazine® *Smith Kline French*)	CRTZ, emetic center antiemetic α_2-adrenergic, D_2-dopaminergic, H_1-histaminergic, M_1-cholinergic antagonists	0.1–0.5 mg/kg IM, SQ q8-12h
Acepromazine (PromAce® *Fort Dodge*)	CRTZ, emetic center antiemetic α_2-adrenergic, D_2-dopaminergic, H_1-histaminergic, M_1-cholinergic antagonists	0.01–0.05 mg/kg IM, SQ q8-12h
Ondansetron (Zofran® *Glaxo Wellcome*)	5-HT_3 receptor antagonist CRTZ, peripheral vagal nerve	0.1 mg/kg PO q12-24h 0.1–0.3 mg/kg IV q8-12h
Dolasetron (Anzemet® *Hoechst Marion Russel*)	5-HT_3 receptor antagonist CRTZ, peripheral vagal nerve	0.5 mg/kg PO, SQ, IV q24h
Metoclopramide† (Reglan® *Robins*)	CRTZ antiemetic, prokinetic agent D_2-dopaminergic antagonist, $5HT_3$-serotonergic antagonist	0.1–0.5 mg/kg PO, IM, SQ q 6-8h 0.01–0.02 mg/kg/hr CRI

Cisapride (Propulsid® *Jansen Pharmaceutica Inc*)	Prokinetic agent 5-HT_4 receptor agonist, 5-HT_1/5-HT_3receptor antagonist	0.1–0.5 mg/kg PO q8-12h

CRTZ, Chemoreceptor trigger zone; *5-HT,* 5-hydroxytryptamine.

* Most of these drugs have not been approved for use in the dog or cat.

† Agent undergoes renal excretion and the dose must be adjusted accordingly to prevent toxicity.

Uremic bleeding can be fatal if associated with CNS hemorrhage but more commonly causes GI bleeding and anemia. Uremic bleeding improves with resolution of the azotemia after intensive diuresis or dialysis. Transfusion of packed RBCs is indicated for animals with severe anemia and active bleeding and may reduce bleeding time through indirect effects on platelet function.[140] Transfusion of platelet-rich plasma will not improve platelet function or reduce bleeding time, because function of the transfused cells is altered upon exposure to uremic plasma.

1748

1749

258.5.8.2 Impaired Immunity

Uremia imposes increased susceptibility to infection due to accumulation of toxins that impair immunity and cellular host defenses.[141,142] The deficiencies in host defenses are compounded by widespread breaches of mucosal integrity associated with GI ulceration, intravenous and bladder catheterization, parenteral medications and feeding, and intervention with hemodialysis, peritoneal dialysis, and immunosuppressive drugs.[141] Infection may be difficult to identify because uremia dampens the febrile response. Strict asepsis during catheter placement and meticulous catheter site care are mandatory for uremic animals. If infection is suspected, blood, urine, and catheter tip cultures should be obtained, and broad-spectrum antibiotic therapy initiated pending culture results. Prophylactic use of antibiotics may foster bacterial resistance or "superinfections" and should be prescribed with caution.

258.5.8.3 Pulmonary Signs

Respiratory complications arise mostly from overhydration, infection, and aspiration of gastric fluids during vomiting. Overhydration is treated by cessation of fluid delivery and diuretic administration to achieve an appropriate dry weight. Animals with severe pulmonary edema and oliguria may require removal of the fluid burden by peritoneal or hemodialysis. Bacterial pneumonia is managed with antibiotics and supportive pulmonary care. Aspiration pneumonia should be treated aggressively with antiemetic therapy, parenteral broad-spectrum antibiotics, and supplemental oxygen or ventilatory support, if required. Uremic pneumonitis is a complication of severe azotemia resulting in a respiratory distress syndrome, noncardiogenic pulmonary edema, and respiratory compromise or failure.[75] Uremic pneumonitis is treated supportively with supplemental oxygenation or mechanical ventilation. It has potential to improve with resolution of the azotemia and is an indication for dialysis. Dogs with leptospirosis frequently develop radiographic and clinical signs consistent with uremic pneumonitis that is independent of the severity of the azotemia. The lesions are induced by endothelial damage and vasculitis.[74]

258.5.9 Nutritional Management of Acute Renal Failure

Protein-calorie malnutrition is a component of the acute uremic syndrome. This includes impaired immune function, increased susceptibility to infection, delayed wound healing, decreased strength, and poor quality of

life. The imposed catabolism exacerbates the hyperkalemia, hyperphosphatemia, acidosis, and azotemia. It increases morbidity and mortality.[143,144] Anorexia, nausea and vomiting, comorbid diseases, uremic toxins, insulin resistance, and hyperparathyroidism contribute to the nutritional inadequacies. Metabolic acidosis is a major stimulus for breakdown of muscle protein and amino acid oxidation and contributes to the ongoing catabolism.[145,146]

An accurate assessment of nutritional status is necessary to guide nutritional therapy. Change in body weight is the simplest parameter to assess. This can be flawed by changes in hydration status, lean body mass, or fat stores. Body condition scoring is a useful index to document sequential changes in body composition, but it is only qualitative and subject to hydration errors and experience of the evaluator.[147,148] Bioelectrical impedance analysis is a new, safe, noninvasive, and reproducible method to precisely quantitate changes in total body water, extracellular fluid volume, and body cell mass with potential application in uremic animals.[149,150] Goals of nutritional therapy are to meet the energy and nutrient requirements of the animal; alleviate the azotemia; prevent alterations in fluid, electrolyte, vitamin, mineral, and acid-base balance; and aid the renal repair. The optimal nutritional regime for dogs and cats with ARF has not been defined, but a high-energy and moderate protein, potassium and phosphate formulation as prescribed for CRF is logical. Sufficient energy must be supplied to prevent catabolism of endogenous protein, spare lean body mass, and minimize azotemia. The illness energy requirement for animals with acute uremia is determined as the resting energy requirement times a stress factor (1.2 to 1.4 for uremic dogs and 1.2 for uremic cats). RER is determined according to the following formulae:

$$\text{RER (kcal/day)} = 70(\text{Wt}_{\text{kg}})^{0.75}$$

or

$$\text{RER (kcal/day)} = 70 + (30 \times \text{Wt}_{\text{kg}})$$

(where Wt_{kg} is the body weight in kilograms[151]

Carbohydrate and fat provide the nonprotein sources of energy required in the diet. Commercial diets, liquid enteral formulations, or parenteral solutions designed for the management of renal failure can be used. These formulations contain a relatively high fat content to increase energy density, and they should be introduced slowly to prevent GI complications, especially pancreatitis.

The optimal protein requirement for animals with acute uremia is not known and is likely to be influenced by underlying and coexistent clinical conditions. Consequently, the minimum protein requirements for normal dogs (1.25 to 1.75 g/kg/day; approximately 8% to 10% protein on a ME basis) and cats (3.8 to 4.4 g/kg/day; approximately 20% to 25% protein on a ME basis) are generally adopted for uremic animals. This degree of restriction may not be necessary or desired in animals with mild or moderate azotemia or greater catabolic stresses, where more liberal protein prescriptions may be needed. Phosphorus, sodium, potassium, and magnesium intake should be restricted to prevent accumulation of these minerals; however, intake must be modified according to the clinical and biochemical dictates of the animal.

Delivery of adequate nutrition is constrained by inappetence and the GI complications of uremia. Oral or enteral feeding may not be possible or recommended in the initial stages of ARF due to gastritis, pancreatitis, or uncontrolled vomiting. Peripheral parenteral nutrition or total parenteral nutrition is indicated under these circumstances to provide interim nutritional support.[152] Peripheral parenteral nutrition is formulated with isotonic solutions administered through a peripheral vein. However, complete nutritional requirements cannot be met by this technique. It should only be used as an adjunct to oral intake or to supply partial nutritional

support not to exceed 5 days. Total parenteral nutrition is formulated to provide all essential nutrients for indefinite periods but requires central venous administration due to the hypertonicity of the nutrient solutions.

Oral or enteral tube feeding is recommended in animals that are not vomiting but fail to achieve caloric requirements. The indications, complications, and technical aspects of enteral feeding have been reviewed recently.[151] Esophageal feeding tubes or percutaneous gastrostomy tubes are invaluable aids for the long-term nutritional support of animals that are likely to have prolonged recovery times. Caloric and protein requirements can be met readily by the intermittent or continuous administration of blended therapeutic diets or liquid enteral preparations formulated for the management of renal insufficiency.[151] The clinical benefits of enteral or parenteral nutrition cannot be overemphasized, but it may not be possible to supply the volume required to achieve the nutritional requirements in oliguric animals without dialysis to alleviate overhydration.

258.5.10 Renal Replacement Therapy

ARF is the most common indication for dialytic intervention in dogs and cats, and modern dialysis equipment and procedures are well suited for uremic animals.[77,104,105] Medical therapies cannot approach the efficacy, efficiency, and clinical benefits that dialysis provides. Without dialysis, animals with severe uremia generally die within 5 to 7 days precluding sufficient opportunity for regeneration or repair of the renal injury. Dialysis extends the life expectancy of uremic animals facilitating their potential for recovery. Peritoneal dialysis uses the peritoneal lining as a dialytic exchange surface across which diffusive and osmotic forces transfer toxic wastes and excessive fluid from the blood to a dialysate solution instilled in the abdominal cavity.[104,108,153] It is a conceptually simple technique applicable in both general and specialty practice but can be a deceptively intensive and fraught with technical and clinical complications.[104,154] Continuous renal replacement therapy (CRRT) is a noninterrupted extracorporeal procedure using hemofiltration for solute and fluid removal. CRRT is less demanding technically than intermittent hemodialysis. It is generally provided in intensive care settings for patients with profound clinical and hemodynamic instability.[121,155] The technical and clinical lure of CRRT has captured the interest of veterinary critical care specialists for the management of acute uremia. Intermittent hemodialysis is the standard extracorporeal therapy for acute uremia in humans and animals. The fluid, electrolyte, and acid-base abnormalities are corrected, and the accumulated uremia solutes are removed from the body by diffusive and convective gradients between blood and the dialysate solution in the artificial kidney.[77,104,105] Hemodialysis has become a routine therapy for severe uremia in both dogs and cats.

Immediate renal replacement therapy is indicated when the clinical consequences of the azotemia, inadequate urine production, and the fluid, electrolyte, and acid-base disturbances cannot be managed with medical therapy alone. General guidelines for patient selection and indications for dialytic therapy are outlined in Box 258-3. Hemodialysis (and peritoneal dialysis and CRRT therapies) can resolve virtually all excretory deficiency of acute uremia.

258.5.10.1 Box • 258-3 Indications for Dialytic Therapy in Animals

258.5.10.1.1 Acute Uremia:

1. Anuria
2. Failure of fluid administration or diuretic therapy to initiate an adequate diuresis

3. Failure of conventional therapy to control the azotemia or the biochemical and clinical manifestations of acute uremia
4. Life-threatening fluid overload
5. Life-threatening electrolyte or acid-base disturbances
6. BUN > 100 mg/dL; serum creatinine > 10 mg/dL
7. Clinical course refractory to conservative therapy for 12–24 hours

258.5.10.1.2 Miscellaneous:

1. Severe overhydration; pulmonary edema; congestive heart failure (CHF)
2. Acute poisoning/drug overdose

To date, failure to recover renal function after 1 to 4 weeks of conventional medical support have been used as benchmarks to predict irreversible from reversible renal failure in animals. However, these criteria have been redefined with the advent of hemodialysis, and many animals with seemingly irreversible disease at the outset of medical management can recover renal function if supported by dialysis beyond the 4-week limit.

258.5.10.2 Azotemia

Even severe azotemia can be corrected completely with just a few hemodialysis sessions, but the expediency of its resolution must be tempered by the tolerance of the animal to rapid changes in serum solute concentrations. Both peritoneal dialysis and CRRT procedures produce a more gradual and continuous resolution of the azotemia throughout the first 2 to 3 days of therapy. For animals that do not recover within this time period, CRRT must be transitioned to intermittent hemodialysis for long-term support.

258.5.10.3 Electrolyte Disturbances

Dialysis is indicated in patients where medical treatments provide only transient resolution of the hyperkalemia and no relief of the excessive potassium load for long-term control. Life-threatening conduction disturbances are frequently corrected within minutes of starting hemodialysis despite the absence of perceptible changes in peripheral blood potassium concentration, thus providing both an immediate and prolonged solution to hyperkalemia.

Abnormalities of other electrolytes or minerals resulting from the uremia, comorbid diseases, or therapy, can be corrected by formulating the dialysate to approximate the serum concentration desired for each solute at the end of the dialysis session. The bicarbonate concentration of the dialysate can be increased above reference values to promote accrual of depleted buffer reserves and to supplement impaired renal bicarbonate generation.

258.5.11 Correction of Fluid Excesses

Excessive fluid load can be removed readily by ultrafiltration using intermittent hemodialysis or CRRT, or by osmotic gradients with peritoneal dialysis. Slow rates of ultrafiltration between 5 to 10 mL/kg/hr generally are tolerated. Increased rates of fluid removal are possible but require careful assessments of the animal's hemodynamic condition and use blood volume monitoring equipment.

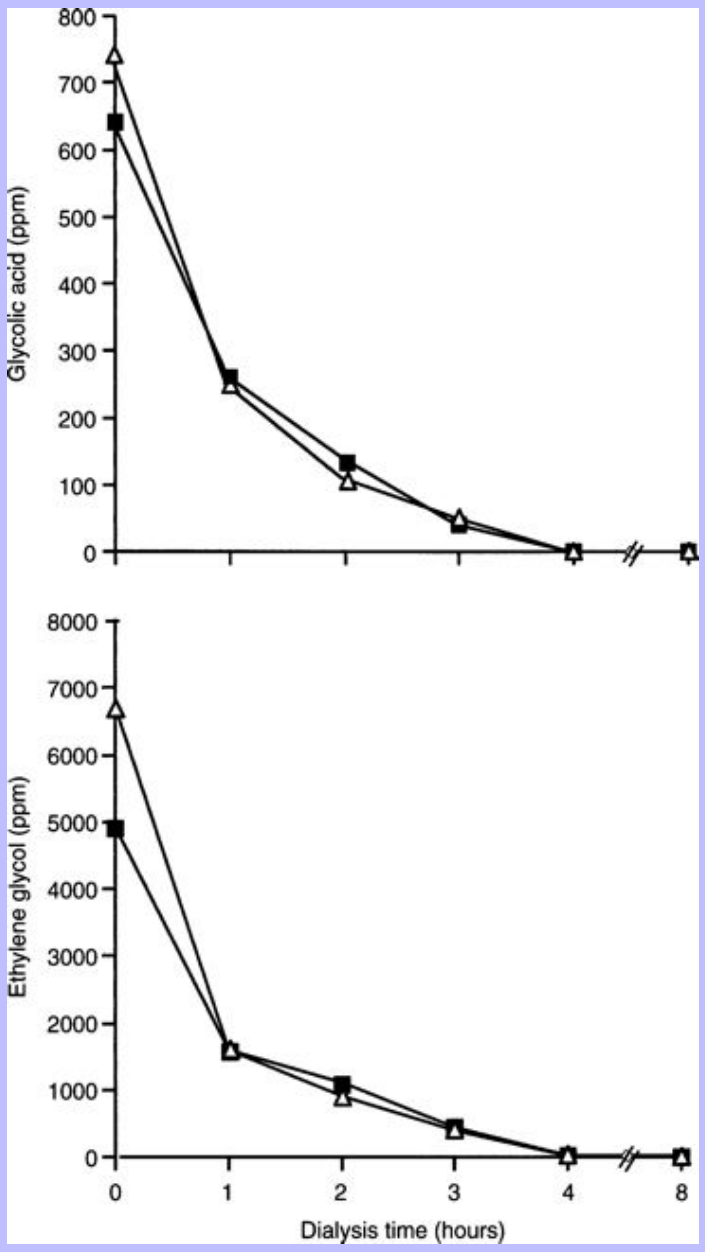
258.5.12 Acute Intoxications

Hemodialysis should be considered for the immediate management of acute poisoning when the toxin is dialyzable, when antidotal therapy has been delayed, or when no specific antidote to the intoxication is available. Hemodialysis is indicated specifically for the treatment of common poisonings including ethylene glycol, methanol, salicylate, lithium, ethanol, phenobarbital, acetaminophen, theophylline, aminoglycosides, tricyclic antidepressants, and possibly metaldehyde.[77,104,105] Peritoneal dialysis and CRRT procedures may be capable of removing a variety of toxins, but these treatments are less efficient than hemodialysis and do not represent satisfactory substitutes.

Hemodialysis will rapidly eliminate ethylene glycol and its metabolites from animals poisoned with antifreeze (Figure 258-7). It should be initiated without any delay as the principal therapy to resolve the intoxication and to support the accompanying fluid, electrolyte, and acid-base disorders associated with the toxicosis.[77] For acute poisoning (within 5 to 6 hours), it is possible to remove all the toxin and prevent development of renal injury with a single dialysis treatment.[77,112] If the treatment is delayed beyond this window, renal injury may be expected, and a series of dialysis treatments must be provided to support the uremia and renal repair.

1750
1751

Figure 258-7 Changes in serum glycolic acid *(upper panel)* and ethylene glycol *(lower panel)* concentrations in two dogs treated with hemodialysis after simultaneous exposure to antifreeze 4 to 6 hours before presentation. Despite the extremely high initial concentrations of these toxins, both dogs recovered uneventfully with no evident renal injury after a single dialysis treatment.



Transplantation of renal allografts from unrelated dogs and cats has become more successful in the past 10 years and provides an alternative renal replacement option for animals that sustain irreparable renal injury.[156–159] Transplantation early in the course of severe renal injuries (antifreeze poisoning) may prove more cost-effective than a protracted course of dialysis.

258.5.13 Outcome and Prognosis

The prognosis for recovery from acute uremia depends on the cause, extent of damage, comorbid diseases, multiple organ involvement, and availability of diagnostic and therapeutic services. Little documentation exists in the veterinary literature to accurately predict the importance of these independent variables. A recent review of 99 cases of ARF in dogs produced by the usual causes documented a mortality of nearly 60% from death or euthanasia.[11] Nearly 60% of the surviving dogs subsequently developed CRF, and only 44% recovered normal renal function. Severity of the azotemia, hypocalcemia, anemia, proteinuria, specific cause (ethylene glycol intoxication), and comorbid systemic disease (DIC) were associated with failure to survive. In this series, 92% of dogs with a history of ethylene glycol ingestion died or were euthanatized due to the poor prognosis. In another series of 37 dogs with confirmed ethylene glycol intoxication, greater than 95% of those with initial azotemia died, whereas all nonazotemic dogs survived.[160] Survival for dogs with hospital-acquired ARF was reported as 38%, with age and initial urine production as significant predictors of mortality.[161]

In contrast to these outcomes in dogs, 9 of 15 (60%) cats with severe ARF secondary to pyelonephritis and ethylene glycol intoxication that were managed with hemodialysis or transplantation recovered with partial or normal renal function.[31] One hundred percent of cats with acute pyelonephritis survived. In these animals, as in other series, the magnitude of the azotemia at presentation did not predict survivability. Similar to previous reports, a recent review of 138 cases of severe ARF in dogs requiring hemodialysis revealed an all-cause mortality of nearly 60% from death or euthanasia.[62] For the majority of surviving dogs, renal function had been substantially recovered by the time of discharge. Survival from infectious (80%) and hemodynamic and metabolic causes (40%) is more favorable than survival from toxic causes (20%).[62] The outcome for dogs with acute leptospirosis is particularly favorable, with survival approaching 90% with either severe (dialysis dependent) or milder forms (medically managed) of ARF.[85]

ARF is a serious and frequently fatal disease in both dogs and cats. Recovery is best for animals with infectious causes and worst for animals with nephrotoxic causes or multiple organ failure. Early recognition, appropriate fluid therapy, and extended support with dialysis offer the greatest opportunity for a favorable outcome.

259 CHAPTER • 259 Renal Transplantation

Cathy E. Langston

Lori L. Ludwig

Chronic renal failure is a progressive, debilitating, and terminal disease. Medical management, although effective initially, is not sufficient for cats with end-stage renal failure. Kidney transplantation offers an avenue of therapy when medical management fails. The first clinical feline renal transplantation was performed in 1987. Several centers now offer this procedure.

259.1 CANDIDATE SELECTION

Ideally, a feline candidate for kidney transplantation should have no medical problems other than kidney failure. Renal diseases appropriately treated with transplantation include acquired conditions (e.g., chronic interstitial nephritis, toxic nephropathy, membranous glomerulonephropathy) and congenital disorders (e.g., renal dysplasia, polycystic kidney disease). Amyloidosis, pyelonephritis, and obstructive nephropathy from calcium oxalate nephrolithiasis are relative contraindications because of potential effects on the transplanted kidney. To avoid injury to the transplanted kidney, cats with ethylene glycol–induced renal failure should not be considered for transplantation until the ethylene glycol and its metabolites have been completely eliminated from the body. Hemodialysis may be necessary to ensure elimination of these metabolites.

An extensive diagnostic evaluation (Box 259-1) should be performed prior to transplantation to identify contraindications to the procedure. These tests commonly are performed locally, especially if significant travel to a transplantation center otherwise would be necessary, to avoid needless travel and expense for the owners of cats that turn out to be poor candidates.

The immunosuppression necessary to prevent graft (renal) rejection in an animal that previously has had pyelonephritis, a bacterial urinary tract infection (UTI), or an indwelling catheter may “reactivate” a latent infection. Infection may cause pyelonephritis in the transplanted kidney and activation of the rejection process.[1] Also, these animals are predisposed to overwhelming systemic infection. Such cats therefore are not ideal candidates, and a 1-to 3-week “test” course of cyclosporine (CyA) and prednisone prior to transplantation is recommended.[2] If urine culture results are positive after such a trial, transplantation should not be performed.

Another potential contraindication to kidney transplantation is inflammatory bowel disease (IBD). The variability of absorption of CyA in cats with IBD increases the risk of rejection. Inflammatory bowel disease may also heighten immune system activation, making immunologic attack on the transplanted kidney more likely.[1] Cats infected with the feline leukemia virus (FeLV) or the feline immunodeficiency virus (FIV) should also be excluded as candidates because of their increased susceptibility to infection.

The immunosuppression associated with renal transplantation has resulted in activation of *Toxoplasma* tissue cysts and clinical disease in several cats. An attempt should be made to assess carefully both the donor and the recipient for toxoplasmosis. A positive toxoplasmosis titer does not determine whether active infection is present. A serologically positive recipient must be considered at higher risk. A seropositive donor should not be used for a seronegative recipient.

A thorough cardiac evaluation, including thoracic radiographs, an electrocardiogram (EKG), and an echocardiogram, should be performed prior to transplantation surgery. Because of the shortened anticipated life span associated with significant cardiac disease, cats with congestive heart failure or diffuse hypertrophy are eliminated as candidates. Intolerance of aggressive fluid therapy or focal hypertrophy are relative contraindications and must be evaluated in light of the entire clinical picture.[2]

Other conditions likely to affect renal function or patient longevity, including uncontrolled hyperthyroidism, diabetes mellitus, or neoplasia, should exclude any cat from consideration for renal transplantation. Hypertension affects about 30% of feline transplantation candidates.[3] Prior to transplantation, antihypertensive therapy should be titrated to control blood pressure.[2] Intensive handling is necessary, particularly in the immediate postoperative period, therefore fractious cats should not undergo transplantation, because they will not tolerate the level of care necessary for a good outcome.

Transplantation is appropriate when medical management fails to maintain the cat in satisfactory condition. It can be difficult to determine the point of decompensation, but good guidelines include weight loss, the development of anemia, or worsening azotemia. Some programs suggest transplantation when a certain creatinine level has been exceeded (e.g., 4 mg/dL). Despite the uncertainty involved in determining the best time for transplantation, a lengthy delay from decompensation to transplantation must be avoided. Severe debilitation with excessive weight loss (greater than 25%) and chronic uremia reduces the success rate of transplantation. Transplantation is not a salvage operation, and cats that are severely debilitated should not be considered for it. Attempts to reverse the debilitation in these cats with enteral nutrition via a feeding tube have been disappointing.[1] Hemodialysis to control azotemia and uremic symptoms has been quite successful, but peritoneal dialysis is not advised because of frequent complications, including peritonitis.

259.2 DONORS

Because sufficient renal function can be provided even by a portion of just one kidney, unilateral nephrectomy for kidney donation does not diminish the quality of life or life span of the donor.[4] Kidney donors should be young cats that have been screened to ensure their general health (i.e., complete blood count [CBC], chemistry panel, urinalysis, and urine culture) and lack of infectious disease (FeLV, FIV, toxoplasmosis).

1752

1753

259.2.1 Box • 259-1 Diagnostic Testing for Candidates for Renal Transplantation

The following diagnostic tests should be performed for any animal being considered for renal transplantation:

- Complete blood count (CBC)
- Chemistry panel
- Thyroid level determination
- Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) testing (cats)
- Blood typing
- Electrocardiogram (EKG) and echocardiogram

- Thoracic radiographs
- Abdominal ultrasonography
- Toxoplasmosis titer
- Urinalysis and culture
- Blood pressure measurement

An intravenous pyelogram allows evaluation of renal structure. Donor cats ideally are the same size or bigger than the recipient, but no more than 0.5 kg smaller. Most programs require the recipient family to adopt the donor cat.

259.3 PREOPERATIVE MANAGEMENT

The cat that is to receive a new kidney (the recipient) should be admitted to the hospital several days prior to the scheduled transplantation surgery. The recipient is cross-matched to several potential donors, and any further evaluation of the donor or recipient should then be completed. Intravenous fluids are given at a rate that maintains hydration or that provides diuresis if the blood urea nitrogen (BUN) is greater than 100 mg/dL. If anemia has not been corrected by previous erythropoietin therapy, blood transfusions can be given to achieve a target packed cell volume (PCV) of 30% or higher. Cyclosporine (NeOral, 3 to 4 mg/kg given orally twice daily) is administered starting 1 to 2 days before surgery. Prednisone (1 mg/kg given orally twice daily) is started the day of surgery. Enteral nutrition is provided by feeding tube if the recipient cat is not eating voluntarily. Blood samples for determination of CyA concentrations are submitted the morning of surgery.

259.4 DONOR SURGERY

If kidney preservation methods are not used, anesthesia is induced in the donor cat approximately 30 minutes before induction in the recipient. The donor is given mannitol (0.25 to 1 g/kg) intravenously prior to harvesting the kidney to protect against acute tubular necrosis associated with warm ischemia.[5] The left kidney is preferred for transplantation because of the longer renal vein. If two renal veins are present, the smallest is ligated and the largest prepared for anastomosis. Kidneys with two renal arteries are usually avoided in cats because both would need to be preserved to ensure adequate renal blood flow. Preservation and anastomosis in dogs with two renal arteries has been reported.[6]

Once the recipient vessels have been prepared, the donor kidney is removed and flushed with ice-cold heparinized saline solution. The surgical team working with the donor closes the abdominal incision while the team working with the recipient performs the vascular anastomosis. If preservation methods are used, the donor kidney is removed, flushed with a storage medium, and stored in solution on ice until the recipient has been prepared. Hypothermic preservation of the harvested kidney has been reported in cats with storage times of up to 7 hours.[7] The advantages of cold preservation include the need for only one surgical team, the additional time available for vessel preparation after kidney harvest, and the longer time before ischemic injury occurs during anastomosis.[5,7]

259.5 RECIPIENT SURGERY

Magnification (×3 to ×10) is required for anastomosis of the vessels and ureters in small dogs and cats. In dogs, the left common iliac vein is sutured to the renal vein in an end-to-side manner, and the iliac and renal arteries are sutured end-to-end. This technique was also initially reported for use in cats; however, it has been associated with neuropraxia and lameness of the pelvic limb on the side of the anastomosis.[9] The technique currently preferred in cats is an end-to-side anastomosis of the renal vein to the caudal vena cava and of the renal artery to the aorta. The time from occluding blood flow to the kidney for harvesting to release of the vascular clamps after anastomosis (warm ischemia time) should be kept to less than 60 minutes.[8]

Several techniques have been described for implantation of the donor ureter into the recipient bladder. A drop-in technique initially was used in cats, because the small diameter of the feline ureter (0.4 mm) makes primary anastomosis technically difficult.[10] With this intravesical technique, a ventral cystotomy is performed, and the ureter is brought into the bladder through a small incision in the dorsal bladder wall. The distal end of the ureter is either attached to the inside of the bladder with a single suture or left free in the bladder lumen. Obstruction of the ureter by granulation tissue was a frequent complication of this technique, therefore it has been replaced by the mucosal appositional technique.[11]

For mucosal apposition, an operating microscope is used to allow visualization of the distal end of the ureter, which is incised longitudinally and then sutured to the bladder mucosa in a simple interrupted pattern. Ureteral obstruction is less common with this technique; however, partial obstruction may still be seen in the immediate postoperative period. An extravesical technique was recently described and may reduce the incidence and severity of postoperative obstruction. With this procedure, a seromuscular incision is made in the ventral surface of the urinary bladder, avoiding a large cystotomy, and a small incision is made in the mucosa at the caudal aspect of the seromuscular incision. The ureteral mucosa is sutured to the bladder mucosa, and the seromuscular layer is closed. In dogs either the intravesical or extravesical mucosal appositional technique can be used.[6]

Before the abdomen is closed, the transplanted kidney is stabilized to the body wall by suturing of the kidney capsule to a pocket in the retroperitoneal membrane or to a muscle flap created in the transversus abdominis muscle.[5,8] This helps prevent graft torsion and vessel avulsion in the postoperative period. In dogs, the native kidneys are usually removed to minimize systemic hypertension unless delayed graft function is suspected.[6] The native kidneys are usually preserved in cats. In all recipients, biopsy of one of the native kidneys should be performed.

259.6 PERIOPERATIVE MANAGEMENT AND COMPLICATIONS

Postoperative treatment should include fluid therapy, immunosuppressive drugs, analgesia, and careful monitoring of the hematocrit, electrolyte balance, and cardiovascular status.

1753

1754

Blood pressure should be monitored every 1 to 2 hours after surgery for the first 48 hours. Hypotension in the postoperative period is dangerous to graft function because of decreased renal blood flow and an increased risk of vessel thrombosis. Hypertension is also dangerous in the postoperative period because it has been associated with central nervous system (CNS) disorders, including seizures.[12] The urine specific gravity and serum BUN and creatinine concentrations should be monitored daily, and these parameters usually improve within 12 to 72 hours after surgery.[8]

Complications seen in the immediate postoperative period may include vessel torsion, hemorrhage, or thrombosis; ureteral leakage or obstruction; malignant hypertension; neurologic abnormalities; and delayed graft function.[12,13] Delayed graft function associated with ischemia-reperfusion injury or partial ureteral obstruction results in lack of improvement in kidney function after surgery. If improvement is not seen within a few days of surgery, abdominal ultrasonography should be performed to assess blood flow in the renal vessels and to evaluate the transplanted ureter for dilatation, which may indicate obstruction. Complete ureteral obstruction or leakage of urine from the ureteroneocystostomy site would require additional surgery to correct the abnormality. Intestinal intussusception has been reported in dogs after transplantation.[6]

259.7 IMMUNOSUPPRESSION

Cyclosporine is a calcineurin inhibitor that blocks the transcription of interleukin-2 (IL-2), impairing T-helper and T-cytotoxic lymphocytes. CyA is not myelosuppressive and has no effect on nonstimulated lymphocytes, thus preserving nonspecific host resistance to infection. The decrease in IL-2 also results in a decrease in other mediators that cause rejection. Prednisone and CyA are synergistic and inhibit T-cell proliferation.

CyA is available as a microemulsified form (NeOral, Novartis Pharma AG, Switzerland; Gengraf, Sangstat Medical Corp., Cambridge, MA). The bioavailability of this formulation is greater and less variable than that of the nonmicroemulsified formulation (Sandimmune, Norvartis), primarily because of more reliable gastrointestinal (GI) absorption. These forms are not interchangeable. The oral form is bitter and should be put in a gelatin capsule. CyA is also available as an intravenous formulation. All forms of CyA must be protected from light.

CyA is cleared by the cytochrome p-450 system. Drugs that induce p-450 enzymes (e.g., phenobarbital) reduce CyA levels. Drugs that compete for clearance by p-450 (e.g., cimetidine, ketoconazole, erythromycin) increase CyA levels. Ketoconazole increases blood levels of CyA twofold in cats and twofold to threefold in dogs.[14,15] Although this reduces the dosage of CyA needed to maintain therapeutic levels, the individual variations in effect and the risk of hepatotoxicity are undesirable. Certain drugs, such as ranitidine, aminoglycosides, trimethoprim, or sulfamethoxazole, can potentiate renal damage.

Because of variations in absorption and metabolism and because the therapeutic window is relatively narrow, CyA blood levels must be closely monitored. The appropriate target range depends on the methodology, sample type, and time after transplantation. Whole blood levels are generally higher than plasma levels, because CyA is extensively bound to the red blood cells. High-performance liquid chromatography (HPLC) provides the most reliable results. Other methods, including immunoassays that use polyclonal or monoclonal antibodies, measure the parent compound and metabolites, which vary in their immunologic effect. Trough levels of 400 to 600 ng/mL as measured by HPLC in whole blood are recommended for the first month. After the first 1 to 3 months, the CyA dosage can be reduced to achieve trough levels of 350 to 450 ng/mL. Fluorescent immunoassay (TDx-FLx assay) yields whole blood levels 1.5 to 4.2 times higher.[5] If HPLC is not readily and reliably available, comparison of HPLC to TDx-FLx values in a minimum of three samples in an individual cat can provide a conversion relationship that allows correct clinical decisions to be made in many cats.[16]

An excess of circulating CyA can cause nephrotoxicity. In humans, values above 1000 ng/mL are associated with azotemia, but many cats tolerate higher levels (up to 3000 ng/mL) before renal toxicity becomes apparent.[17] In contrast, some cats have developed CyA nephrotoxicity at trough levels of 700 to 800 ng/dL.[5] The serum creatinine concentration rarely exceeds 2 to 3 mg/dL from CyA toxicity. Increases in the serum creatinine

concentration usually occur 1 to 2 days after the CyA level reaches high values and normally decline within 1 to 2 days of a decrease in the drug to acceptable levels.[5] Adverse effects of CyA in cats include mild GI signs. Dogs may exhibit gastrointestinal irritation, weight loss, gingival hypertrophy, papillomatosis, shedding, and hypertrichosis.

Prednisone is a standard component of transplantation immunosuppression. It inhibits production of some cytokines (IL-1, IL-6, gamma interferon) that are essential for T-cell production and function. Prednisone also inhibits production of local chemotactic factors, prostaglandins, thromboxanes, and leukotrienes. By 1 month after surgery, the initial dosage of 1 mg/kg given every 12 hours can be reduced to 0.5 to 1 mg/kg given orally every 24 hours. Other immunosuppressive drugs are rarely used in feline renal transplant recipients. Azathioprine (0.3 mg/kg given orally every 3 days) has been used in a few cases, but myelosuppression is a potential problem associated with this drug. In dogs, azathioprine has been used successfully with CyA and prednisone, but hepatotoxicity and pancreatitis are noted side effects. Leflunomide analogs are showing promise, but the expense makes this drug unlikely to become the first-line drug of choice.

259.8 MONITORING

Weekly examination is recommended for the first month after transplantation. At each examination the BUN, creatinine, cyclosporine levels, PCV, and body weight are evaluated. The owner should bring in a urine sample for assessment of the urine specific gravity; cystocentesis and urinary catheterization should be avoided to reduce the risk of inducing urinary tract infection. Each examination should be arranged so that a trough CyA level can be drawn. The owner should administer the next dose immediately after blood sampling to maintain the dosing schedule.

As the cat clinically improves and the CyA levels stabilize, examinations are reduced to every 2 weeks for a month, then monthly for 3 months. At that point, quarterly examinations are usually sufficient. Urine culture, complete chemistry panel, and CBC are performed two to four times a year, and a cardiac consultation should be done yearly. Monthly measurement of antibody titers to *Toxoplasma gondii* for the first 6 months has been recommended.[18]

259.9 COMPLICATIONS

259.9.1 Rejection

Hyperacute rejection from preformed antibodies occurs in the first several hours after transplantation and has not been reported in clinical cases. In the absence of immunosuppression, acute rejection results in destruction of the kidney in 5 to 8 days. Acute rejection is typically reported within the first 2 to 3 months or at any time CyA levels decline to subtherapeutic values. Early clinical signs, which may be vague, include general malaise, vomiting, anorexia, and depression; the serum creatinine concentration may not be elevated in early rejection. Aggressive antirejection therapy should be started with any suspicion of rejection to reduce the damage to the kidney. Intravenous CyA is administered over 4 to 6 hours (i.e., 6.6 mg/kg given every 24 hours, or 4 mg/kg given twice daily diluted in 20 to 100 mL of 0.9% saline or 5% dextrose).[1,5] Intravenous prednisolone sodium succinate (10 mg/kg given every 12 hours) is also administered. Intravenous fluid therapy is administered to maintain hydration. The BUN and creatinine concentrations should improve within 24 to 48 hours. Once these concentrations have normalized and the cat is taking food, intravenous medications can be changed to the oral form.

Chronic allograft nephropathy can be caused by chronic rejection or nonimmunologic factors. Arterial hyperplasia, which leads to graft ischemia, is the predominant lesion of chronic allograft nephropathy. Nonimmunologic factors, such as glomerular hyperfiltration due to small kidney size and a reduced number of nephrons, hypertension-induced vascular injury, and cyclosporine toxicity, have not been recognized as major problems in feline transplantation. Graft survival in cats with chronic allograft nephropathy is about 3 years.

259.9.2 Ureteral Obstruction

Ureteral obstruction caused by stricture formation occurs most commonly 7 to 14 days after surgery. Signs include an increase in the creatinine concentration, a decrease in the urine specific gravity, and a dilated renal pelvis and/or ureter on abdominal ultrasonography. Surgical revision of the neoureterostomy site is indicated. Use of a mucosal apposition surgical technique has markedly reduced the incidence of this complication. Obstruction secondary to retroperitoneal fibrosis, an uncommon cause, occurs at $1^{1}/_{2}$ to 5 months after surgery.

259.9.3 Neurologic Signs

A variety of neurologic signs can be encountered in the postoperative period, including seizures, disorientation, obtundation, or coma.[19] In humans, several potential causes have been identified, including infection, hypertension, CyA toxicity, hypomagnesemia, uremic encephalopathy, erythropoietin therapy, and underlying neurologic disease.[12] Cyclosporine has been associated with postoperative neurologic signs, although CyA levels have not been consistently increased in cats that showed neurologic abnormalities. An immediately functioning graft has been proposed to decrease solute concentrations rapidly, as in dialysis disequilibrium syndrome, a neurologic complication associated with rapid osmolar shifts. A BUN concentration greater than 100 mg/dL and a serum creatinine concentration greater than 10 mg/dL increase the risk of CNS disease by tenfold; preoperative hemodialysis should be considered in this population.[12] Control of hypertension postoperatively reduces neurologic signs, making hypertensive encephalopathy a plausible cause of such signs.[3]

259.9.4 Hypertension

Severe hypertension that occurs in the first 48 hours after surgery can lead to neurologic signs, ataxia, stupor, seizures, blindness, ocular hemorrhage, or retinal detachment. The exact reason for the development of postoperative hypertension is unknown. Preoperative hypertension does not predict postoperative hypertension, although volume expansion during surgery may play a role. Vasoactive substances generated in the transplanted kidney during the warm ischemia time may be released when the vascular clamps are opened, resulting in hypertension. Pain associated with the surgery may exacerbate the hypertension. Diligent blood pressure monitoring for at least 48 hours after surgery is advised. If hypertension develops, treatment with a fast-acting antihypertensive agent is indicated (e.g., hydralazine, 2.5 mg given subcutaneously).[3]

259.9.5 Infection

The immunosuppression necessary to prevent rejection predisposes recipients to infection. Over 50% of human transplant recipients develop infection in the first year, and bacterial UTI is the most common type. In humans, common infections (UTI, surgical wound infection, pneumonia) tend to occur more often in the first

month, corresponding to the highest levels of immunosuppression. In cats, bacterial UTI, viral upper respiratory infections, toxoplasmosis, and a variety of fungal infections have been reported.

Because CyA primarily interferes with cell-mediated immunity, unusual infections may arise. Toxoplasmosis has caused fatal infections in three cats and one dog.[18] Infections occurred 3 weeks to 6 months after surgery and were associated with administration of increased immunosuppressive medications in three of the four cases. Transmission of toxoplasmosis from the donor to the recipient was suspected in one case; reactivation of latent infection was suspected in the three with high levels of immunosuppression. Close monitoring of seropositive recipients after surgery is recommended, and treatment with clindamycin is advised if titers rise. Transplant recipients should avoid situations that might expose them to large numbers of other cats, including boarding kennels.

259.9.6 Neoplasia

Human renal transplant recipients on long-term immunosuppressive therapy have a higher rate of neoplasia compared to the general population. The rate of *de novo* cancer in feline renal transplant recipients is 9.5% to 14%. Lymphosarcoma is the most common neoplasm. Other reported malignancies include squamous cell carcinoma, malignant round cell tumors, hepatic carcinoma, bronchogenic adenocarcinoma, transitional cell carcinoma, and intestinal adenocarcinoma.[5,20]

259.9.7 Miscellaneous Complications

A variety of other complications have been reported. A hemolytic-uremic–like syndrome was reported in three cats[21]; it was characterized by hemolysis, thrombocytopenia, and thrombotic microangiopathy. Intrarenal thrombosis leads to renal cortical necrosis. In children, this syndrome is typically caused by *E. coli* O157:H7 endotoxin; other causes in renal transplant recipients include acute vascular rejection, malignant hypertension, and nephrotoxicity arising from CyA, tacrolimus, or antilymphocyte antibody administration. In cats, the outcome has been graft failure and death. Retroperitoneal fibrosis, characterized by the development of fibrous tissue around the ureter and renal capsule, has been encountered. Surgical debulking of this tissue can relieve ureteral obstruction and renal compression.[22] Hypercalcemia was reported in one cat as a result of primary hyperparathyroidism.[23] Prednisone and CyA have been implicated in the development of post-transplantation diabetes mellitus, which has been recognized in cats.[24]

259.10 OUTCOME

The outcome after transplantation has improved as veterinary surgeons have gained more experience with the procedure. Perioperative mortality is approximately 25%. For cats discharged from the hospital, the 6-month survival rate is 60% to 70%. Mortality is highest in the first 6 months after surgery. Older age at surgery (over 10 years) predicts a worse outcome, particularly in the first 6 months, but in one study these deaths were not attributed to age-related diseases.[12] The overall 3-year survival rate is 40% to 50%.[5,12] In one study, one third of deaths were due to allograft rejection.[12] CNS disease, neoplasia, viral upper respiratory infection, hemolytic-uremic syndrome, gastrostomy tube peritonitis, and a variety of other causes of death have also been reported.

1755 1756

259.11 CANINE TRANSPLANTATION

Renal transplantation is not as well established in dogs as in cats. Problems with the efficacy and toxicity of immunosuppressive drugs in dogs make sufficient immunosuppression more difficult. Unacceptable GI toxicity of many immunosuppressive drugs precludes their routine use. Long-term survival in unrelated dogs using rabbit antidog antithymocyte serum, CyA, azathioprine, and prednisone have been reported, but antithymocyte serum is not commercially available.[6] Protocols involving leflunomide, CyA, and prednisone, or CyA, azathioprine, and prednisone are undergoing evaluation in unrelated dogs that are haplotype mismatched.

259.12 SUMMARY

Renal transplantation provides a method of treating end-stage renal disease in cats. Successful long-term outcomes are possible, with improved quality of life in addition to prolonged longevity. Careful patient selection is advised. Long-term immunosuppression is necessary. Multiple complications have been encountered, but improvements in surgical technique, management, and monitoring are gradually extending the average survival time of transplant recipients. The procedure is becoming more widely available, and more clients are requesting evaluation and referral of their pets.

260 CHAPTER • 260 Chronic Kidney Disease

David J. Polzin

Carl A. Osborne

Sheri Ross

260.1 OVERVIEW OF CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is the most common kidney disease in dogs and cats. Regardless of the cause or causes of nephron loss, CKD is characterized by irreversible structural lesions. After correcting any reversible primary diseases and prerenal or postrenal components of renal dysfunction, further improvement in kidney function should not be expected in patients with CKD, because compensatory and adaptive changes designed to sustain kidney function have largely already occurred. However, unless additional kidney injury occurs or CKD is very advanced, rapid deterioration of intrinsic kidney function is also unusual. The magnitude of kidney dysfunction typically remains stable or slowly declines over months to years.[1,2] However, it may not be necessary for the disease process responsible for the initial kidney injury to persist for progressive dysfunction to occur. Therefore irrespective of underlying causes, CKD is often described as an irreversible and progressive disease.

Patients with CKD often survive for many months to years with a good quality of life. Although as yet no treatment can correct existing irreversible kidney lesions of CKD, the clinical and biochemical consequences of reduced kidney function can often be ameliorated by supportive and symptomatic therapy. In addition, therapy may be designed to interrupt mechanisms that contribute to the self-perpetuation of progressive CKD.

260.1.1 Chronic Kidney Disease—Defined

Kidney disease is defined as the presence of functional or structural abnormalities in one or both kidneys. It is recognized by reduced kidney function or the presence of kidney damage. Kidney damage is defined as either (1) microscopic or macroscopic renal pathology detected by kidney biopsy or direct visualization of the kidneys or (2) markers of renal damage detected by blood or urine tests or imaging studies (Box 260-1).[3] The severity and clinical implication of kidney disease varies greatly depending on the magnitude of kidney involvement.

CKD is defined as (1) kidney damage that has existed for at least 3 months, with or without decreased glomerular filtration rate (GFR), or (2) a reduction in GFR of more than 50% from normal persisting for at least 3 months. The authors recommend that a duration of at least 3 months be used as the benchmark criterion for confirming the diagnosis of CKD based on the observation that renal compensatory hypertrophy and improvement in renal function may continue for up to 3 months after acute loss of nephrons.

260.1.2 Terms and Concepts Related to Kidney Disease, Kidney Failure, and Uremia

Use of the terms *kidney disease*, *kidney insufficiency, kidney failure, azotemia,* and *uremia* as synonyms may result in misdiagnosis and formulation of inappropriate or even contraindicated therapy. In addition, it may result in misinterpretation of epidemiologic data. For example, in the past, confusion has occurred in the

interpretation of statistics about the frequency of kidney lesions reported by pathologists. Some investigators misinterpreted data regarding the frequency of morphologic evidence of kidney disease and suggested that all cases with kidney disease had kidney failure.

260.1.2.1

260.1.2.1 Box • 260-1 Markers of Kidney Damage*

260.1.2.1.1 Blood Markers

Elevated blood urea nitrogen (BUN) concentration

Elevated serum creatinine concentration

Hyperphosphatemia

Hyperkalemia or hypokalemia

Impaired urine-concentrating ability

Proteinuria

Cylinduria

Renal hematuria

Inappropriate urine pH

Inappropriate urine glucose concentration

Cystinuria

260.1.2.1.3 Imaging Markers—Abnormalities in Kidney

Size

Shape

Location

Density

Number

* Markers must be confirmed to be of renal origin to be evidence of kidney damage.

Kidney disease should not be used synonymously with *kidney failure* or *uremia*. Depending on the quantity of renal parenchyma affected and the severity and duration of lesions, kidney disease or diseases may or may not cause kidney failure or uremia. The clinical relevance of the difference between kidney disease and kidney failure is emphasized by the fact that symptomatic and supportive therapies designed to correct fluid, electrolyte, acid-base, nutrient, and endocrine imbalances in patients with kidney failure typically are not appropriate for patients with kidney disease without kidney dysfunction.

Kidney disease may affect glomeruli, tubules, interstitial tissue, and vessels. Some kidney diseases may be associated with dysfunction (e.g., some forms of nephrogenic diabetes insipidus and some forms of renal tubular acidosis) or biochemical abnormalities (e.g., cystinuria) without detectable morphologic alterations. Others may be associated with morphologic kidney disease (anomalies, infections, endogenous or exogenous toxin-induced lesions, immune-mediated lesions, damage caused by hypercalcemia and other mineral imbalances, traumatic lesions) that affects one or both kidneys with variable effects on kidney function. The specific cause or causes of kidney disease or diseases may or may not be known; however, quantitative information about kidney function (or dysfunction) is not defined or implied by the term *kidney disease*.

Kidney function *adequate* for homeostasis does not require that *all* nephrons be functional. The concept that adequate kidney function is not synonymous with normal kidney function is of importance in understanding the difference between kidney disease and kidney failure; formulating meaningful prognoses; and formulating therapy. The term *kidney failure* is analogous to liver failure or heart failure in that a level of organ dysfunction is described rather than a specific disease entity. Similarly, the term *kidney insufficiency* implies kidney dysfunction, but at a level that is less severe than kidney failure. The kidneys perform multiple excretory, regulatory, and biosynthetic functions including selective elimination of waste products of metabolism from the body, maintenance of fluid, acid-base and electrolyte homeostasis, and synthesis of a variety of hormones. Failure to perform these functions may not be an *all or none phenomenon*. For example, in slowly progressive kidney diseases, failure to appropriately concentrate or dilute urine according to body need typically precedes failure to eliminate waste products of metabolism of such magnitude that it causes azotemia. In turn, laboratory detection of impaired ability to eliminate waste products of metabolism (such as urea and creatinine) and to maintain electrolyte and nonelectrolyte solute balance within normal limits typically precedes the onset of polysystemic signs of kidney dysfunction. Clinical signs and polysystemic disorders caused by abnormalities of water, electrolyte, acid-base, endocrine, and nutrient balance are not invariably present in patients with primary kidney failure (i.e., not all patients with primary kidney failure are uremic). This is related, at least in part, to the reserve capacity of the kidneys and the ability of unaffected nephrons to undergo compensatory hypertrophy and hyperplasia.

In dogs, acute loss of two thirds or more of functional nephrons is associated with loss of adequate urine-concentrating ability, whereas acute loss of three fourths or more of functional nephrons results in azotemia. However, over the subsequent weeks to months, urine-concentrating ability and excretory function improve as a consequence of compensatory hypertrophy and hyperplasia of surviving nephrons. As a consequence, 3 months after loss of three fourths of functioning nephrons, renal concentrating ability is often adequate and azotemia is no longer present. Chronic renal insufficiency therefore implies a 75% reduction in GFR that typically corresponds to a loss of substantially more than 75% of the functional nephrons.

Azotemia is defined as an abnormal concentration of urea, creatinine, and other nonprotein nitrogenous substances in blood, plasma, or serum. Azotemia is a laboratory finding with several fundamentally different causes. Because nonprotein nitrogenous compounds (including urea and creatinine) are endogenous substances, abnormally elevated concentrations in serum may be caused by an increased rate of production (by the liver for urea; by muscles for creatinine), or by a decreased rate of loss (primarily by the kidneys). Because

azotemia may be caused by factors that are not directly related to the urinary system and by abnormalities of the lower urinary tract (LUT) not directly related to the kidney, *azotemia* should not be used as a synonym for kidney failure or uremia. Although the concentrations of serum urea nitrogen (SUN) and creatinine are commonly used as crude indices of GFR, meaningful interpretation of these parameters depends on recognition and evaluation of prerenal, primary renal, and postrenal factors that may reduce GFR.

Uremia is defined as (1) abnormal quantities of urine constituents in blood caused by primary generalized kidney disease *and* (2) the polysystemic toxic syndrome which occurs as a result of abnormal kidney function. When the structural and functional integrity of both kidneys has been compromised to such a degree that 1757
polysystemic signs of kidney failure are clinically manifested, the relatively predictable symptom complex 1758
called *uremia* appears, regardless of underlying cause. In some instances, uremic crises may suddenly be precipitated by prerenal disorders or, less commonly, postrenal disorders in patients with previously compensated primary kidney failure. Uremia is characterized by multiple physiologic and metabolic alterations that result from impaired kidney function.

In summary, kidney disease may precede kidney insufficiency and failure, and likewise, kidney insufficiency and failure may precede uremia. In some situations, kidney disease may not progress to kidney insufficiency or failure. In others, prerenal events may precipitate a uremic crisis in patients with chronic kidney insufficiency or failure. In untreated patients with kidney disease, uremia is always accompanied by kidney failure and azotemia.

260.1.3 Staging Chronic Kidney Disease

Patients with CKD can be categorized into stages along a continuum of progressive kidney disease.[4] The value of staging CKD is to facilitate application of appropriate clinical practice guidelines for diagnosis, prognosis, and treatment. The International Renal Interest Society (IRIS) has proposed a four-tier system for staging CKD in dogs and cats (Box 260-2 and 260-3; Figures 260-1 and 260-2). Although the specific values used to categorize patients with CKD into these stages are inherently arbitrary, staging is nonetheless useful for establishing prognosis and managing patients with CKD.

The stage of CKD is assigned based on the level of kidney function. The level of GFR is accepted as the best measure of overall kidney function in health and disease.[3] Ideally, the stage of CKD would be assigned based on measured GFR values. However, because of technical and economic constraints, GFR is usually estimated in dogs and cats by serum (or plasma) creatinine concentration. Limitations on specificity and sensitivity of serum creatinine concentration as an estimate of GFR can lead to misclassification. Ideally, two or more serum creatinine values obtained when the patient is fasted and well hydrated should be determined over several weeks to stage CKD. Further, variations between laboratories, patient-specific characteristics (e.g., breed, age, gender, body condition, and lean body mass) and transient prerenal and postrenal events may influence serum creatinine values. Reduced muscle mass, a common manifestation of advanced CKD, may result in a substantial reduction in serum creatinine concentration relative to true GFR. Greyhounds reportedly have higher serum creatinine concentrations, presumably due to their athletic nature.[5] Because of these variations, published reference ranges for serum creatinine are often exceedingly broad. Using the staging system described here, some patients classified as having mild renal azotemia (stage 2) may have serum creatinine values within published reference ranges. As a consequence, the patient's overall clinical status should be considered when interpreting serum creatinine concentration and other laboratory tests and when planning patient management.

260.1.3.1 **Box • 260-2 Stages of Canine Chronic Kidney Disease**

260.1.3.1.1 **Stage 1 (Nonazotemic)**

Markers of renal disease present

Proteinuria: Classify—P/NP/BP

Hypertension: Classify—Hc/Hnc/NH/BH/HND

260.1.3.2.2 Stage 2 (Mild Renal Azotemia)

Markers of renal disease present

Creatinine 1.6–2.8 mg/dL (140–250 µmol/L)

Proteinuria: Classify—P/NP/BP

Hypertension: Classify—Hc/Hnc/NH/BH/HND

260.1.3.2.3 Stage 3 (Moderate Renal Azotemia)

Creatinine 2.8–5.0 mg/dL (251–440 µmol/L)

Proteinuria: Classify—P/NP/BP

Hypertension: Classify—Hc/Hnc/NH/BH/HND

260.1.3.2.4 Stage 4 (Severe Renal Azotemia)

Creatinine > 5.0 mg/dL (> 440 µmol/L)

Proteinuria: Classify—P/NP/BP

Hypertension: Classify—Hc/Hnc/NH/BH/HND

P, Proteinuria; *NP,* nonproteinuria; *BP,* borderline proteinuria; *Hc,* hypertension with complications; *Hnc,* hypertensive with no complications; *NH,* nonhypertensive; *BH,* borderline hypertensive; *HND,* hypertension not determined.

Stage 1 CKD includes dogs and cats with CKD that are not azotemic, whereas stage 2 CKD includes dogs and cats that are mildly azotemic (see Boxes 260-2 and 260-3). Patients in these stages of CKD typically do not have clinical signs of kidney dysfunction with the exception of polyuria and polydipsia. Occasionally cats with stage 2 CKD may have weight loss or selective appetites. However, patients may have clinical signs resulting from their kidney lesions (e.g., acute pyelonephritis, nephrolithiasis). Patients with marked proteinuria or systemic hypertension due to CKD may have clinical signs related to these aspects of kidney disease. Renal function is often stable for an extended period in nonproteinuric, nonhypertensive (NH) dogs and cats with stages 1 and 2 CKD. However, when progression does occur in this group of patients, it may occur largely as a consequence of their primary kidney disease.[4] Patients with stages 1 and 2 CKD should be evaluated with the goals of identifying and providing specific treatment for their primary kidney disease. In addition, renal function should be monitored to assess for possible progression of their kidney disease.

1758

1760

Figure 260-1 Classification of canine chronic kidney disease (CKD) based on serum creatinine concentrations. Firm evidence of renal disease in stage 1 would generally be morphologic, such as abnormal renal architecture on survey radiographs, abnormal renal ultrasound findings, or biopsy diagnosis of renal disease. Classification of prerenal azotemia (generally due to dehydration or renal ischemia) or postrenal azotemia (generally due to ureteral obstruction, urethral obstruction, or a rupture of a portion of the urinary tract) is based on careful evaluation of the history and physical examination and other clinical or imaging findings. This determination may require additional tests. Classification of azotemia as renal is based on the presence of azotemia with no identifiable prerenal or postrenal causes and urine specific gravity (USG) less than 1.030. (Developed by the International Renal Interest Society, www.iris-kidney.com. Used with permission.)

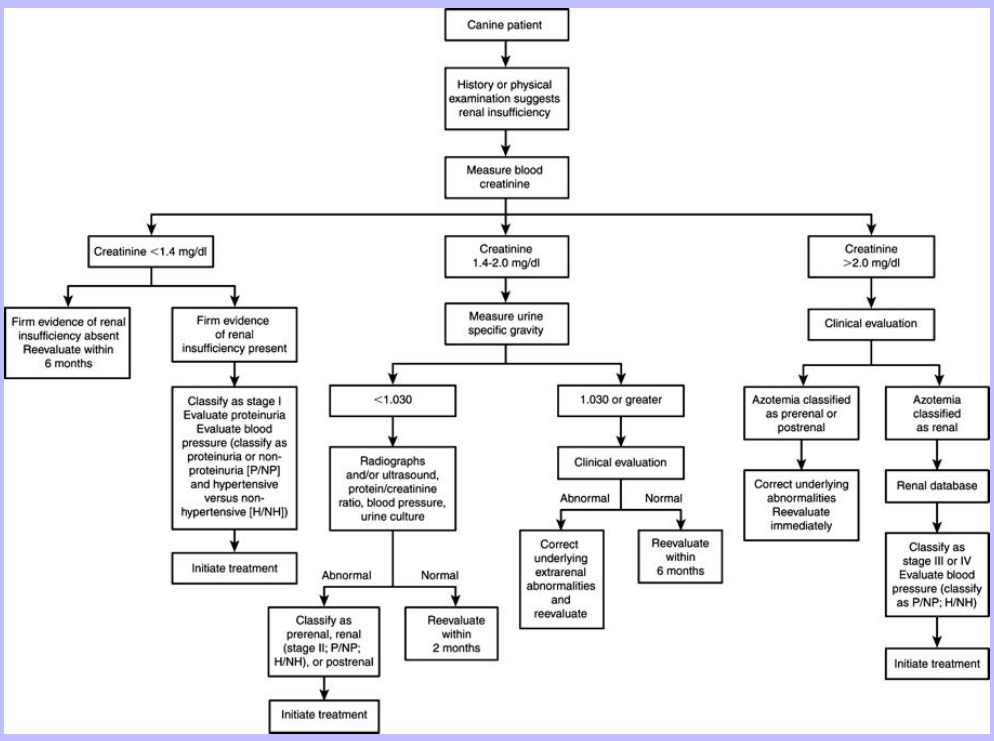

Figure 260-2 Classification of feline chronic kidney disease (CKD) based on serum creatinine concentrations. Firm evidence of renal disease would generally be morphologic, such as abnormal renal architecture on survey radiographs, abnormal renal ultrasound findings, or biopsy diagnosis of renal disease. Classification of prerenal azotemia (generally due to dehydration or renal ischemia) or postrenal azotemia (generally due to ureteral obstruction, urethral obstruction, or a rupture of a portion of the urinary tract) is based on careful evaluation of the history and physical examination and other clinical or imaging findings. Classification of azotemia as renal is based on the presence of azotemia with no identifiable prerenal or postrenal causes and urine specific gravity (USG) less than 1.040. (Developed by the International Renal Interest Society www.iris-kidney.com. Used with permission.)

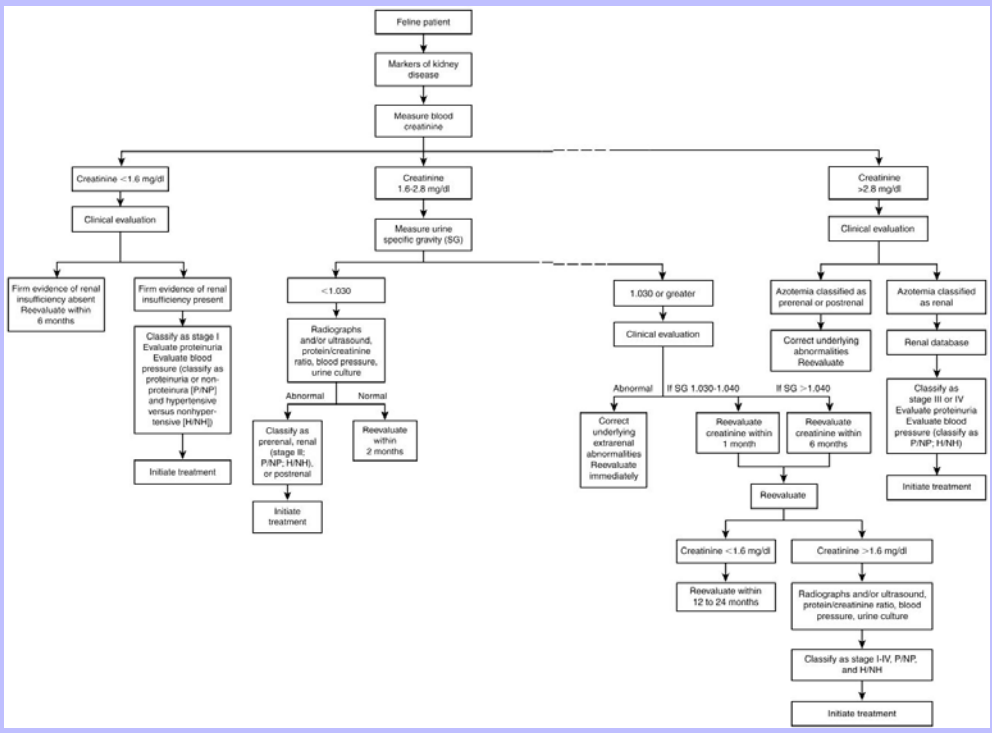

Patients with moderate azotemia are classified as stage 3 CKD. Patients in this stage may have clinical signs referable to their loss of kidney function; however, with appropriate treatment, they typically do not have clinical signs of overt uremia. Patients with stage 3 CKD may progress due to inherent mechanisms of

spontaneous progression, as well as their underlying kidney disease. Therefore in addition to identifying and treating primary kidney disease, therapy designed to modify factors promoting progression of renal disease may be of benefit to these patients.

Stage 4 CKD includes dogs and cats with severe azotemia (serum creatinine values greater than 5.0 mg/dL). This stage is also called *chronic kidney failure* and is frequently associated with clinical signs that occur as a consequence of loss of kidney function. Diagnostic and therapeutic initiatives in this stage include those appropriate for stage 3 patients, as well as therapy designed to prevent or ameliorate signs of uremia.

It is useful to further subclassify patients according to their urine protein loss and systemic blood pressure. Proteinuria and hypertension may influence prognosis and may be amenable to therapeutic intervention. Classification of patients as proteinuric necessitates eliminating hemorrhage, inflammation, or both as the cause for proteinuria and determination of the urine protein/creatinine ratio. For both dogs and cats, patients are classified as proteinuric (P) when their protein/creatinine ratio exceeds 1.0. Values between 0.5 and 1.0 are classified as borderline proteinuric (BP). Values less than 0.5 are classified as nonproteinuric (NP). Patients with borderline proteinuria should be re-evaluated after 2 months to reassess classification. In some patients, classification of proteinuria may change due to the natural course of their disease or in response to therapy. The role of microalbuminuria in this classification scheme remains to be determined.

The lack of consensus as to what blood pressure values constitute hypertension in dogs and cats obfuscates any classification of patients as to their hypertension status. It is likely that "normal" blood pressure values for dogs and cats will change as more data become available. The IRIS has proposed the following hypertension classification system for dogs and cats: Patients may be classified as hypertensive with no complications (Hnc) when their systolic blood pressure exceeds 160 mm Hg and no extrarenal evidence of hypertension exists (i.e., ocular, neurologic, or cardiac changes consistent with hypertensive injury). Patients may be classified as hypertensive with extrarenal complications (Hc) when their systolic blood pressure exceeds 150 mm Hg and extrarenal evidence of hypertension is present. Patients may be classified as borderline hypertensive (BH) when their systolic blood pressure is between 150 mm Hg and 180 mm Hg and no extrarenal evidence of hypertension exists. Patients may be classified as NH when their systolic blood pressure is less than 150 mm Hg. If blood pressure has not been determined, the patient should be classified as hypertension not determined (HND).

260.1.4 Affected Population

CKD is a common cause for illness and death in dogs and cats. It is among the most common diseases recognized in older cats. The prevalence of kidney disease has been estimated to range between 0.5%[6] and 7%[7] in dogs and between 1.6%[6] and 20%[7] in cats.

Although frequently considered a disease of older animals, CKD occurs with varying frequency in dogs and cats of all ages. In a retrospective study of cats with CKD, 53% of affected cats were over 7 years old, but animals ranged in age from 9 months to 22 years.[8] In a study on age distribution of kidney disease in cats based on data submitted from 1980 to 1990 to the Veterinary Medical Data Base at Purdue University, 37% of cats with renal failure were less than 10 years old, 31% of cats were between the ages of 10 and 15, and 32% of cats were older than 15 years of age.[9] Similarly, in a study of cats with CKD reported in 1988, their mean age was 12.6 years with a range of 1 to 26 years.[10] Mean age among 45 control cats in this study was 10.0 years. During 1990, the prevalence of kidney disease among cats of all ages was reportedly 16 cases for every 1000 cats examined. During the same year, the prevalence of kidney disease among cats 10 years of age or

older was 77 per 1000 cats examined, and among cats older than 15 years, 153 per 1000.[8] Maine coon, Abyssinian, Siamese, Russian blue, and Burmese cats were disproportionately reported as affected.

Although renal failure apparently occurs less commonly in dogs than cats, its incidence increases similarly with age. Based on data submitted from 1983 to 1992 to the Veterinary Medical Data Base at Purdue University, 18% of dogs with renal failure were less than 4 years old, 17% of dogs were between the ages of 4 and 7, 20% of dogs were between the ages of 7 and 10, and 45% of dogs were older than 10 years of age. During this period, the prevalence of renal failure among dogs of all ages was nine cases for every 1000 dogs examined. The prevalence of renal failure among dogs 7 to 10 years of age was 12.5 per 1000 dogs examined; among dogs 10 to 15 years, 24 per 1000, and among dogs older than 15 years, 57 per 1000.

260.1.5 ## Causes of Chronic Kidney Disease

CKD may be initiated by a variety of different familial, congenital, or acquired diseases (Box 260-4). In a study of biopsy findings in 37 dogs with primary renal azotemia, chronic tubulointerstitial nephritis was observed in 58%, glomerulonephropathy occurred in 28%, and amyloidosis was observed in 6%.[11] In cats, tubulointerstitial nephritis was observed in 70%, glomerulonephropathy occurred in 15%, lymphoma was observed in 11%, and amyloidosis occurred in 2%. Unfortunately, the initiating cause or causes of CKD often cannot be identified at the time of diagnosis. The initiating causes of diseases thought to originate in the tubulointerstitium have been especially elusive. Although bacteria can cause tubulointerstitial lesions, in the authors' experience, a bacterial urinary tract infection (UTI) is more often a sequela of the immunocompromised condition associated with renal failure than the cause. In one retrospective study of renal failure cats, bacterial UTI was detected in 20% of the patients.[9] Glomerulonephropathies have been linked to a variety of neoplastic, metabolic, and infectious and noninfectious inflammatory processes.[12] Periodontal disease has been linked to microscopic renal lesions in dogs, but a cause-and-effect relationship has not been established.[13] Feline immunodeficiency virus (FIV) has been linked to renal disease in cats, although few cats with CKD are FIV positive.[14,15] Subcutaneous administration of feline herpesvirus 1 (FHV-1), calicivirus, and panleukopenia virus vaccines grown in feline tissue culture systems to kittens have been shown to induce production of antifeline renal tissue antibodies in serum (Lappin and colleagues).[16] This observation prompts the question as to whether repeated vaccinations play a role in development of chronic renal disease.

Bilateral hydronephrosis

- Spay granulomas
- Transitional cell carcinoma—bladder trigone location
- Nephrolithiasis

Polycystic

Hypercalcemia

- Malignancy
- Primary hyperparathyroidism

Idiopathic

Difficulty in detecting the inciting cause of CKD is associated with three phenomena related to the evolution of progressive renal diseases. First, various components of nephrons (glomeruli, peritubular capillaries, tubules, and interstitial tissue) are functionally interdependent. Second, the functional and morphologic responses of tissues comprising the kidneys to different causative agents are limited. Third, after maturation of nephrons, which occurs at approximately 1 month of age, new nephrons cannot be formed to replace others irreversibly destroyed by disease. Progressive irreversible lesions initially localized to one portion of the nephron are eventually responsible for development of lesions in the remaining but initially unaffected portions of nephrons. For example, progressive lesions (such as amyloid or immune complex disease) confined initially to glomeruli will subsequently decrease peritubular capillary perfusion. Reduced peritubular capillary perfusion will in turn result in tubular epithelial cell atrophy, degeneration, and necrosis. Recent

studies suggest that tubular epithelial cells may also be damaged as a consequence of glomerular proteinuria. Secondary tubular damage may be related, at least in part, to excessive tubular cell uptake of filtered proteins or protein-bound substances.[17] Studies showing that the rate of disease progression correlates with the amount of proteinuria, and that therapy designed to reduce proteinuria retards progression, support the concept that glomerular proteinuria damages tubules. The secondary processes of inflammation and fibrosis amplify these processes. An influx of T cells and macrophages into the interstitium may cause further tubular injury, and macrophages in particular produce profibrotic substances. Ultimately nephron destruction initiated by glomerular disease will simulate repair by substitution of functioning nephrons with nonfunctional connective tissue.

Similarly, generalized progressive interstitial disease initially caused by bacteria eventually destroys tubules and glomeruli and stimulates inflammation and fibrosis. Thus irrespective of the initiating cause, replacement of the majority of the damaged nephrons with collagenous connective tissue results in overall reduction in kidney size and impaired renal function.

Because of the structural and functional interdependence of various components of nephrons, differentiation of different progressive renal diseases that have reached an advance stage is often difficult. Functional and structural changes prominent during earlier phases of progressive generalized renal diseases may permit identification of a specific cause and localization of the initial lesion to glomeruli, tubules, interstitium, or vessels. With time, however, destructive changes of varying severity (atrophy, inflammation, fibrosis, and mineralization of diseased nephrons), superimposed on compensatory and adaptive morphologic and functional of remaining partially and totally viable nephrons, provide a functional and morphologic similarity to the findings associated with these diseases.

Despite the irreversibility of generalized renal lesions associated with CKD, it is important to formulate diagnostic plans to try to identify the underlying cause and to determine if it is still active. Although specific therapy directed at eliminating or controlling the primary cause will not substantially alter existing renal lesions, it is important in the context of minimizing further nephron damage. Renal diseases potentially amenable to specific therapy include bacterial pyelonephritis, chronic urine outflow obstruction, nephrolithiasis, renal lymphoma (particularly in cats), hypercalcemic nephropathy, and some immune-mediated diseases.

Acute onset of nonurinary disorders, especially those that interfere with compensatory polydipsia, may precipitate a uremic crisis in patients with asymptomatic CKD (so-called acute-on-chronic uremic crisis). However, if acute decompensation of CKD has been caused by reversible factors, correction of them will often result in recompensation of the CRF.

260.1.6 Prognosis of Chronic Kidney Disease

Cats with stages 2 and 3 CKD commonly survive 1 to 3 years, whereas dogs with stage 3 CKD typically survive about 6 to 12 months. However, many survive much longer. A host of factors influence prognosis of CKD, both favorably and unfavorably. Included among these factors are the quality of medical care provided to the patient and the level of owner commitment. The estimate of prognosis often influences the owner's decisions about treatment options in complying with recommendations for management of the patient. A comprehensive evaluation of the patient is the best way to establish a reasonably accurate prognosis.

Prognosis for patients with CKD is usually subcategorized according to the probability of immediate survival (short-term prognosis) and survival over the subsequent months to years (long-term prognosis). A guarded prognosis indicates that the chances for recovery are unpredictable. Fair, good, or excellent prognoses indicate

varying degrees of probable recovery, whereas poor or grave prognoses indicate that recovery is improbable or hopeless. Loss of renal function is irreversible in patients with CKD. In this context, recovery refers to improvement of biochemical deficits and excesses and amelioration of clinical signs rather than recovery of renal function.

Factors to be considered in establishing meaningful prognoses for patients with CKD include (1) the nature of the primary renal disease, (2) severity and duration of clinical signs and complications of uremia, (3) probability of improving renal function (reversibility—primarily of prerenal, postrenal, and newly acquired primary renal conditions), (4) severity of intrinsic renal functional impairment, (5) rate of progression of renal dysfunction with or without therapy, and (6) age of the patient. In addition, blood pressure and the magnitude of proteinuria are risk factors influencing prognosis in dogs with CKD.[18]

Severity of uremic signs is often a relatively good predictor of short-term prognosis. Patients with stable CKD without clinical signs of uremia usually have a good short-term prognosis. Untreated patients with severe clinical signs of uremia typically have a guarded to poor short-term prognosis. However, it is best to determine whether renal function and clinical signs can be therapeutically improved in such cases before establishing the short-term prognosis. A uremic crisis often occurs in patients that present with CKD as a consequence of superimposed acute renal failure or prerenal or postrenal conditions. Although CKD is an irreversible condition, improvement of renal function is potentially possible when uremia results from the sum effects of CKD and a potentially reversible cause of azotemia. If treatment results in improved renal function and ameliorates clinical signs of uremia, the short-term prognosis often becomes guarded to good.

Severity of renal dysfunction as determined by serum creatinine concentration or measurement of GFR provides a less accurate means of assessing short-term prognosis than does the clinical condition of the patient. The relationship between magnitude of renal dysfunction and clinical signs of uremia is often unpredictable. Therefore short-term prognosis should not be established based on a single measurement of the severity of renal dysfunction. In addition, a single determination of renal function is unreliable as an index of the potential for improvement in renal function.

Assessment of the severity of renal dysfunction is typically more useful in establishing long-term prognoses. In general, severe renal dysfunction is associated with shorter long-term survival and, often, a lower quality of life. This generalization is supported by findings of a recent study of cats with spontaneous CKD.[2] For cats with CKD without apparent clinical signs and having a mean plasma creatinine concentration of 2.6 mg/dL, mean survival was 397 days. For cats with CKD with one or more clinical signs attributable to CKD and a mean plasma creatinine concentration of 3.6 mg/dL, mean survival was 313 days. Uremic cats with a mean plasma creatinine concentration of 10.3 mg/dL survived less than 3 days. However, in a recent clinical trial in dogs with spontaneous CKD, mean serum creatinine concentration did not appear to influence survival when dogs were fed a renal diet. Median survival for 21 dogs with a mean serum creatinine concentration of 3.3 mg/dL was 615 days. Median survival for a subpopulation of dogs in this group with serum creatinine values between 2.0 and 3.1 mg/dL was also 615 days. However, among 17 dogs fed a maintenance diet in this study, median survival for dogs with a mean serum creatinine of 3.7 mg/dL was 252 days, whereas survival for the subpopulation with serum creatinine values between 2.0 and 3.1 mg/dL was 461 days. In summary, the prognosis should be established in the context of the clinical condition of the patient, rate of progression of renal dysfunction, response to therapy, cause of the underlying renal disease (if known), and other complicating factors (e.g., UTI, nephrotic syndrome).

1763

1764

Systemic hypertension has been linked to progression of CKD in humans for decades.[19] Increased systolic blood pressure has been shown to increase risk of uremic crises and death in dogs with spontaneous CKD.[18] In

this study, systolic blood pressure values determined at the time of initial patient evaluation were compared with long-term outcome. Increased risk of developing a uremic crisis and of death was observed in the patients with the highest blood pressure values. In addition, a greater decline in renal function over time was observed in these dogs. Although this study was not designed to prove a cause-and-effect relationship between hypertension and progressive renal disease, it does indicate that initial blood pressure values should be considered in formulating a prognosis for dogs with CKD. The prognostic significance of blood pressure values in cats with CKD has yet to be established.

Results of a clinical trial from the University of Minnesota Veterinary Medical Center revealed that proteinuria is a risk factor for uremia and death in dogs with spontaneous kidney disease.[20] In this study, the risk of death associated with CKD increased by 60% for each unit of urine protein/creatinine ratio above 1.0. Whether proteinuria conferred this adverse risk as an independent mediator of renal injury or as a consequence of the biologic behavior of glomerular diseases is unclear. In dogs, glomerulopathies have been associated with poor long-term prognoses.[12] This may be related to the observation that proteinuria has been implicated in promoting progressive renal injury.[21] Therapeutic amelioration of proteinuria using angiotensin-converting (ACE) inhibitors may stabilize renal function in humans and dogs with glomerular disease, further suggesting a likely role for proteinuria in the progression of CKD.[22]

Compared with the rate of progression of CKD in middle-aged to older dogs with acquired renal disease, CKD often progresses at a much slower rate in dogs with congenital and familial nephropathies such as renal dysplasia. A comparably slower rate of progression has also been observed in young dogs with acquired CKD (e.g., after nephrotoxin exposure). Many of these patients appear remarkably resistant to developing clinical signs of uremia despite substantial elevations in serum creatinine and urea nitrogen concentrations.

260.2 CLINICAL CONSEQUENCES OF CHRONIC RENAL FAILURE

260.2.1 Uremia

Uremia is the clinical state toward which all progressive, generalized renal diseases ultimately converge. Diverse clinical and laboratory findings characterize uremia and emphasize the polysystemic nature of CKD (Box 260-5). The term *uremia* was adopted originally because of the presumption that all of the abnormalities result from retention in the blood of end-products of metabolism normally excreted in the urine. However, uremia involves more than renal excretory failure alone. A variety of metabolic and endocrine functions normally performed by the kidney are also impaired, resulting in anemia; malnutrition; impaired metabolism of carbohydrates, fats, and proteins; defective use of energy; alterations in immunity; and metabolic bone disease.

Urea, once thought to be “the” uremic toxin, is not a major cause of uremic toxicity, although it may contribute to some of the clinical abnormalities, including anorexia, malaise, and vomiting. Numerous nitrogenous compounds with a molecular mass of 500 to 12,000 D (so-called middle molecules) are retained in CKD and appear to contribute to morbidity and mortality in uremic subjects.[23] In addition to impaired excretion, many middle-sized molecules along with various cytokines and growth factors accumulate in CKD because the kidney's capacity for catabolizing many substances is also impaired. Further, plasma levels of many polypeptide hormones, including parathyroid hormone (PTH), insulin, gastrin, glucagon, luteinizing hormone (LH), and prolactin, increase in patients with CKD because of impaired renal catabolism and enhanced glandular secretion.

260.2.2 Gastrointestinal Consequences

Gastrointestinal (GI) complications are common and prominent clinical signs of uremia. Anorexia and weight loss are nonspecific findings that may precede other signs of uremia in dogs and cats. The patient's appetite may be selective for certain foods, and it may wax and wane throughout the day. Factors promoting weight loss and malnutrition include anorexia, nausea, vomiting and the subsequent reduction in nutrient intake, hormonal and metabolic derangements, and catabolic factors related to uremia, particularly acidosis.

Anorexia appears to be multifactorial in origin. Recent research, using a rodent model, has suggested that an *anorectic factor* in the plasma of uremic patients that can suppress appetite.[24] It appears to be a middle molecule in size and may be a peptide. Elevated serum leptin concentrations have also been implicated as a factor contributing to anorexia.[25]

Hyperthyroidism (cats)

Nephroliths and ureteroliths

Urinary tract infections (UTIs)

Vomiting is a frequent, but inconsistent finding in uremia. It results from the effects of as yet unidentified uremic toxins on the medullary emetic chemoreceptor trigger zone and from uremic gastroenteritis. The severity of vomiting correlates crudely with the magnitude of azotemia. Because uremic gastritis may be ulcerative, hematemesis may occur. Vomiting may be a more frequent complaint in uremic dogs than cats. Nonetheless, vomiting is reportedly found in one quarter to one third of cats with clinical signs of uremia.[2] Vomiting may impair compensatory polydipsia, enhancing the risk of dehydration and exacerbating prerenal azotemia and clinical signs of uremia.

Uremic gastropathy is characterized microscopically by glandular atrophy, edema of the lamina propria, mast cell infiltration, fibroplasia, mineralization, and submucosal arteritis. Elevated gastrin levels have been implicated in development of uremic gastropathy.[26] Gastrin induces gastric acid secretion directly by stimulating receptors located on gastric parietal cells and by increasing histamine release from mast cells in the gastric mucosa. Enhanced histamine release may also promote GI ulceration and ischemic necrosis of the mucosa through a vascular mechanism characterized by small venule and capillary dilatation, increased endothelial permeability, and intravascular thrombosis.[27] Because up to 40% of the circulating gastrin is metabolized by the kidneys, reduced renal function may promote hypergastrinemia.

Elevated gastrin levels have been documented in cats with spontaneous CKD.[26] Although the prevalence of hypergastrinemia appeared to increase as renal dysfunction became more severe, there was great variability of gastrin levels among cats with similar degrees of renal dysfunction, suggesting that additional factors (in addition to the degree of renal impairment) likely affect serum gastrin levels in CKD.

Gastrin-induced gastric hyperacidity may lead to uremic gastritis, GI hemorrhage, nausea, and vomiting. Back diffusion of hydrochloric acid and pepsin into the stomach wall may lead to hemorrhage, inflammation, and release of histamine from mast cells. Thus the cycle may be perpetuated as mast cell–derived histamine causes further stimulation of parietal cells to produce hydrogen ions. However, gastric hyperacidity is not universally found with uremic gastritis. Some human uremic patients have hypochlorhydria. Thus hypergastrinemia is not the only reason for uremic gastritis. Other factors implicated in the genesis of uremic gastropathy include psychologic stress related to illness, an increase in proton back diffusion caused by high urea levels, erosions caused by ammonia liberated by bacterial urease acting on urea, ischemia caused by vascular lesions, decreased concentration and turnover of gastric mucous, and biliary reflux due to pyloric incompetence (which may be an indirect consequence of elevated gastrin levels).

In a recent study of 80 cats with spontaneous CKD, dysphagia and oral discomfort occurred in 7.7% of uremic cats and 38.5% of cats with end-stage renal failure.[2] Periodontal disease was observed in 30.8% of uremic and 34.6% of end-stage CKD cats in the same study. Halitosis was reported in 7.7% of cats in both groups. Moderate to severe CKD may result in uremic stomatitis characterized by oral ulcerations (particularly located on the buccal mucosa and tongue), brownish discoloration of the dorsal surface of the tongue, necrosis and sloughing of the anterior portion of the tongue (associated with fibrinoid necrosis and arteritis), and uriniferous breath. The mucous membranes may also become dry (xerostomia). Degradation of urea to ammonia by bacterial urease may contribute to many of these signs. Poor oral hygiene and dental disease may exacerbate the onset and severity of uremic stomatitis.

Uremic enterocolitis, manifested as diarrhea, may occur in dogs and cats with severe uremia, but it is typically less dramatic and less common than uremic gastritis. Owners of 80 cats with spontaneous CKD did not report

diarrhea.[2] However, when present, uremic enterocolitis is often hemorrhagic. Considerable GI hemorrhage may initially escape clinical detection. Intussusception may occasionally complicate uremic enterocolitis. Constipation is a relatively common complication of CKD, particularly in cats. Primarily it appears to be a manifestation of dehydration, but it can occur as a complication of intestinal phosphate-binding agents.

260.2.3 Impaired Urine-Concentrating Ability, Polyuria, Polydipsia, and Nocturia

Among the earliest and most common clinical manifestations of CKD is onset of polyuria, polydipsia, and sometimes nocturia due to reduced urine-concentrating ability. Polydipsia was the single most commonly reported clinical sign reported in a study of 80 cats with CKD. Cat owners recognized polydipsia over twice as often as polyuria. Although urine specific gravity (USG) values of cats in stages 2, 3, and 4 CKD are usually below 1.035, the authors have seen cats that have remained persistently (up to 18 months) azotemic prior to losing adequate concentrating ability (i.e., specific gravity >1.040).

A decrease in adequate urine-concentrating ability results from several factors including increased solute load per surviving nephron (solute diuresis), disruption of the renal medullary architecture and counter-current multiplier system by disease, and primary impairment in renal responsiveness to antidiuretic hormone (ADH). Loss of renal responsiveness to ADH may result from an increase in distal renal tubular flow rate, which limits equilibration of tubular fluid with the hypertonic medullary interstitium. Additionally, ADH-stimulated adenyl cyclase activity and water permeability in the distal nephron may be impaired in uremia.[28] Polydipsia is of course a compensatory response to polyuria. If fluid intake fails to keep pace with urinary fluid losses, dehydration will ensue because of the inability to conserve water by concentrating urine. Dehydration subsequent to inadequate fluid intake is a common problem in cats with CKD.

260.2.4 Arterial Hypertension and Cardiovascular Consequences

Hypertension may be either a cause or consequence of CKD. When present, it may adversely affect long-term prognosis.[18] It is a common complications of CKD, reportedly occurring in up to 66% of cats with CKD.[29] Although one recent study suggested that hypertension may be unusual in dogs with CKD,[30] other studies have reported incidences of from 30% to 93% of dogs with CKD.[18,30] Dogs with glomerular diseases are at increased risk for hypertension.

The pathophysiology of arterial hypertension and its complications is described in Chapters 129 and 130.

260.2.5 Neuromuscular Consequences

260.2.5.1 Encephalopathies and Neuropathies

Metabolic encephalopathies and peripheral neuropathies may occur in dogs and cats with uremia.[31,32] It is reported that as many as 65% of dogs and cats with primary renal insufficiency or renal failure have neurologic manifestations. Of dogs with neurologic signs, altered consciousness (31% of patients) and seizures (29% of patients) were the most common signs.[32] In the authors' experience, acute onset of altered mentation is an important neurologic finding in dogs and cats with CKD that typically heralds a poor short-term prognosis. Other common signs include limb weakness, ataxia, and tremors. Patients may develop what has been described as the *twitch-convulsive* state, wherein the simultaneous combination of tremor, myoclonus, and seizures is seen. In advanced CKD, patients may have neurologic signs that are

cyclical and episodic, varying from day to day. The severity and rate of progression of neurologic signs appears to vary directly with the rapidity with which uremia develops.

The pathogenesis of uremic neurologic signs remains unclear, but important roles for PTH and the uremic environment are suspected.[31] Both the sodium potassium adenosine triphosphate pump and several of the calcium pumps are altered in uremia. Alterations in the calcium pumps have been thought to be due at least in part to PTH acting through monophosphate-independent pathways. Calcium pumps are particularly suspected of playing a role in uremic encephalopathy because they mediate neurotransmitter release and information transfer at nerve terminals. Clinical signs of tremors, myoclonus, and tetany may develop due to hypocalcemia. Arterial hypertension may also lead to neurologic signs in patients with otherwise well-controlled renal failure. Clinical signs are acute in onset and may include seizures, behavioral changes, dementia, isolated cranial nerve deficits, and death. In the authors' experience, many of the patients with acute onset of neurologic signs also had hypertension.

Imbalances of neurotransmitter amino acids within the brain have also been implicated in uremic encephalopathy. Analysis of cerebrospinal fluid (CSF) in humans with uremic encephalopathy has shown decreased levels of glutamine and GABA, as well as increased levels of glycine, dopamine, and serotonin.

260.2.5.2 Myopathies

Hypokalemic polymyopathy is occasionally observed in association with CKD, primarily in cats. Because of the influence of potassium on resting cell membrane potentials, potassium imbalances typically manifest clinically as neuromuscular dysfunction. Hypokalemia increases the magnitude (i.e., increases electronegativity) of the resting potential, thereby hyperpolarizing the cell membrane, making it less sensitive to exciting stimuli. The cardinal and most dramatic sign of hypokalemia, regardless of cause, is generalized muscle weakness. In hypokalemic polymyopathy, muscle weakness and pain present clinically as cervical ventroflexion and a stiff, stilted gait.[33] Mild cardiac rhythm disturbances may also occur. Serum creatinine kinase and other muscle enzyme activities may be elevated, and in severe instances, rhabdomyolysis may occur.

Muscle dysfunction unrelated to serum potassium concentrations may also occur in uremia. In humans with CKD, accumulation of a dialyzable uremic toxin derived from dietary protein has been shown to promote abnormalities in sarcolemma ion flux leading to reduced muscle membrane potential.

260.2.6 Hematologic Consequences

260.2.6.1 Anemia

The anemia of renal failure is usually characterized by normochromic and normocytic red blood cells (RBCs). Usually hypoplasia of the erythroid precursors in the bone marrow occurs, with little or no interference with normal leukopoiesis and megakaryocytopoiesis. On blood smears, spiculed and deformed red cells (burr cells or echinocytes) may be noted. Although affected by the patient's age, species, specific renal diagnosis, and concurrent diseases, the severity and progression of the anemia correlates with the degree of renal failure and worsens with progressive renal failure in both dogs and cats.[34]

The hematocrit may become profoundly low. At these low hematocrits, compensatory mechanisms such as increased levels of 2,3 DPG; lowered peripheral vascular resistance; and an elevated cardiac output (in the

absence of previous cardiac disease) help maintain tissue oxygenation. Clinical signs of anemia include pallor of the mucous membranes, fatigue, listlessness, lethargy, weakness, and anorexia.

Anemia in patients with CKD is multifactorial and may be exacerbated by concurrent illness. Although experimental and clinical evidence exists for the supporting roles of shortened red cell life span, nutritional abnormalities, erythropoietic inhibitor substances in uremic plasma, blood loss, and myelofibrosis, erythropoietin deficiency has clearly emerged as the principal cause of anemia in humans and animals with CKD. The peritubular fibroblasts of the renal cortex appear to be the major source of erythropoietin synthesis. It may also be produced by renal interstitial fibroblasts. The kidneys synthesize erythropoietin on demand in response to intrarenal tissue hypoxia due either to decreased oxygen-carrying capacity (anemia) or decreased oxygen content (hypoxia). Many CKD patients have a relative, rather than absolute, erythropoietin deficiency in that plasma levels exceed the normal range.[35] However, when compared with equivalently anemic but nonuremic patients, plasma erythropoietin concentrations are lower. Anemic CKD cats have been reported to have plasma erythropoietin concentrations similar to normal cats.[36] Erythropoietin deficiency of CKD has been hypothesized to result from decreased renal mass resulting in an insufficient cellular capacity for new hormone synthesis.

Other clinically important causes for anemia in dogs and cats with CKD are iron deficiency and chronic GI blood loss. In most patients, iron deficiency can only be detected by measuring serum iron, staining bone marrow biopsy samples for iron content, or through response to iron supplementation. Chronic GI hemorrhage may occur even in the absence of characteristic color changes in the feces. It can be suspected based on a hematocrit level that is unexpectedly low relative to the magnitude of renal dysfunction, and an elevation in the SUN/serum creatinine ratio.

260.2.6.2

Hemorrhagic Consequences of Uremia

Uremia may be associated with a hemorrhagic diathesis that is characterized by bruising, GI hemorrhage with hematemesis or melena, bleeding from the gums, or hemorrhage subsequent to venipuncture. GI hemorrhage can be an important route of blood loss leading to anemia and exacerbating azotemia and uremia. In renal failure, bleeding results from an acquired qualitative platelet defect, abnormalities in the interaction of platelets and the vessel wall, and biochemical and rheologic abnormalities in the blood itself.[37] Uremic platelet dysfunction appears to be multifactorial in origin. The platelet count is usually within the normal range or mildly decreased. Abnormal platelet aggregability, diminished thromboxane-A_2 production, abnormal intracellular calcium mobilization, and increased intracellular cAMP have been described in uremic platelets.[37] Abnormal glycoprotein function may impair platelet adhesiveness to the subendothelium. In addition, uremia may be associated with increased release of prostacyclin and nitric oxide, which may also impair adhesion of platelets to the endothelium. The largest polymers of von Willebrand's factor, which predominate in the platelet adhesion process, are decreased in uremia. Uremic toxins have also been implicated in impairing platelet function. For example, elevated levels of plasma guanidinosuccinic acid, interfere with activation of platelet factor III by ADP, thus leading to abnormal platelet function. Administration of desmopressin acetate (DDAVP) has been shown to shorten bleeding times and improve clinical bleeding in uremic humans.[37] DDAVP is thought to stimulate release of large multimeric von Willebrand's factor complexes from endothelial cells and platelets.

Unfortunately, development of tachyphylaxis often limits usefulness of DDAVP after 2 or 3 doses. Alternative therapies have included administration of cryoprecipitates or conjugated estrogens, which may have similar effects. Increasing hematocrit values to above 30 by transfusion or administration of

erythropoietin has also been shown to improve bleeding times in humans. Increasing hematocrit may improve bleeding times by a rheologic effect or by increasing hemoglobin concentrations that may in turn inactivate the platelet-inhibiting effects of nitric oxide. 1766 1767

260.2.7 Renal Secondary Hyperparathyroidism

260.2.7.1 Incidence and Pathophysiology

In a recent study of cats with spontaneous CKD, the overall prevalence of renal secondary hyperparathyroidism was 84%.[38] Hyperparathyroidism occurred in 100% of cats with end-stage CKD and 47% of asymptomatic cats with only biochemical evidence of CKD. Hyperparathyroidism was even detected in some cats with normal serum calcium and phosphorous concentrations. Plasma PTH concentrations have been reported to increase as serum creatinine concentrations increase.[39]

The pathogenesis of hyperparathyroidism in CKD is multifactorial. Renal secondary hyperparathyroidism occurs in association with phosphorous retention, hyperphosphatemia, low circulating 1,25-dihydroxyvitamin D (calcitriol) levels, reduced blood ionized calcium concentration, and skeletal resistance to the calcemic action of PTH. However, in early to moderate renal failure, it is difficult to dissect out the specific factors responsible for hyperparathyroidism because the increase in PTH serves to prevent hypocalcemia, hyperphosphatemia, and the decrease in calcitriol formation.[40] Phosphorous retention and hyperparathyroidism develop early in CKD, although serum calcium and phosphorus concentrations remain within normal limits.[41] Phosphorous retention is intimately related to development of secondary hyperparathyroidism.[42,43]

Relative or absolute deficiency of calcitriol has been hypothesized to play a pivotal role in development of renal secondary hyperparathyroidism.[44] Calcitriol, the most active form of vitamin D, is formed by 1α-hydroxylation of 25-hydroxycholecalciferol in renal tubular cells. PTH promotes renal 1α-hydroxylase activity and formation of calcitriol. In turn, calcitriol limits PTH synthesis by feedback inhibition. Phosphrous retention inhibits renal 1α-hydroxylase activity. Early in the course of CKD, the inhibitory effects of phosphorus retention on renal tubular 1α-hydroxylase activity limits calcitriol production. Because calcitriol normally inhibits PTH synthesis, reduced calcitriol synthesis promotes renal secondary hyperparathyroidism. Initially, the resultant hyperparathyroidism increases 1α-hydroxylase activity despite continued phosphorous retention, thereby restoring calcitriol production toward normal. However, normalization of calcitriol production occurs at the expense of persistently elevated plasma PTH activities—a classic example of the *trade-off hypothesis*. As renal failure progresses, loss of viable renal tubular cells ultimately limits renal calcitriol synthetic capacity and calcitriol levels subsequently remain low. Deficiency of calcitriol leads to skeletal resistance to the action of PTH and elevates the set point for calcium-induced suppression of PTH secretion. Skeletal resistance to PTH limits skeletal release of calcium, whereas elevating the setpoint for PTH secretion allows hyperparathyroidism to persist even when plasma ionized calcium concentrations are normal or elevated.[39,44]

Recent evidence suggests that phosphorous retention may also play a primary role in promoting hyperparathyroidism. Phosphorous has been shown to stimulate PTH secretion in parathyroid cell cultures.[45] Further, phosphorous restriction in dogs and humans with CKD has been shown to decrease PTH secretion without changing serum calcitriol levels.[46,47] In untreated human patients with mild to moderate CKD (serum creatinine concentration ≤3.0 mg/dL), serum phosphorus concentrations correlated

directly with PTH, independent of serum calcium and 1,25-dihydroxyvitamin D levels.[48] Interestingly, this correlation was present despite the fact that most patients had serum phosphorous concentrations within the normal range. Notably, in both humans and cats, overt hyperphosphatemia may not be a prerequisite for phosphorous to have an effect on PTH secretion.[38,48] It has been suggested that high phosphorous intake may accentuate uremia-induced abnormal phosphorous metabolism causing increased parathyroid cell phosphorous concentration.[48] *In vitro* studies have suggested that parathyroid glands exposed to elevated phosphorous levels respond by increasing PTH secretion.[45] Reduced 1,25-dihydroxycholecalciferol may have a permissive effect, may have an additional direct effect on PTH secretion in this setting, or it may have both.[48]

In more advanced renal failure, only serum calcium concentration correlated with serum PTH activity.[48] Impaired intestinal absorption of calcium due to low serum calcitriol levels likely plays an important role in hyperparathyroidism in these advanced renal failure patients. Blood ionized calcium concentrations are often reduced in cats with spontaneous CRF; in one study, over 50% of cats with advanced end-stage CKD were hypocalcemic.[38]

260.2.7.2

Clinical Consequences

Although renal secondary hyperparathyroidism and renal osteodystrophy, are well-documented effects of CKD, clinical signs associated with renal osteodystrophy are uncommon in dogs and cats. In dogs, it most often occurs in immature patients, presumably because metabolically active growing bone is more susceptible to the adverse effects of hyperparathyroidism. For unexplained reasons, bones of the skull and mandible may be the most severely affected and may become so demineralized that the teeth become moveable and fibrous changes are obvious, particularly in the maxilla. Marked proliferation of connective tissue associated with the maxilla may cause distortion of the face. Jaw fractures can occur but are uncommon. Other possible but uncommon clinical manifestations of severe renal osteodystrophy include, cystic bone lesions, bone pain, and growth retardation.

Although excessive levels of PTH affect bones and kidneys, it affects the function of other organs and tissues, including brain, heart, smooth muscles, lungs, erythrocytes, lymphocytes, pancreas, adrenal glands, and testes as well.[49] Toxicity of PTH appears to be mediated through enhanced entry of calcium into cells with PTH or PTH2 membrane receptors. Sustained PTH-mediated calcium entry leads to inhibition of mitochondrial oxidation and production of ATP. Extrusion of calcium from cells is reduced because of the impairment in ATP production and disruption of the sodium-calcium exchanger. Persistently increased basal cytosolic calcium levels promote cellular dysfunction and death.[39]

Potential nonskeletal clinical consequences of hyperparathyroidism include mental dullness and lethargy, weakness, anorexia, and an increased incidence of infections due to immunodeficiency.[39] Hyperparathyroid-induced cellular dysfunction may lead to carbohydrate intolerance, platelet dysfunction, impaired cardiac and skeletal muscle function (due to impaired mitochondrial energy metabolism and myofiber mineralization), inhibition of erythropoiesis, altered red cell osmotic resistance, altered B cell proliferation, synaptosome and T cell dysfunction, and defects in fatty acid metabolism.[39,50] Excess PTH levels may also promote nephrocalcinosis and consequent progressive loss of renal function.[39]

Renal secondary hyperparathyroidism may be associated with substantial enlargement of the parathyroid glands. This finding may be of clinical importance in cats because of frequent coincident hyperthyroidism

that may be suggested by the presence of a thyroid nodule palpable in the cervical region. In a recent report, hyperplastic parathyroid glands were palpable as paratracheal masses in 11 of 80 cats with spontaneous CKD.[2] Care should be taken to confirm hyperthyroidism prior to treatment because both hyperparathyroidism and hyperthyroidism can lead to paratracheal masses.

1767

1768

Plasma PTH concentrations should be determined by methods that measure intact PTH using a two-site immunoradiometric or immunochemiluminometric assay. The two-site method uses antibodies directed against two different regions of the intact PTH molecule. A commercially available two-site immunoradiometric assay (Allegro Intact PTH, Nichols Institute Diagnostics, San Juan Capistrano, CA) has been validated for use in dogs and cats. Only intact PTH will be recognized because it will be the only form of the peptide to have both determinants. Older PTH assays typically detect those species of hormone that contain amino acids located in the midregion (43 to 68) of the PTH molecule.

However, because renal insufficiency and failure results in reduced renal clearance of the nonbiologically active midregion PTH fragments, these methods do not accurately reflect parathyroid glandular secretion. Thus renal secondary hyperparathyroidism is best monitored by use of a two-site assay for intact hormone.

260.2.8 Laboratory Findings

260.2.8.1 Metabolic Acidosis

Metabolic acidosis is a common manifestation of CKD. It results primarily from the limited ability of failing kidneys to excrete hydrogen ions, because of reduced ammoniagenesis, decreased filtration of phosphate and sulfate compounds, and decreased maximal renal tubular proton secretion.[51] Impaired renal tubular reabsorption of filtered bicarbonate may also contribute to acidosis. Bicarbonate wasting and chloride retention results in hyperchloremic (normal anion gap) acidosis. When phosphorous and organic acid (uric acid, hippuric acid, lactic acid) retention is sufficient, high anion gap acidosis results.

A combination of tubular reabsorption of filtered bicarbonate and excretion of hydrogen ions with ammonia and urinary buffers, primarily phosphorous, maintains normal acid-base balance. As renal function declines, hydrogen ion excretion is maintained largely by increasing the quantity of ammonium excreted by surviving nephrons. However, at some level of renal dysfunction, the capacity to further increase renal ammoniagenesis is lost and metabolic acidosis ensues. Decreased medullary recycling of ammonia due to structural renal damage may also contribute to impaired ammonium excretion.

Chronic metabolic acidosis may promote a variety of adverse clinical effects including anorexia, nausea, vomiting, lethargy, weakness, muscle wasting, weight loss, and malnutrition. Alkalization therapy is often of value in reversing these signs. In addition, chronic mineral acid feeding to dogs has been shown to increase urinary calcium excretion and progressive bone demineralization, the magnitude of which depends on age and dietary calcium levels. Studies on the effects of dietary acidification in cats have revealed that chronic metabolic acidosis can cause negative calcium balance and bone demineralization or negative potassium balance, which may in turn promote hypokalemia, renal dysfunction, and taurine depletion.[52]

Severe acidemia may result in decreased cardiac output, arterial pressure, and hepatic and renal blood flows and centralization of blood volume.[53] Centralization of blood volume results from peripheral arterial vasodilatation and central venoconstriction. Decreases in central and pulmonary vascular compliance may predispose patients to pulmonary edema during fluid administration, an effect that may be particularly

important in patients with acute uremic crises requiring intensive fluid therapy. Acidemia also promotes re-entry arrhythmias and a reduction in the threshold for ventricular fibrillation. Severe acidosis may also influence carbohydrate and protein metabolism, serum potassium concentrations, and brain metabolism.

Chronic acidosis may promote protein malnutrition in patients with CKD. Protein catabolism is increased in patients with acidosis to provide a source of nitrogen for hepatic glutamine synthesis, glutamine being the substrate for renal ammoniagenesis.[54] The combined effects of reduced protein synthesis due to uremia and accelerated proteolysis due to acidosis promote elevations in blood urea nitrogen (BUN), increased nitrogen excretion, and negative nitrogen balance typical of uremic acidosis. Altered branched chain amino acid metabolism appears to be involved. Chronic metabolic acidosis increases the activity of muscle branched chain keto acid dehydrogenase, the rate-limiting enzyme in branched chain amino acid catabolism. This is important in that branched chain amino acids are rate limiting in protein synthesis and play a role in regulation of protein turnover. Alkalization therapy effectively reverses acidosis-associated protein breakdown. Clinicians speculate that changes in intracellular pH accompanying acidosis lead to alterations in gene transcription which increase the activity of the cytosolic, ATP-and ubiquitin-dependent protein degradation pathway. Severe chronic metabolic acidosis has the potential to induce a cycle of progressive protein malnutrition and metabolic acidosis. Excessive protein catabolism may lead to protein malnutrition despite adequate dietary intake. This process may then accelerate breakdown of endogenous cationic and sulfur-containing amino acids, thus promoting further acidosis.

Acidosis poses a particularly vexing problem for CKD patients consuming protein-restricted diets. Dietary protein requirements appear to be similar for normal humans and humans with CKD unless uremic acidosis is present. When acid-base status is normal, adaptive reductions in skeletal muscle protein degradation protect patients consuming low-protein diets from losses in lean body mass. Metabolic acidosis blocks the metabolic responses to dietary protein restriction in two ways: (1) it stimulates irreversible degradation of the essential, branched chain amino acids; and (2) it stimulates degradation of protein in muscle.[54] Thus acidosis may limit the ability of patients to adapt to dietary protein restriction. Metabolic acidosis also suppresses albumin synthesis in humans and may reduce the concentration of serum albumin. These findings have not yet been confirmed in dogs and cats.

260.2.8.2 Azotemia

Azotemia is defined as an excess of urea or other nonprotein nitrogenous compounds in the blood. Loss of renal function leads to accumulation of a wide variety of nonprotein nitrogen-containing compounds, including urea and creatinine. Many waste products of protein catabolism are excreted primarily by glomerular filtration. Thus patients with primary renal failure have impaired ability to excrete proteinaceous catabolites because of marked reduction in GFR. Retention of metabolic waste may be further aggravated by impaired tubular secretion, and by extrarenal factors that promote renal hypoperfusion and increased catabolism of body tissues. Although accumulation of wastes is largely the result of decreased renal excretion or increased protein catabolism, production of some compounds may also be increased (e.g., guanidine). Because these compounds are derived almost entirely from protein degradation, their production increases when dietary protein increases.

Urea is synthesized using nitrogen derived from amino acid catabolism. Urea may be excreted by the kidneys, retained in body water, or metabolized to ammonia plus carbon dioxide by bacteria in the GI tract. Ammonia produced in the GI tract is recycled to urea in the liver yielding no net loss of nitrogen or urea. Regardless of whether urea per se is toxic, BUN concentrations are typically directly related to the protein content of the diet. Further, in patients with renal failure, BUN concentrations tend to correlate reasonably

well with clinical signs of uremia. For practical purposes, BUN may thus be viewed as a marker of retained *uremic toxins*.

In addition to increasing protein intake and declining renal function, BUN concentrations may also be increased by GI hemorrhage, enhanced protein catabolism, decreasing urine volumes (due to prerenal factors such as dehydration), and certain drugs (e.g., glucocorticoids). Urea nitrogen concentrations may decline with portosystemic shunts, hepatic failure, and low protein diets. Reduced BUN concentration may also indicate protein calorie malnutrition. Because many extrarenal factors may influence BUN concentration, creatinine is often used as a more reliable measure of GFR in patients with CKD. 1768 1769

BUN concentrations should be interpreted with knowledge of simultaneously obtained serum creatinine values, particularly in patients consuming reduced protein diets. The ratio of BUN/serum creatinine concentration should decline when dietary protein intake is reduced. In patients consuming reduced protein diets, an increase in the ratio of BUN/serum creatinine concentrations may suggest poor dietary compliance, enhanced protein catabolism, GI hemorrhage, dehydration, anorexia or declining muscle mass.

260.2.8.3 Hyperphosphatemia

The kidneys play a pivotal role in regulating phosphorus balance because they are the primary route of phosphorus excretion. Renal phosphorus excretion is the net of glomerular filtration less tubular reabsorption of phosphorus. If dietary phosphorus intake remains constant, a decline in GFR will lead to phosphorus retention and ultimately hyperphosphatemia. However, during the early stages of renal failure, serum phosphorus concentrations typically remain within the normal range because of a compensatory decrease in phosphorous reabsorption in the surviving nephrons. This renal tubular adaptation is largely an effect of renal secondary hyperparathyroidism. Increased PTH levels promote renal excretion of phosphorous by reducing the tubular transport maximum for phosphorous reabsorption in the proximal tubule via the adenyl cyclase system. When GFRs decline below about 20% of normal, this adaptive effect is no longer is able to prevent hyperphosphatemia.

In dogs with CKD, serum phosphorus concentrations typically parallel SUN concentrations. Thus hyperphosphatemia is common in azotemic patients but unexpected in patients with nonazotemic renal disease. The primary consequence of hyperphosphatemia is development and progression of secondary hyperparathyroidism. Increases in serum PTH activities in dogs and humans with CKD are closely associated with the degree of hyperphosphatemia.[39,48] Hyperphosphatemia was found to be 72% efficient in predicting hyperparathyroidism in cats with CKD.[38]

The combination of hyperphosphatemia and a normal plasma calcium concentration produces an elevated calcium-phosphate product ($Ca \times PO_4$ in units of mg/dL). If the calcium-phosphate product exceeds approximately 70, a tendency exists for calcium phosphate to precipitate in arteries, joints, and soft tissues. This process is commonly called *metastatic calcification*. Calcification is especially prominent in proton-secreting organs, such as the stomach and kidneys, in which basolateral bicarbonate secretion results in an increase in pH that promotes calcium hydrogen phosphate (brushite) precipitation.[55] However, myocardium, lung, and liver are also commonly mineralized in patients with CKD.

Hyperphosphatemia has been directly linked to increased mortality in humans and dogs with CKD.[56,57] In humans with CKD receiving hemodialysis therapy, the adjusted relative risk of mortality was stable in patients with serum phosphorous concentrations below 6.5 mg/dL, but increased significantly above this

level.[56] Patients with serum phosphorous in the 6.6 to 7.8 mg/dL range had 13% higher mortality than patients in the reference range (4.6 to 5.5 mg/dL). Patients in the 7.9 to 16.9 mg/dL range had a relative mortality risk 34% higher than patients in the reference range. Mild hyperphosphatemia (5.0 to 6.5 mg/dL) was not associated with an elevated mortality risk.

The calcium × phosphorous product showed a mortality risk trend similar to that seen for phosphate with patients with Ca × PO_4 products greater than 72 having a relative mortality risk of 1.34 relative to products between 42 and 52 mg^2/dL^2.[56] Mortality risk associated with hyperphosphatemia appeared to be independent of elevated PTH levels, which alone appeared to have only a weak association with mortality. However, the statistical association between PTH and mortality may have been impaired by use of multiple methods for PTH assay in the patients studied. Analysis of calcium revealed no correlation with relative risk of death.[2]

260.2.8.4 Hypercalcemia, Hypocalcemia, and Hypermagnesemia

Hypocalcemia is a common disorder of calcium found in patients with renal failure. In a recent report, ionized hypercalcemia was detected in 6% and ionized hypocalcemia in 26% of 80 cats with spontaneous CKD.[38] Further, mean blood ionized calcium concentration was significantly lower in CKD cats in this study than in normal control cats, and over half of the cats with advanced end-stage CKD were hypocalcemic. However, when these same 80 cats were evaluated using total serum calcium concentrations, hypercalcemia was found in 21% of the cats, whereas hypocalcemia was detected in only 8%. Clearly, serum total calcium concentrations do not reliably reflect ionized calcium concentrations in cats with CKD. Similar discrepancies have been observed in dogs with CKD.[58] The mechanism of serum total hypercalcemia in the face of normal to reduced blood ionized calcium concentrations is unclear but may be related to increased concentrations of calcium complexed to retained organic and inorganic anions such as citrate, phosphate, or sulfate.

In patients with hypercalcemia, it is important to ascertain whether hypercalcemia is the cause, rather than result of CKD. Hypercalcemia due to malignancy or hypervitaminosis D is most likely to induce renal failure. One way of discriminating the cause-and-effect relationship between hypercalcemia and renal failure is to determine the patient's blood ionized calcium concentration. Only ionized hypercalcemia promotes renal failure. However, true ionized hypercalcemia may occur in patients with CKD as a consequence of excessive doses of calcitriol or calcium-containing intestinal phosphate-binding agents or in patients with severe renal secondary hyperparathyroidism with marked hyperplasia of the parathyroid glands. The authors have also observed small increases in ionized calcium concentrations in dogs with early to moderate CKD that are not receiving calcitriol or calcium therapy and do not have advanced hyperparathyroidism. The mechanism of ionized hypercalcemia in these dogs is unclear.

Hypermagnesemia is common in CKD because the kidneys are primarily responsible for magnesium excretion.[38] Typically in CKD, the protein binding of magnesium is normal, complexed magnesium is usually increased, and ionized magnesium may be increased, normal, or decreased. Although the homeostatic mechanisms involved in the control of magnesium are not well documented, they appear to rely on the bone, gut, and kidney, as found with calcium and phosphorous control.

260.2.8.5 Hypokalemia

An association between CKD and hypokalemia has been recognized in cats by several investigators.[59,60] In contrast, hypokalemia appears to be an uncommon finding in untreated dogs with CKD, occurring primarily as an iatrogenic complication of fluid therapy in this species. A particularly intriguing concept is that hypokalemia may be a cause of CKD in cats, rather than simply a consequence of it. In a recent uncontrolled study of the long-term effects of feeding a potassium-restricted, acidifying diet, evidence of renal dysfunction developed in three of 9 cats; renal lesions consisting of lymphoplasmacytic interstitial nephritis and interstitial fibrosis were observed in five of the 9 cats.[60] However, it is not clear whether potassium depletion or hypokalemia preceded the onset of renal failure. In another study, four of seven cats with induced CKD fed a diet containing 0.3% potassium developed hypokalemia, whereas four cats with normal renal function fed the same diet did not develop hypokalemia.[61] Interestingly, muscle potassium content decreased in normokalemic cats with spontaneous CKD, indicating that a total-body deficit of potassium may develop well before the onset of hypokalemia.[62] These findings support the concept that reduced renal function precedes development of hypokalemia.

1769

1770

The mechanism of hypokalemia in cats with CKD has remained elusive, but inadequate intake and increased renal losses appear to be likely candidates. Inadequate intake of potassium could reflect decreased appetite or insufficient dietary potassium content. Dietary risk factors for hypokalemia include acidifying ingredients, reduced magnesium content, and high protein content. It has yet to be established that renal potassium wasting occurs in cats with CKD.

Normally the kidneys closely regulate potassium. Although large quantities of K+ appear in glomerular filtrate, essentially all is reabsorbed before reaching the distal tubules. The majority of potassium appears in urine as a result of potassium secretion from tubular cells into the lumen in the distal nephron. Potassium excretion in these segments of the nephron is sensitive to tubular flow rates; rapid urine formation promotes potassium secretion, whereas slow urine formation limits potassium secretion. Distal potassium secretion is modulated by potassium reabsorption by the intercalated cells in the cortical and outer medullary collecting tubules. Thus in potassium depletion, net potassium absorption rather than secretion may occur in the distal nephron.

In patients with CKD, the residual nephrons maintain potassium balance by increasing distal tubular secretion of potassium. GI secretion of potassium (primarily in the colon) also appears to increase in CKD and may play an important role in modulating potassium balance. Because of these adaptations, most dogs and cats with CKD are able to tolerate normal dietary potassium intake (about 0.6% dry matter) until renal dysfunction is very severe. However, the ability to rapidly excrete a potassium load may be impaired in CKD resulting in transient hyperkalemia.

Although hypokalemia continues to be detected with some regularity in cats with CKD, its neuromuscular manifestations are uncommon. Presumably this change is the result of an increase in the potassium content of feline diets that has occurred over the past decade in response to the problem of hypokalemia in cats with CKD.

Although generalized muscle weakness has been described as the cardinal sign of hypokalemia, decreased renal function and anorexia are probably more common manifestations of hypokalemia in cats with CKD. In many cats with CKD and hypokalemia, renal function improves after potassium supplementation and restoration of normokalemia, suggesting that hypokalemia may induce a reversible, functional decline in

GFR. Recently, renal function was shown to be adversely affected in normal cats when an acidified, potassium-restricted diet was fed.[63] Potassium depletion and acidosis appeared to have additive effects in impairing renal function in this study. Based on these results, it was hypothesized that in cats with CKD, a self-perpetuating cycle of excessive urinary potassium losses and whole-body potassium depletion may develop that is likely to further decrease in renal function. Feeding acidified diets or dietary acidifiers to cats with CKD was suggested to exacerbate their tendency develop potassium depletion.

Potassium imbalances may disrupt a variety of cell functions. Hypokalemia-impaired protein synthesis has been hypothesized to promote weight loss and poor hair coat.[33] Marked potassium depletion has also been linked to polyuria resulting from decreased renal responsiveness to ADH. This antagonism to ADH appears to be due to interference with generation and action of cyclic AMP and to impairment of the countercurrent mechanism. Locally generated prostaglandins may mediate at least part of this effect.

260.2.9 Progression of Chronic Kidney Disease

A progressive decline in kidney function typically occurs over months to years in dogs and cats with naturally occurring kidney diseases.[64] It is logical to assume that CKD progresses as a consequence of continuing renal damage induced by the disease process that initiated CRF. Although this assumption may be at least partially correct for some patients, the initiating cause cannot be identified at the time of diagnosis of CKD in most patients. Instead, renal lesions observed in progressive nephropathies of diverse origins typically include focal segmental glomerulosclerosis and tubulointerstitial lesions (including tubular dilation and interstitial inflammation and fibrosis). Glomerular lesions accompanied by varying levels of proteinuria are typical of progressive kidney diseases including primary tubulointerstitial diseases. In humans, both the decline in GFR and long-term prognosis are more closely related to the extent of associated tubulointerstitial lesions than glomerular lesions.[65]

In rodents, loss of a critical mass of functional renal tissue invariably leads to failure of the remaining nephrons, suggesting that CKD may progress through mechanisms independent of the initiating cause.[66] For example, removal of approximately three quarters or more of the nephrons in rats by surgical resection, infarction, or a combination of these techniques, results in a syndrome of progressive azotemia, proteinuria, arterial hypertension, and eventually death due to uremia. Lesions that develop in the remaining kidney remnant include focal segmental glomerulosclerosis and tubulointerstitial lesions, including tubular dilation and interstitial inflammation and fibrosis. Progressive renal injury and loss of renal function occurs in this rodent model of kidney failure, despite the fact that the remaining kidney remnant was initially normal.

Numerous studies have been performed in an attempt to determine if findings obtained in partially nephrectomized rodents are relevant in dogs and cats. Reducing renal mass in dogs and cats resulted in mild proteinuria, glomerulopathy, and tubulointerstitial renal lesions.[61,67,68] Although these findings are consistent with observations in rats, reducing renal mass by seven eighths or less did not consistently result in a progressive decline in GFR. In studies performed at the University of Georgia, progressive decline in GFR was detected in dogs in which renal mass had been reduced by fifteen sixteenths.[57] These findings confirm that progressive renal disease develops in dogs; however, a marked reduction in renal mass may be necessary to initiate this process in an otherwise normal remnant kidney.

The preponderance of clinical and experimental evidence suggests that in dogs and cats with stages 3 and 4 CKD, progression of renal disease may result, at least in part, from factors unrelated to the activity of the

inciting disease.[4,69,70] These factors may include intraglomerular hypertension, glomerular hypertrophy, hypertension, proteinuria, tubulointerstitial disease, and intrarenal precipitation of calcium phosphate.

260.2.9.1 Intraglomerular Hypertension and Glomerular Hypertrophy

Long-term elevations in intraglomerular pressure, resulting from transmission of systemic pressures, glomerular hemodynamic processes, or both, appear to be deleterious over time. Intraglomerular hypertension, with consequent glomerular hyperfiltration, occur as a compensatory event designed to maintain the total GFR as nephrons are lost to disease. In glomerular diseases, intraglomerular hypertension may also occur as a compensatory adaptation to reduction in permeability of the glomerular capillary wall 1770
to small solutes and water. In this setting, the fall in GFR is minimized by elevating intraglomerular 1771
pressure. Primary renal vasodilatation may occur in some diseases such as diabetes mellitus. A compensatory increase in glomerular size may also occur in all of these settings.

The mechanisms by which intraglomerular hypertension and hypertrophy injure glomeruli are incompletely understood, because multiple factors are involved. Intraglomerular hypertension may directly injure endothelial cells of the glomerular capillaries. In addition, increased glomerular diameter and increased capillary wall stress may cause detachment of glomerular epithelial cells from the glomerular capillary walls. The consequent focal areas of denudation permit increased flux of water and solutes through the glomerular capillary wall. However, macromolecules cannot cross the glomerular basement membrane and are trapped in the subendothelial space.

The result is formation of characteristic *hyaline deposits* in glomeruli that progressively narrow the capillary lumens, thereby decreasing glomerular perfusion and filtration. Increased strain on mesangial cells can stimulate them to produce cytokines and extracellular matrix. The release of cytokines, such as transforming growth factor-β (TGF-β) and platelet-derived growth factor, may mediate the rise in matrix synthesis.[71] The consequent expansion of mesangial matrix further encroaches on the capillary surface area.

Although these effects lead to the characteristic glomerular lesions of progressive nephropathies, intraglomerular hypertension also impairs glomerular permselectivity leading to proteinuria. Proteinuria is thought to be an important pathophysiologic link between glomerular injury, tubulointerstitial injury, and progression of renal disease.

260.2.9.2 Systemic Hypertension

In humans, the association between systemic hypertension and kidney disease is well established. The Multiple Risk Factor Intervention Trial (MRFIT) identified systemic hypertension as a significant risk factor for development of end-stage kidney disease.[72] A similar association has recently been identified in dogs.[18] Further, in the Modification of Diet in Renal Disease (MDRD) study, the level of systemic blood pressure was linked to progression of kidney disease among black and proteinuric human CKD patients.[73]

Systemic hypertension leads to progression of kidney disease, at least in part, through unopposed transmission of systemic hypertension to the glomerular capillary bed resulting in glomerular injury. This event occurs particularly in patients with CKD because autoregulation of blood flow, which normally protects glomerular capillaries from excessive pressure, is impaired. Studies in dogs and cats have confirmed that reduced kidney function is associated with an adaptive preglomerular vasodilatation that permits transmission of systemic hypertension to the glomerular capillaries.[70,74]

260.2.9.3 Proteinuria

Proteinuria itself may contribute to progressive renal injury.[20] Proteinuria is a strong, independent risk factor for progression to end-stage CKD in humans.[75] Studies performed at the University of Minnesota Veterinary Medical Center have shown proteinuria to be a risk factor for uremia and death in dogs with naturally occurring CKD. Proteinuria has also been reported to be related to progression of renal disease in dogs with induced renal failure.[69] A relationship between proteinuria and progression of renal disease has not yet been established in cats. Proteinuria may promote progressive renal injury in several ways. Some proposed mechanisms include mesangial toxicity, tubular overload and hyperplasia, toxicity from specific proteins such as transferrin containing iron, and induction of proinflammatory molecules such as monocyte chemoattractant protein-1. Excessive proteinuria may injure renal tubules via toxic or receptor-mediated pathways or via an overload of lysosomal degradative mechanisms. Abnormally filtered proteins accumulate in the renal proximal tubular lumens where, after endocytosis into proximal tubular cells, they contribute to renal tubulointerstitial injury through a complex cascade of intracellular events. These events include up-regulation of vasoactive and inflammatory genes such as the endothelin-1 (ET-1) gene, the monocyte chemoattractant protein-1 (MCP-1) gene, which encodes for an inflammatory peptide involved in macrophage and T-lymphocyte recruitment, and the RANTES (regulated on activation, normal T cell expressed and secreted) that encodes for a chemotactic molecule for monocytes and memory T cells.[76] Formed in excessive amounts, these molecules are secreted toward the basolateral side of tubular cells and incite an inflammatory reaction. In addition, complement components escaping through glomerular capillary walls may initiate interstitial injury. Small lipids bound to filtered proteins may also be liberated during resorption. Inflammatory or chemotactic properties of these lipids may promote tubulointerstitial disease. Finally, inspissation of filtered proteins due to tubular reabsorption of water in the distal nephron may lead to formation of casts that obstruct nephrons.

260.2.9.4 Tubulointerstitial Disease in Glomerulopathies

In humans, primary glomerular diseases are typically associated with varying degrees of tubulointerstitial lesions. Remarkably, it is the intensity of the accompanying or evolving injury in the tubulointerstitium, rather than injury in glomeruli, that is the most reliable overall predictor of decline in renal function.[77] In contrast, primary tubulointerstitial diseases as a group are the more indolent and slowly progressive of all human nephritides. Although the etiopathogenesis of canine and feline nephropathies is often uncertain, current evidence suggests that a substantial portion of canine CKD results from primary glomerulopathies, whereas the majority of feline CKD appears to be of tubulointerstitial origin.[11,78] The indolent course of CKD commonly observed in cats may be related to the tubulointerstitial origin of their disease, whereas many dogs experience a more aggressive decline in renal function, perhaps as a consequence of the glomerular origin of their primary renal disease.

Glomerular diseases have the capacity to incite tubulointerstitial disease. Although the mechanisms underlying the development of tubulointerstitial disease in this setting are not incompletely understood, multiple factors have been hypothesized to contribute.[77] As described previously, proteinuria is an important factor.[79] Additional factors include tubular ischemia related to decreased postglomerular blood flow; loss of tolerance with subsequent tubulointerstitial damage secondary to immune mechanisms of glomerular injury; seeping of inflammatory mediators from inflamed glomeruli; renal deposition of calcium phosphate; and enhanced tubular ammoniagenesis leading to complement-mediated injury of the

tubulointerstitium.[77] Evidence indicates that an active immunologic process may be involved in the tubulointerstitium of patients with glomerulonephritidies beginning early in the course of disease. In some instances this process appears to represent an extension of the inflammation in glomeruli.[77] In some models of renal disease, corticosteroids or other immunosuppressive therapy can ameliorate the tubulointerstitial damage without effect on glomeruli.[80]

260.2.9.5 Intrarenal Precipitation of Calcium Phosphate

Phosphate retention begins early in the course of CKD and has been implicated in promoting progressive renal injury in several species, including dogs and cats.[57,70,81] A role for phosphorus in promoting progressive CKD is based on the observation that dietary phosphorus restriction limited renal-related mortality in dogs and renal mineralization in cats. Phosphorus may promote progression of CKD, at least in part, by precipitation with calcium in the renal interstitium. This renal mineralization may then initiate an inflammatory reaction, resulting in renal interstitial fibrosis and tubular atrophy.

1771

1772

260.2.9.6 Other Factors

260.2.9.6.1 Lipids and progression

Experimental studies in rodents indicate that hyperlipidemia may promote progression of renal disease.[82] This association is based on the observation that cholesterol loading enhanced glomerular injury, whereas reducing lipid levels with drugs such as lovastatin slowed the rate of progressive injury. Factors responsible for these effects are incompletely understood. Exposing glomerular and tubular cells to low-density lipoprotein and its oxidized variant stimulates their proliferation, induces injury and apoptosis, and stimulates them to produce extracellular matrix contributing to fibrosis.[19] An additive effect of hyperlipidemia and proteinuria has been described in humans with CKD.[83] Although hypercholesterolemia is common in dogs and cats with CKD, the clinical applicability of these findings in other species is unclear. Evidence that lipid reduction is beneficial in humans with CKD is conflicting. However, a meta-analysis of 13 prospective controlled studies indicated that lipid reduction was associated with a lower rate of decline in kidney function and decreased proteinuria.[84]

260.2.9.6.2 Metabolic acidosis

Metabolic acidosis has been theorized to enhance progression of renal failure by activation of the alternative complement pathway as a result of enhanced renal ammoniagenesis.[77] In human patients with CKD, reducing renal ammoniagenesis and renal tubular peptide catabolism was accompanied either by reduced renal tubular injury or by tubular hyperfunction. However, recent studies in rats have failed to confirm a role for acidemia and enhanced renal ammoniagenesis in renal injury and progression of renal failure.[85] Longer-term studies have suggested that effects initially attributed to enhanced renal ammoniagenesis may have been transient or related to the timing of therapeutic intervention in the previous study. These researchers concluded that metabolic acidosis neither causes nor exacerbates chronic renal injury. Further, the renal protective effect of alkali therapy is unproven in humans with CKD. Studies performed by the authors in cats with induced CKD have likewise failed to identify an adverse effect of chronic acidosis on renal structure or function.

260.2.9.6.3 Chronic hypoxia

It has been hypothesized that chronic oxygen deprivation to the tubulointerstitial compartment contributes to scarring in the tubulointerstitium.[86] Chronic hypoxia is thought to result from compromise of blood flow to the interstitial capillary network downstream from inflamed glomeruli. Concurrently, the peritubular capillary network downstream from other vasodilated glomeruli may be damaged subsequent to transmission of systemic blood pressures to this normally low-pressure capillary network. The resultant tubulointerstitial hypoxia is hypothesized to promote fibrosis by regulating gene expression of a broad spectrum of molecules including growth factors, hormones, vasoactive compounds, and enzymes. For example, *in vitro* studies have indicated that hypoxia is a profibrotic stimulus for tubular epithelial cells, interstitial fibroblasts, and renal microvascular endothelial cells. Hypoxia has been shown to induce a wide variety of growth factors, including many implicated in the pathogenesis of progressive renal disease, such as TGF-β1 and platelet-derived growth factor (PDGF).

The apparent beneficial role for ACE inhibitors in minimizing progressive renal diseases is consistent with the proposed role for chronic hypoxia. In theory, ACE inhibition could protect the kidneys by enhancing interstitial oxygen delivery through dilating the efferent arterioles, reducing vascular resistance, and improving microvascular flow through the interstitium.

260.3 DIAGNOSTIC EVALUATION

Patients with CKD should be evaluated to determine their diagnosis (type of kidney disease), severity, complications, comorbid conditions (concurrent diseases unrelated to CKD), and risk for continued loss of kidney function.[3] Morphologic diagnoses usually require evaluation of kidney biopsy samples. However, renal biopsies are indicated only when the benefits of renal biopsies (e.g., the results are likely to substantially change the prognosis or treatment) outweigh the associated risks.

Severity of CRD is classified based on the level of renal function. Serum creatinine concentration is the most commonly used measure of severity of renal dysfunction and is the basis for staging CKD (see Box 260-2). To optimize accuracy of staging of CRD, serum creatinine concentrations used to stage CRD should be evaluated when the patient is well hydrated. Multiple measurements are desirable to establish accuracy and stability of renal dysfunction. However, renal function may be more accurately measured using plasma clearances of iohexol, inulin, or other substances excreted exclusively by glomerular filtration.[87–91] Plasma clearance studies are indicated in at least three settings. First, they provide an accurate measure of renal dysfunction in stages 1 and 2 patients where serum creatinine determinations may be insensitive.

Second, they provide a basis for dose adjustments for drugs that are potentially toxic and are excreted primarily by the kidneys. Third, they are an excellent means of assessing progression of CKD. Because body muscle mass commonly declines as CKD progresses through stages 3 and 4, endogenous production of creatinine from muscle creatine may decline, confounding interpretation of serial serum creatinine values.

Appropriate management of complications and comorbid conditions may improve patient quality of life, as well as short-term and long-term survival (see Box 260-5). Diagnostics necessary to identify complications and comorbid conditions associated with CKD are outlined in Box 260-6. The prevalence of complications of CKD is mainly related to the level of renal function as reflected in the stage of CKD. CKD is typically characterized by alterations in a variety of kidney functions in addition to impaired GFR. These may include impairment of the (1) filtration barrier for plasma proteins (resulting in albuminuria and proteinuria), (2) reabsorption or secretion of

water or specific solutes, and (3) various endocrine functions (anemia due to erythropoietin deficiency, calcitriol deficiency, and renal secondary hyperparathyroidism). These functional derangements are the basis of most complications of CKD.

Comorbid conditions are concurrent diseases other than CKD. Because patients with CKD are typically middle-aged to older, they often have a substantial number of comorbid conditions. Comorbid conditions of particular frequency and concern for dogs and cats with CKD include UTIs, urolithiasis, urinary obstruction, degenerative joint diseases, dental and other oral diseases, and cardiac disease. In addition, hyperthyroidism and upper urinary tract uroliths are common and important comorbid conditions in cats with CKD. In a survey of 48 cats with CKD, the authors found that 27 had upper urinary tract stones. Comorbid conditions may have an important influence on prognosis and treatment.

The level of kidney function tends to decline over time for most patients with CKD. It is important to assess the risk for loss of kidney function so that therapy may be designed to minimize progressive decline in GFR can be initiated. The risk of progression of kidney disease is affected by diagnosis and by modifiable and nonmodifiable factors. Some of these factors can be assessed even before the decline in GFR (Box 260-7). Therapies designed to slow progression of CKD may be specific for the diagnosis (e.g., antibiotics for bacterial pyelonephritis), whereas others are supportive (e.g., dietary intervention, antihypertensive therapy and angiotensin-converting enzyme [ACE] inhibitors). 1772 1773

260.3.1

Box • 260-6 Problem-Specific Data Base for Patients with Chronic Renal Failure

1. Medical history including medication review
2. Physical examination including retinal examination
3. Urinalysis with urine sediment
4. Quantitative urine culture
5. Complete blood count (CBC)
6. Urine protein/creatinine ratio (if indicated by urinalysis)
7. Serum urea nitrogen (SUN) concentration
8. Serum creatinine concentration
9. Serum (or plasma) electrolyte and acid-base profile including:
    a. Sodium, potassium, and chloride concentrations
    b. Blood gas analysis or total serum CO2 concentrations
    c. Calcium, phosphorus, and albumin concentrations
10. Arterial blood pressure
11. Kidney-bladder-urethra survey radiographs
    a. Kidneys—size, shape, location, number

b. Uroliths or masses affecting kidneys, ureters, or urethra

c. Urinary bladder—size, shape, location, uroliths

12. Clinician should consider:

a. Additional imaging studies as indicated (clinician should rule out urinary obstruction, renal uroliths, pyelonephritis, renal cystic disease, perinephric pseudocysts, and renal neoplasia):

i. Renal ultrasound

ii Intravenous urography

b. Determining glomerular filtration rate (GFR)

i. Plasma clearance of iohexol, inulin, creatinine, or other

ii Classical clearance methods or scintigraphic methods

c. Determining parathyroid hormone (PTH) and ionized calcium levels for managing renal secondary hyperparathyroidism

d. Skeletal radiographs for evidence of renal osteodystrophy, measurement of carbamylated hemoglobin concentration, or parathyroid gland ultrasonography when the distinction between acute and chronic kidney disease (CKD) remains unresolved

e. Renal biopsy

f. Prior to initiating therapy, clinician should consider freezing aliquots of serum (or plasma) and urine for additional diagnostics that may be desired later

260.4 TREATMENT OF CHRONIC KIDNEY DISEASE

260.4.1 Overview of Treatment

Treatment of CKD should generally include specific therapy, prevention and treatment of complications of decreased kidney function, management of comorbid conditions, and therapy designed to slow loss of kidney function.[3] To this end, a clinical action plan should be developed for each patient based on their diagnosis, stage of CKD, existing complications and comorbid conditions, and risk factors for progression of their kidney disease.

260.4.1.1 Box • 260-7 Risk Factors That May Promote Progression of Renal Failure

260.4.1.1.1 Risk Factors for Acute Decline in Renal Function:

Volume depletion

Urinary obstruction

Potentially nephrotoxic drugs:

- Antibiotics
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Angiotensin-converting enzyme (ACE) inhibitors and angiotensin-2 receptor blockers
- Intravenous radiographic contrast agents

260.4.1.1.2 Risk Factors for Long-Term Decline in Renal Function

Active renal disease

Urinary tract infection (UTI)

Nephrolithiasis and ureterolithiasis

Systemic hypertension

Proteinuria

Inappropriate diet

Specific therapy for CKD is based on a renal diagnosis. Treatment is directed at the etiopathogenic processes responsible for the patient's primary renal disease. Because the renal lesions of CKD are irreversible, they cannot be completely reversed or eliminated by specific therapy. Nonetheless, progression of renal lesions may be slowed or stopped by therapy designed to eliminate active renal diseases. Specific therapies are described in the chapters of this text on glomerular diseases, bacterial infections, familial renal diseases, and renal tubular disease. Unfortunately, a renal diagnosis amenable to specific therapy is not obtained for most patients.

Treatment directed at the complications of decreased kidney function is often termed *conservative medical management*. It consists of supportive and symptomatic therapy designed to correct deficits and excesses in fluid, electrolyte, acid-base, endocrine, and nutritional balance thereby minimizing the clinical and pathophysiologic consequences of reduced renal function. Conservative medical management also includes therapy designed to limit the progressive loss of renal function.

The goals of conservative medical management of patients with chronic primary renal failure are to (1) ameliorate clinical signs of uremia; (2) minimize disturbances associated with excesses or losses of electrolytes, vitamins, and minerals; (3) support adequate nutrition by supplying daily protein, calorie, and mineral requirements; and (4) modify progression of renal failure.[92] These goals are best achieved when recommendations regarding conservative medical management are individualized to patient needs based on clinical and laboratory finding. Because CRF is progressive and dynamic, serial clinical and laboratory assessment of the patient and modification of the therapy in response to changes in the patient's condition is an integral part of conservative medical management.

260.4.2 Dietary Therapy

260.4.2.1 Dietary Modifications in Renal Failure

Diet therapy has been a mainstay in the management of canine and feline CKD for decades and it continues to be the most commonly recommended treatment for these patients. In the past, the emphasis has been on reducing protein content. Although protein content continues to play an important role in diet formulation, other diet modifications are also important in managing renal failure patients. Diets recommended for dogs and cats with renal failure are modified from typical maintenance diets in several ways, including reduced protein, phosphorus, and sodium content; increased B-vitamin content and caloric density; and a neutral effect on acid-base balance. Feline renal failure diets are typically supplemented with additional potassium. Canine renal failure diets may have an increased omega-3/omega-6 polyunsaturated fatty acid (PUFA) ratio. Diets may also have added fiber designed to enhance GI excretion of nitrogenous wastes. Of these diet modifications, only phosphate, omega-3 PUFA, and protein have been extensively examined.

260.4.2.1.1 Diet phosphate

Renal diets are limited in phosphorus content to limit phosphorus retention, hyperphosphatemia, renal secondary hyperparathyroidism, and progression of renal disease. Phosphate balance results largely from the interaction between dietary intake and renal excretion. Ingested phosphate is cleared from blood by glomerular filtration, and then total excretion is adjusted by modifying proximal tubular reabsorption. As renal function declines, renal tubular reabsorption of phosphorus declines (increasing renal excretion) in an attempt to compensate for the reduction in glomerular filtration, thereby maintaining phosphorus balance. However, if phosphorus intake continues unabated, the renal adaptive capacity soon becomes overwhelmed and phosphorus retention and hyperphosphatemia develop.

Although phosphorus retention and hyperphosphatemia probably do not cause clinical signs, they may promote renal secondary hyperparathyroidism and renal mineralization that enhances progressive decline in renal function. Dietary phosphorus restriction has been shown to enhance survival and a slow decline in renal function in dogs with induced renal failure.[57] In cats, dietary phosphorus restriction has been shown to limit renal mineralization.

Available evidence supports a recommendation for dietary phosphate restriction for dogs and cats in stages 3 and 4 CKD. Because protein is a major source for phosphate, it is usually necessary to limit dietary protein to limit diet phosphate content.

260.4.2.1.2 Omega-3 polyunsaturated fatty acid

Dietary supplementation with omega-3 PUFA have been shown to be beneficial in dogs with induced CKD. Compared with dogs fed diets high in saturated fats or omega-6 PUFA, dogs consuming a diet supplemented with omega-3 PUFA had lower mortality, better renal function, fewer renal lesions, less proteinuria, and lower cholesterol levels.[93] In dogs fed the omega-3 PUFA diet, renal function actually increased and remained above baseline over 20 months of study. Lesions of glomerulosclerosis, tubulointerstitial fibrosis, and interstitial inflammatory cell infiltrates were also diminished in dogs fed the omega-3 PUFA diet. A variety of effects attributed to omega-3 PUFA supplementation may have contributed to the favorable renal effects observed, including their tendency to reduce

hypercholesterolemia, suppress inflammation and coagulation (by interfering with the production of proinflammatory, procoagulant prostanoids, thromboxanes, or leukotrienes), lower blood pressure, favorably influence renal hemodynamics, provide antioxidant effects, or limit intrarenal calcification. A subsequent study supported possible roles for altered lipid metabolism, glomerular hypertension and hypertrophy, and urinary eicosanoid metabolism in the beneficial renal effects of omega-3 PUFA.[94]

Available evidence supports a recommendation for dietary supplementation with omega-3 PUFA for dogs in stages 3 and 4 CKD. The optimum quantity of omega-3 PUFA supplementation and ratio of omega-3/omega-6 PUFA appropriate for renal diets have not been conclusively established. Additional omega-3 PUFA supplementation may not be appropriate for dogs already consuming a renal diet enhanced with omega-3 PUFA. Currently, no evidence supports a recommendation for or against omega-3 PUFA supplementation for cats with CKD.

260.4.2.1.3 Diet protein

Although the ideal quantity of protein to feed dogs and cats with CKD remains unresolved, a general consensus of opinion supports the fact that reducing protein intake ameliorates clinical signs of uremia in CKD and is therefore indicated for stage 4 CKD. BUN can be used as a crude measure of compliance with dietary recommendations because it declines as dietary protein intake is reduced. Although not generally regarded as an important uremic toxin, BUN is a surrogate marker for retained nonprotein nitrogenous waste products and typically correlates better with clinical signs than serum creatinine concentration.

The concept of reducing dietary protein intake in CKD patients that do not have clinical signs of uremia has been questioned. Limiting protein intake has been advocated for these patients to slow progression of CKD. This suggestion derives from studies in rats indicating that dietary protein restriction limits glomerular hyperfiltration and hypertension and slows the spontaneous decline in kidney function that follows reduction in kidney mass.[66] Studies in humans have supported the concept that protein restriction slows progression of CKD, albeit this effect may be small.[95] In contrast, multiple studies have failed to confirm a beneficial role for protein restriction in limiting progression of kidney disease in dogs or cats.[92] When not excessive, limiting protein intake does not appear to have any adverse effects, and it may be easier to initiate treatment with renal diets before the onset of clinical signs of uremia. In addition, protein restriction may delay onset of clinical signs of uremia as renal disease progresses. Although a role for protein restriction in slowing progression of canine and feline CKD has not been entirely excluded, available evidence fails to support a recommendation for or against protein restriction in patients with stage 3 CKD.

260.4.2.2 Diet Therapy—Evidence from Clinical Trials

The effectiveness of diet therapy in minimizing uremic episodes and mortality in dogs with naturally occurring stage 3 and stage 4 CKD has been established in a double-masked, randomized, controlled clinical trial.[1] The study compared a renal diet to a prototypical canine maintenance diet. The renal diet was characterized by reduced quantities of protein, phosphorus, and sodium compared with the maintenance diet, and it was supplemented with omega-3 PUFA. In this study the risk of developing an uremic crisis was reduced by approximately 75% in dogs fed the renal diet compared with dogs fed an adult maintenance diet, and the median interval before development of uremic crisis in dogs fed the renal diet was twice as long as that observed in dogs fed the maintenance diet. Further, the risk of death irrespective of the cause

was reduced by at least two thirds when dogs were fed the renal diet, and renal death risk was reduced by 70%.

Dogs fed the renal diet survived at least 13 months longer than dogs fed the maintenance diet. In addition, owners of dogs fed the renal diet reported significantly higher quality of life scores for their dogs than owners of dogs consuming the maintenance diet. The delay in development of uremic crises and reduced mortality observed in dogs fed renal diet was associated, at least in part, with reduction in the rate progression of renal failure.

The effectiveness of diet therapy in cats has been tested in a prospective study comparing a renal diet characterized by protein and phosphorus restriction to no diet change.[64] Cats that would not accept the renal diet, either due to pet or owner issues, continued to eat their regular diet. Therefore this study was neither randomized nor blinded, but it nonetheless yielded results similar to those observed in the canine study. Cats fed the renal diet (median survival time [MST], 633 days) survived substantially longer than cats that continued to consume their regular diet (MST, 264 days). In addition, plasma urea nitrogen, phosphorus, and PTH concentrations were reduced in cats that consumed the renal diet.

1774
1775

260.4.2.3 Indications for Diet Therapy

In the past, criteria for timing of dietary intervention in dogs and cats with spontaneous CKD have been based on empiric observations. An often-cited guideline has been to initiate dietary therapy when serum creatinine exceeds 2.5 mg/dL or the SUN exceeds 60 to 80 mg/dL. More recently, one investigator recommended a staged approach whereby dietary phosphorus restriction and omega-3 PUFA dietary supplementation be implemented in dogs with serum creatinine values below 4.0 mg/dL with dietary protein restriction recommended only in dogs with serum creatinine values exceeding 4.0 mg/dL.[4] However, the clinical trial data available to date have demonstrated a benefit of dietary intervention in both stage 3 and stage 4 CKD. In a randomized, controlled clinical trial in dogs with naturally occurring CKD, diet therapy significantly reduced the risk of uremic crises and death in dogs with serum creatinine concentrations between 2.0 and 3.0 mg/dL.[1] These studies did not selectively determine the benefits of modifying individual dietary components, but rather report the results of a *diet effect*. Although studies on individual dietary components have been reported in dogs and cats with induced renal failure, the potential interactions between components have not been examined, nor have the results of these studies been confirmed in clinic patients.

Currently available data supports recommending therapy with appropriately modified diets in dogs and cats in stages 3 and 4 CKD. The value of diet therapy in stages 1 and 2 CKD has not been established; therefore no evidence supports a recommendation for or against diet therapy in these patients.

260.4.3 Drugs—Medication Review and Dose Modification

A review of current medications should be performed at each clinic visit, including dose adjustment based on level of kidney function, detection of potential adverse effects on kidney function or complications of CKD, detection of drug interactions, and, where indicated, therapeutic drug monitoring.[3] The clinician should ensure that all current medications are still necessary and that new medications have specific indications and do not pose a risk of drug interaction.

Because the kidneys are responsible for elimination of many drugs from the body, renal drug clearance is reduced as renal function declines, causing the half-life of the drug to be prolonged. In addition, distribution, protein binding, and hepatic biotransformation of drugs may be altered. For example, two protein-binding defects are seen in renal failure.[50] One group of primarily acidic drugs shows decreased binding leading to increases in free, active drug fractions in plasma (e.g., theophylline, methotrexate, diazepam, digoxin, salicylate). The effect of this change in binding is that lower doses of drugs are required to achieve therapeutic levels, but conventional doses may result in toxic levels. Basic drugs, such as propranolol or cimetidine, have increased binding leading to a decrease in free drug levels, thus diminishing the therapeutic effect. Increased total drug levels may be required to achieve the desired therapeutic effect with these drugs. However, these effects may be complicated by decreased renal clearance of the drugs.

Further, accumulation of active drug metabolites may augment drug potency or toxicity.

The sum effect of these changes is that for many drugs normally excreted by the kidneys, a tendency exists for drugs to accumulate in patients with renal failure. Excessive drug accumulation promotes an increased rate of adverse drug reactions and nephrotoxicity. If drugs requiring renal excretion must be administered to patients with renal failure, dose regimens should be adjusted to compensate for decreased organ function. However, dose adjustments may not be appropriate for drugs that are administered to a physiologic endpoint or effect such as antihypertensive agents.[96]

Because drug accumulation in patients with reduced kidney function is primarily a result of reduced renal drug clearance, dose adjustments should be made according to changes in drug clearance. Net renal excretion of a drug is a composite of glomerular filtration, tubular secretion, and tubular reabsorption. Generally it is assumed that these three factors all decline in parallel. Therefore drug clearance may be estimated by measuring GFR, either by plasma disappearance rate (e.g., iohexol disappearance rate) or classical clearance studies. Drug dose may then be adjusted according to the percentage reduction in GFR (i.e., the ratio of patient GFR/normal GFR), also known as the dose fraction (K_f):

$$K_f = (\text{patient GFR}/\text{normal GFR})$$

Dose regimens can be adjusted by increasing the normal dose interval or decreasing the normal dose in direct proportion to K_f.[97] The interval extension method is particularly useful for drugs with wide therapeutic ranges and long plasma half-lives in patients with renal impairment. Interval lengthening will result in wide swings of the plasma drug concentrations from peak to trough levels. If the range between the toxic and therapeutic levels is too narrow, either toxic or subtherapeutic plasma concentrations may result. For drugs excreted 100% unchanged by the kidneys, a precise increase in dose interval may be calculated by dividing the normal dosing interval by K_f:

$$\text{Modified dose interval} = (\text{normal dose interval}/K_f)$$

For example, if a drug is normally administered every 8 hours and the patient's GFR is 25% of normal (i.e., $K_f = 0.25$), then the appropriate dosing interval is (8 hrs ÷ 0.25) or 32 hrs. The calculated dose interval should be rounded to a convenient time schedule.

Alternatively, the size of the individual doses can be reduced while maintaining the normal time interval between doses. Decreasing the individual doses reduces the difference between peak and trough plasma concentrations. This effect is important for dugs with narrow therapeutic ranges and short plasma half-lives in

patients with renal dysfunction and is recommended for drugs for which a relatively constant blood level is desired. Dose reduction may be determined by multiplying the normal dose by K_f:

$$\text{Modified dose reduction} = (\text{normal dose} \times K_f)$$

For example, if the normal dose is 10 mg/kg given every 8 hours and the patient's GFR is 25% of normal (i.e., $K_f = 0.25$), then the appropriate dose is (10 mg/kg × 0.25) or 2.5 mg/kg given every 8 hours. Even using the reduced dose, normal interval method, the first dose of drug should be administered at the usual dose to initiate therapeutic drug concentrations in tissues and blood.

There have been no controlled clinical trials to establish the efficacy of the two methods for drug dose alteration in patients with CKD. Prolonging the dose interval is usually more convenient and less expensive. A combination of interval prolongation and dose size reduction may also be convenient and effective.

1775

Dose of antimicrobial drugs may be modified according to three general patterns, depending on the fraction of the drug eliminated by the kidneys (Table 260-1): (1) doubling the dosing interval or halving the drug dose in patients with severe reduction in renal function, (2) increasing the dose interval according to ranges of creatinine clearance values, and (3) precise dose modification as described previously. Drugs in the first category are relatively nontoxic. The second class includes drugs requiring dose modification according to GFR values because they are more likely to be toxic. For drugs in this class, dosing interval is increased twofold when GFR is between 1.0 and 0.5 mL/min/kg, threefold when GFR is between 0.5 and 0.3 mL/min/kg, and fourfold when GFR is less than 0.3 mL/min/kg. Drugs in the third class include relatively toxic antimicrobial drugs that are excreted solely by glomerular filtration (particularly aminoglycoside antibiotics). They require precise dose modification according to Kf. For these drugs, increased interval, fixed dose regimens appear to result in less nephrotoxicity than reduced dose, fixed interval methods. A combination of dose reduction and interval extension has been recommended for animals with markedly reduced kidney function (GFR < 0.7 mL/min/kg).

1776

Table • 260-1 Drug Dose Modifications for Patients with Renal Insufficiency and Failure

DRUG	ROUTE(S) OF EXCRETION*	NEPHRO-TOXIC?	DOSE ADJUSTMENT IN RENAL FAILURE†

* Routes of excretion: R, Renal; H, hepatic; GI, gastrointestinal; O, other (minor route in parentheses).

† Dose modification: N, Normal; D/I, half dose or double dose interval (in severe renal dysfunction); C cr, adjust according to Ccr (see text); Pr, precise dose modification (see text—clinician should adjust it according to Kf); C/I, contraindicated; A, clinician should avoid in advanced renal failure.

Although GFR is the preferred measure of renal dysfunction for modifying drug therapy, serum creatinine concentration is a more universally available measure of renal dysfunction. A regression equation relating serum creatinine concentration to GFR in dogs has been established.[98]

Although the relationship between serum creatinine concentration and GFR is not linear, the reciprocal of serum creatinine concentration may be used to approximate GFR when serum creatinine concentration is less than 4 mg/dL. This rule of thumb will overestimate GFR when serum creatinine concentration exceeds 4 mg/dL. Despite increased expense and effort involved, it is recommend that GFR be used as the basis for modifying drug dose schedules whenever possible. This recommendation is particularly relevant when a potentially nephrotoxic drug must be administered.

Patients with preexisting renal disease and renal failure may also be predisposed to nephrotoxicity. For this reason, nephrotoxic drugs and drugs requiring renal excretion should generally be avoided in patients with renal failure. Where possible, less nephrotoxic drugs should be chosen. If nephrotoxic drugs are unavoidable, therapeutic drug monitoring and serial evaluation of renal function is essential.

So-called complementary medications (sometimes called *herbal medicines*, *naturopathic remedies*, and *phytomedicines*) are becoming increasingly popular. The potential for interactions with prescribed medications or simple adverse consequences in patients with reduced kidney function should be considered for patients receiving these medications. Herbal products that should be avoided in patients with renal dysfunction include aristolochic acid, barberry, buchu, Chinese herbal drugs, juniper, licorice, and noni juice.[96]

260.4.4 Phosphorus Retention, Hyperphosphatemia, and Renal Secondary Hyperparathyroidism

Serum phosphorus concentrations represent the net balance between dietary intake and renal excretion of phosphorus. Therefore maintaining serum phosphorus concentrations within the normal range as renal function is lost requires modification of phosphorus intake. In theory, optimum control of hyperphosphatemia would be achieved by reducing dietary phosphorus intake *in proportion* to the decrease in GFR.

Without treatment, phosphorus retention, hyperphosphatemia and renal secondary hyperparathyroidism occurs in most dogs and cats with stage 3 or stage 4 CKD.[39,99] Although hyperphosphatemia has been linked to pruritus, conjunctivitis, renal osteodystrophy, and soft-tissue calcification in humans, hyperphosphatemia *per se* is rarely linked to clinical signs in dogs and cats with CKD. Rather, minimizing phosphorus retention and hyperphosphatemia is an important therapeutic goal in patients with CKD because it appears to limit renal secondary hyperparathyroidism and prolong survival.[57,99]

The first step in correcting hyperphosphatemia is to restore hydration and correct prerenal hyperphosphatemia. Minimizing long-term phosphorus retention and hyperphosphatemia may be accomplished by limiting dietary phosphorus intake, oral administration of agents that bind phosphorus within the lumen of the intestines, or a combination of these methods. The usual approach is to start with diet therapy and add phosphorous binding agents if diet therapy alone fails to normalize serum phosphorous concentrations. Diet therapy with or without phosphate-binding agents normalizes serum phosphorus levels in most patients. However, phosphorus restriction alone appears to be insufficient to normalize serum PTH levels in some patients.[39,99] In such patients, a combination of limiting phosphorus intake combined with administration of calcitriol has been recommended.[39] Nagode and colleagues[39] have suggested that normalization of PTH levels using calcitriol therapy may provide clinical benefits that cannot be achieved by phosphorus restriction alone, including amelioration of many clinical signs associated with CKD. However, clinical trials of long-term calcitriol therapy are needed to establish the value of this therapy in dogs and cats with CKD. Calcitriol therapy is described later in this chapter.

1776

1777

260.4.4.1 Dietary Phosphorus Restriction

Dietary phosphorus restriction is an important and effective intervention for normalizing phosphorus balance. It may be effective in normalizing serum phosphorus concentrations in most stage 3 and some stage 4 CKD patients. It will also decrease the dose of intestinal phosphorus-binding agents needed to bind dietary phosphorus in patients with more severe hyperphosphatemia. Dietary phosphorus restriction is

clearly indicated for patients with hyperphosphatemia. However, because phosphorus retention and hyperparathyroidism may occur before serum phosphorus concentrations exceed normal limits, and because fasting serum phosphorus concentrations may not accurately reflect overall phosphorus balance, phosphorus restriction may be indicated before the onset of overt hyperphosphatemia.[100]

Because proteins are a major source of dietary phosphorus, manufactured and homemade renal diets are usually restricted in both protein and phosphorus content. Typical commercial dog foods contain approximately 1% to 2% phosphorus on a dry matter basis and provide about 2.7 mg/kcal or more phosphorus. Modified protein diets designed for dogs with renal failure may contain as little as 0.13% to 0.28% phosphorus on a dry matter basis and provide about 0.3 to 0.5 mg/kcal of phosphorus. Typical commercial cat foods contain from 1% to 4% phosphorus on a dry matter basis and provide about 2.9 mg/kcal or more phosphorus. Modified protein diets designed for cats with renal failure may contain as little as 0.5% phosphorous on a dry matter basis and provide about 0.9 mg/kcal of phosphorus.

Phosphorus retention in CKD appears to occur in multiple compartments. As dietary phosphorus restriction reduces serum phosphorus levels, phosphorus leaches out of tissues, delaying the overall reduction in serum phosphorus concentration. Thus the overall efficacy of dietary phosphorus restriction in reducing serum phosphorus concentrations may not occur until the patient has been consuming the phosphorus-restricted diet for several weeks. In a study in cats with renal insufficiency and failure, the effect of restricting dietary phosphorus intake was apparent after 28 to 49 days.[99] Samples obtained for determinations of serum phosphorus concentration should be collected after a 12-hour fast to avoid postprandial effects. Sample hemolysis should be avoided because canine RBCs contain substantial quantities of phosphorus.

The minimum goal of therapy is to bring serum phosphorus concentration to within the normal range, although concentrations between 4.0 and 6.0 mg/dL may be preferred. Although PTH levels generally decline as serum phosphorus levels decline, normalization of serum phosphorus concentrations is not always accompanied by normalization of PTH concentration. In a recent clinical study of cats with chronic renal insufficiency and failure, dietary phosphorus restriction was associated with a normal serum phosphorus concentration in 12 of 13 cats, whereas PTH concentration was normalized in only eight of these 13 cats.[99] It is unclear whether further reducing serum phosphorus concentration within the normal range or using normalization of PTH levels as the preferred therapeutic endpoint would be of any clinical benefit.

Hypercalcemia was reported to develop in two cats managed with dietary phosphorous restriction.[99] The significance of the relationship, if any, between dietary phosphorus restriction and hypercalcemia in these two cats is unclear.

Unfortunately, as renal failure becomes more advanced, dietary phosphorus restriction alone may be insufficient to prevent hyperphosphatemia. When hyperphosphatemia persists despite dietary phosphorus restriction, administration of intestinal phosphorus-binding agents should be considered.

260.4.4.2 Intestinal Phosphorus-Binding Agents

Phosphorus-binding agents should be used in conjunction with dietary phosphorus restriction when dietary therapy alone fails to reduce serum phosphorus concentrations to the normal range. Dietary phosphorus intake should be reduced before initiating therapy with intestinal phosphorus-binding agents to minimize the quantity of phosphorus that must be bound. High dietary phosphorus content may greatly limit the effectiveness of phosphorus-binding agents or substantially increase the dose required to achieve the

desired therapeutic effect.[101] Administration of 1500 to 2500 mg of aluminum carbonate to dogs with moderate CKD failed to consistently correct hyperphosphatemia when dogs were fed diets containing greater than 1.0% phosphorus on a dry matter basis.[102]

Currently available phosphorus-binding agents include aluminum-based and calcium-based exchange compounds that liberate varying amounts of their associated cation (e.g., aluminum, calcium) as dietary phosphorus is bound. Factors that may influence selection of a specific phosphorus-binding agent include availability, palatability, and the associated cation. Aluminum-based binding agents have generally been preferred for dogs and cats because they are effective, inexpensive, and seemingly have few side effects. However, concern about the potential toxic effects of aluminum in humans has caused many aluminum-containing drugs to be removed from the market. Encephalopathies, microcytic anemia, and bone disease (particularly osteomalacia) related to aluminum toxicity have been extensively reported in human patients treated with these drugs. The potential for toxicity of aluminum salts in dogs and cats has been confirmed, but little evidence suggests that use of these drugs leads to clinically important aluminum toxicity in dogs and cats. Calcium-based drugs have the potential to promote hypercalcemia, particularly when administered between meals or used in combination with calcitriol.

Aluminum-containing intestinal phosphorus-binding agents include aluminum hydroxide, aluminum carbonate, and aluminum oxide. Initial doses of 30 to 100 mg/kg/day have been recommended for these aluminum-based phosphorus-binding agents. They are available over-the-counter in liquid, tablet, or capsule forms from most pharmacies as antacid preparations. In humans, capsules and tablets are less effective than liquids, but liquid preparations may be unpalatable to some dogs and cats. Sucralfate, a complex polyaluminum hydroxide salt of sulfate used primarily for treatment of GI ulcerations, may also be effective in binding phosphorus within the intestine.

Calcium-based phosphorus-binding agents include calcium acetate, calcium carbonate, or calcium citrate. Because calcium-based products may promote clinically significant hypercalcemia, it is recommended that serum calcium concentrations be monitored intermittently when using these drugs. They should not be used in hypercalcemic patients. When indicated, they may be used between meals as a source of additional dietary calcium. Calcium supplementation may increase the efficacy of phosphorus restriction in normalizing renal secondary hyperparathyroidism.

Reduced doses of calcium carbonate and calcium acetate may be used concurrent with aluminum-based binding agents to limit risks of both hypercalcemia and aluminum toxicity. However, calcium citrate may promote absorption of aluminum and should therefore not be used in concert with aluminum-based binding agents. Calcium acetate is the most effective calcium-based phosphorus-binding agent and the agent least likely to induce hypercalcemia because it releases the least amount of calcium compared with the amount of phosphorus it binds.[101] Initial doses of 60 to 90 mg/kg/day have been recommended for calcium acetate and 90 to 150 mg/kg/day for calcium carbonate. Some calcium carbonate preparations may not be effective because they fail to dissolve well in the GI tract; clinicians may investigate this by examining the stool or obtaining radiographs of the abdomen for evidence of radiodense tablets that have failed to dissolve.

1777 1778

The most recent addition to the phosphorus-binding armamentarium is the cationic polymer agent sevelamer hydrochloride (Renagel® Tablets and Capsules, Genzyme Corp., Cambridge, MA). The primary advantage of this drug is that it does not promote hypercalcemia or absorption of aluminum. However, it is more expensive than older phosphorus-binding agents. In addition, concerns have been raised over its potential for inducing vitamin-K deficiency and hemorrhage. In preclinical studies in rats and dogs, sevelamer hydrochloride reduced vitamin D, E, K, and folic acid levels when given at doses of six to 100

times the recommended human dose. In clinical trials in humans, no evidence of reduction in serum levels of vitamins was seen; however, patients in this study were receiving vitamin supplements. Scant information exists on the safety, effectiveness, or dose of sevelamer in dogs and cats. Based on extrapolating the recommended dose from humans, an initial dose of 30 and 135 mg/kg per day divided and given with meals may be considered. Because the contents of Renagel® (Genzyme Corp.) expand in water, the manufacturer recommends that tablets and capsules should be swallowed intact and should not be crushed, chewed, broken into pieces, or taken apart prior to administration. Sevelamer reportedly lowers total and low-density lipoprotein cholesterol concentrations and elevated high-density lipoprotein cholesterol levels in humans.[103] Consideration should be given to monitoring clotting ability using the prothrombin time (PT) if this drug is used in dogs or cats with CKD.

Intestinal phosphorus-binding agents render ingested phosphorus and the phosphorus contained in saliva, bile, and intestinal juices unabsorbable. Because the primary goal is limiting absorption of phosphorus contained in the diet, administration of phosphorus-binding agents should be timed to coincide with feeding. These agents are best administered with or mixed into the food, or just prior to each meal. It is particularly important that calcium-based phosphorus-binding agents be administered with meals both to enhance the effectiveness of phosphorus binding and to minimize absorption of calcium and the risk of hypercalcemia.

Dose of phosphorus-binding agents should be individualized to achieve the desired serum phosphorus concentration. The effectiveness of therapy should be assessed by serial evaluation of serum phosphorus concentrations at about 2-to 4-week intervals. Dose of calcium-based phosphorus-binding agents should be decreased if serum calcium concentrations exceed normal limits; additional aluminum-based agents should be used in these patients if hyperphosphatemia persists.

260.4.5 Dehydration

Fluid balance in patients with polyuric renal failure is maintained by compensatory polydipsia. If water consumption is insufficient to compensate for polyuria, dehydration is the result. This may occur as a consequence of lack of intake or lack of access to fresh, clean, unadulterated water. Cats and some dogs with chronic kidney disease (CKD) fail to consume sufficient water to prevent chronic or recurrent dehydration. In addition, acute GI fluid losses resulting from renal or nonrenal causes may lead to extracellular fluid volume depletion.

Dehydration and volume depletion promote renal hypoperfusion and prerenal azotemia that may exacerbate the clinical and laboratory abnormalities of chronic renal insufficiency and failure. In addition to prerenal azotemia, dehydration may be associated with electrolyte disturbances such as hyperphosphatemia, hyperkalemia, and metabolic acidosis. Clinical signs characteristic of dehydration include decreased appetite, lethargy, and constipation. In some patients, prerenal azotemia may precipitate uremic crisis. Further, if dehydration and decreased renal blood flow are allowed to persist, additional ischemic renal damage may occur.

Patients that develop recurrent episodes of signs consistent with dehydration are candidates for intermediate-to long-term subcutaneous fluid therapy to be administered at home by the owner. The principal benefits of subcutaneous fluid therapy include improved appetite and activity and reduced constipation. The decision to recommend administration of subcutaneous fluids should be made on a case-by-case basis. Not every patient with chronic kidney disease and failure requires or will benefit from fluid therapy. Although a substantial number of cats with CKD appear to benefit from subcutaneous fluid therapy, proportionately fewer dogs

require fluid therapy. In addition, home administration of subcutaneous fluids is not appropriate for all owners. Although it is inexpensive, it does require time and may cause stress on the owner-pet relationship. It also has the potential to promote hypokalemia, hypertension, and fluid overload. Although a risk of subcutaneous infections exists, this appears to be an uncommon complication when owners are taught proper technique.

Normal saline or lactated Ringer's solution are the fluids most commonly used for home subcutaneous fluid therapy. They are well tolerated by most cats and dogs and appear to be reasonable choices for most patients. However, chronic administration of lactated Ringer's solution or normal saline as the principal maintenance fluid source may cause hypernatremia because they fail to provide sufficient electrolyte-free water. Ideally, fluids selected for chronic parenteral administration should provide free water and electrolytes for maintenance. A solution containing 0.45% saline and 2.5% glucose supplemented with 20 mEq/L of potassium chloride meets these requirements. Unfortunately, fluids containing dextrose may be irritating when administered subcutaneously, and their use should be discontinued if the patient indicates discomfort when they are given. A typical cat or small dog receives approximately 75 to 150 mL of fluids given daily or as needed. Chronic subcutaneous fluid therapy can result in fluid overload in some patients, particularly when fluid volumes in excess of those recommended here are used. The authors have seen several cats have severe dyspnea due to pleural effusion given large quantities of fluid (200 to 400 mL/day). This condition can usually be avoided by reducing the volume of fluids administered.

Response to long-term subcutaneous fluid therapy should be monitored by serially assessing hydration status, clinical signs, hematocrit, total serum protein concentrations, blood pressure, and SUN, creatinine, phosphorus, potassium, total CO_2, sodium, and chloride concentrations.

260.4.6 Hypokalemia and Potassium Depletion

Potassium depletion and hypokalemia are common in cats with CKD. Estimates of the prevalence of hypokalemia in this population of cats are in the range of 20% to 30%.[2,8,9] Total body potassium depletion is likely to be even more common than hypokalemia.[62] In contrast, hypokalemia is rarely recognized as a complication of canine CKD. The mechanisms underlying development of hypokalemia in cats with CKD remain unclear, but inadequate potassium intake coupled with increased urinary and fecal losses (or both) have been hypothesized to play a role.

1778

1779

Although increasing the potassium content of renal diets has reduced the incidence of overt clinical signs of hypokalemia, hypokalemia remains a common laboratory finding in cats with renal insufficiency and failure. The antihypertensive agent amlodipine may promote hypokalemia in cats with chronic renal insufficiency and failure.[104]

Hypokalemia and potassium depletion may affect the kidneys or muscles of cats with CKD. Diets low in potassium and high in acid content have been implicated in impairing renal function and promoting development of lymphoplasmacytic tubulointerstitial lesions in cats.[33,60–63] Potassium depletion may result in reduced renal blood flow and GFR as a consequence of angiotensin II and thromboxane-mediated renal vasoconstriction. In addition, hypokalemia may promote polyuria by impairing renal responsiveness to ADH and by stimulating the brain thirst centers through increased levels of angiotensin II. Hypokalemic polymyopathy, characterized by generalized muscle weakness and cervical ventroflexion, is a well-recognized complication of chronic renal insufficiency and failure in cats.

Oral supplementation of potassium has been recommended for cats with renal insufficiency and failure to treat or prevent renal and muscular consequences of potassium depletion and hypokalemia. Although a consensus

of opinion suggests that cats with hypokalemia should receive potassium supplementation, the justification for *prophylactic* potassium supplementation in normokalemic cats is not well established. Although potassium supplementation is unlikely to be medically harmful to polyuric, normokalemic cats, administration of an oral medication may impose an unnecessary burden on both the cat and the cat owner. Patient acceptance may be a limitation due to the unpleasant flavor of potassium salts that is difficult to mask.

Oral replacement is the safest and preferred route for administering potassium. Parenteral therapy is generally reserved for patients requiring emergency reversal of hypokalemia or for patients that cannot or will not accept oral therapy. Potassium chloride may be added to fluids administered subcutaneously up to 30 mEq/L.

Potassium may be supplemented orally as the gluconate or citrate salts. Potassium chloride is not recommended because of its lack of palatability and acidifying nature. Potassium gluconate may be administered orally as tablets, flavored gel, or in a palatable powder form (Tumil-K, Virbac Corp., Fort Worth, TX). Depending on the size of the cat and severity of hypokalemia, potassium gluconate is given initially at a dose of 2 to 6 mEq per cat per day. Acidosis is a major risk factor for development of hypokalemia and therefore should be rectified early in the management of hypokalemia. Potassium citrate solution (Polycitra®-K Syrup, Baker Norton, Miami, FL) is an excellent alternative that has the advantage of providing simultaneous alkalinization therapy. Potassium citrate is initially given at a dose of 40 to 60 mg/kg/day divided into two or three doses. If muscle weakness is present, it usually resolves within 1 to 5 days after initiating parenteral or oral potassium supplements. Potassium dose should thereafter be adjusted based on the clinical response of the patient and serum potassium determinations. Serum potassium concentration should initially be monitored every 7 to 14 days and the dose adjusted accordingly to establish the final maintenance dose. In patients with hypokalemic polymyopathy, it may be necessary to monitor serum potassium concentrations every 24 to 48 hours during the initial phase of therapy. It is unclear whether all cats require long-term potassium supplementation; however, preliminary evidence suggests that such therapy is likely to be required by at least some older cats with chronic kidney disease.

Routine supplementation of low oral doses of potassium (2 mEq/day) has been recommended for all cats with chronic kidney disease.[59] This recommendation appears to be based on the as yet unproved hypothesis that in some cats with CKD, hypokalemia and potassium depletion might promote a self-perpetuating cycle of declining renal function, metabolic acidosis, and continuing potassium losses. It is proposed that supplementation may stabilize renal function before potassium depletion exacerbates the disease. Some investigators have observed positive responses to potassium supplementation in several normokalemic cats that had chronic renal insufficiency and failure. However, results of a recent clinical trial suggested that in cats with chronic renal insufficiency and failure that initially had normal serum potassium concentrations, daily supplementation for 6 months with 4 mEq of potassium gluconate was not demonstrably superior to providing sodium gluconate in restoring muscle potassium stores.[62] However, there were only a small number of cats enrolled in this clinical trial. In addition, median muscle potassium content did increase in the potassium supplemented cats from 328 to 402 mEq/kg, a value close to the value of 424 mEq/L established for normal cat muscle. Thus although the value of providing supplemental potassium to cats with chronic kidney disease having normal serum potassium concentrations has not been established, it is clear that muscle potassium, and probably total body potassium stores, are likely to be reduced in cats with chronic kidney disease, increasing the risk for developing hypokalemia. Further, evidence from this study indicates that chronic supplementation of 2 to 4 mEq/day of potassium is unlikely to be associated with significant adverse events. Based on current data, a recommendation cannot be made for or against routine supplementation of potassium.

Diets that are acidifying and restricted in magnesium content may promote hypokalemia. Therefore they should generally be avoided in cats with CKD. Intensive fluid therapy during uremic crises, particularly with

potassium-deficient fluids, may promote hypokalemia in cats or dogs that were not previously hypokalemic. Therefore serum potassium concentrations should be monitored during fluid therapy, and maintenance fluids should be supplemented with potassium chloride to prevent iatrogenic hypokalemia (concentrations of 13 to 20 mEq/L are appropriate for maintenance fluids). Potassium given intravenously should not be administered at a rate exceeding 0.5 mEq/kg/hr.

260.4.7 Metabolic Acidosis

Alkalinization therapy designed to correct metabolic acidosis plays an important role in management of patients with CKD. Potential benefits of alkalinization therapy in these patients include (1) ameliorating signs of uremic acidosis, including anorexia, lethargy, nausea, vomiting, muscle weakness, and weight loss; (2) minimizing the catabolic effects of metabolic acidosis on protein metabolism[54]; (3) enhancing the patient's capacity to adapt to additional acid stress resulting from such factors as diarrhea, dehydration, or respiratory acidosis; (4) limiting skeletal damage (demineralization and inhibited skeletal growth) resulting from bone buffering; and (5) rectifying adverse effects of severe acidosis on the cardiovascular system (impaired myocardial contractility and enhanced venoconstriction).[105]

Although data are unavailable for dogs, a recent study in cats with chronic renal insufficiency and failure indicated that metabolic acidosis occurred in less than 10% of cats with stage 3 CKD, but it approaches 50% of cats in uremic crisis.[2] Based on this data, it appears that only a minority of cats with clinically stable CKD are likely to benefit from routine alkalinization therapy. Thus the decision to intervene with alkalinization therapy should be based on a laboratory assessment of the patient's acid-base status. Unfortunately, no clinical data provides an obvious intervention threshold for treating metabolic acidosis in dogs and cats. However, in studies performed at the authors' research center, clinicians have been unable to demonstrate any adverse clinical effects of mild to moderate chronic metabolic acidosis in cats with induced chronic renal insufficiency and failure. In absence of clear clinical data, the authors recommend considering alkalinization therapy for dogs and cats with stable chronic renal insufficiency and failure when blood gas analysis confirms plasma bicarbonate values remain below 15 mmol/L on more than one determination. However, for patients with metabolic acidosis associated with a blood pH below 7.10, immediate parenteral intervention with sodium bicarbonate should be considered to increase the blood pH above this value.[105]

1779

1780

Because serum total CO_2 measurements are of questionable accuracy and yet remain the most common tool for establishing acid-base status for most dogs and cats, the authors recommend that blood gas analysis be performed to confirm metabolic acidosis whenever total CO_2 declines below 15 mmol/L. Low serum or plasma total CO_2 values obtained by autoanalyzer techniques should be confirmed by blood gas analysis because falsely low total CO_2 readings may occur when blood collection tubes are not fully filled or are exposed to air while awaiting analysis.[106] In addition, there may be a substantial systematic difference between blood bicarbonate concentrations determined by blood gas analysis and serum total CO_2 concentrations determined on autoanalyzers due to inherent differences in the analytic methods. Appropriate reference ranges are equipment and method specific.

Treatment options for alkalinization therapy include diet, sodium bicarbonate, and potassium citrate. Most renal diets are neutral to slightly alkalinizing in effect and are an appropriate first step in mitigating metabolic acidosis. When several weeks of diet therapy alone fails to ameliorate the metabolic acidosis, alkalinization therapy should be considered.

Oral sodium bicarbonate is the most commonly used alkalinizing agent for patients with metabolic acidosis of chronic renal insufficiency and failure. Because the effects of gastric acid on oral sodium bicarbonate are unpredictable, the dose should be individualized for each patient. A suggested initial dose of sodium bicarbonate is 8 to 12 mg/kg body weight given every 8 to 12 hours. Unfortunately, many dogs and cats find sodium bicarbonate distasteful unless given as tablets. Sodium bicarbonate is available as 5-and 10-grain tablets.

Potassium citrate may offer the advantage, especially in cats, of allowing for the simultaneous treatment of both hypokalemia and acidosis with a single drug. Metabolic acidosis, when accompanied by potassium depletion or magnesium depletion, may respond poorly to alkali therapy alone. However, in that potassium doses required for adequate correction of hypokalemia may exceed the citrate dose required to correct acidosis, a risk exists for excessive alkalinization. Starting doses of 40 to 60 mg/kg every 8 to 12 hours are recommended.

Regardless of the alkalinizing agent chosen, administration of several smaller doses is preferred to a single large dose to minimize fluctuations in blood pH. The patient's response to alkalinization therapy should be determined by performing blood gas analysis 10 to 14 days after initiating therapy. Ideally, blood should be collected just prior to administration of the drug. Dose of the alkalinizing agent should be adjusted to maintain blood bicarbonate concentrations within the normal range. Because urine pH is often insensitive as a means of assessing the need for or response to treatment, it is not recommended for this purpose.

260.4.8 Arterial Hypertension

260.4.8.1 Rationale for Treatment

CKD is the most common recognized cause for arterial hypertension in dogs and cats. In these species, hypertension has been linked to renal, ocular, neurologic, and cardiac complications. In dogs with naturally occurring chronic renal insufficiency and failure, higher initial blood pressure has been reported to be a risk factor for uremic crisis and mortality.[18] In addition, retinopathy and hypertensive encephalopathy were detected in three of 14 dogs with blood pressure values exceeding 180 mm Hg in this study. However, firm evidence that pharmacologically lowering blood pressure will prevent or ameliorate the renal and extrarenal complications of arterial hypertension in dogs is lacking.

Lethargy, blindness, retinal hemorrhage and detachment, cerebral hemorrhage, seizures, stupor, and ventricular hypertrophy have been reported in cats with hypertension.[107–109] Although it is likely that elevated blood pressure promotes progressive renal injury in cats, as yet no reported evidence confirms this relationship. However, in contrast to dogs, studies exist that support the clinical value of therapeutic intervention for hypertension in cats. Subcutaneous administration of the antihypertensive drug hydralazine was reported to reduce the prevalence of seizures that developed as a consequence of hypertension after renal transplantation.[108] In a recent study using a surgically induced model of hypertensive renal insufficiency, only two of 10 cats receiving the antihypertensive agent amlodipine developed evidence of hypertensive retinal lesions, whereas these lesions developed in seven of 10 cats receiving placebo.[107]

260.4.8.2 Indications for Treatment

Unless evidence for hypertension-related organ injury is seen (e.g., retinal lesions, neurologic signs) or the systolic blood pressure is greater than 200 mm Hg, the decision to initiate antihypertensive therapy is not an emergency. Before initiating therapy for arterial hypertension, the patient's blood pressure should be established based on blood pressure determinations performed at three successive clinic visits. Every effort should be made to minimize the risk that measured elevations in blood pressure represent a transient “white coat” effect, rather than a sustained elevation in blood pressure.[110]

Patients with blood pressure values exceeding 160/100 mm Hg should be considered for treatment. Although specific values for diagnosis of arterial hypertension have not been established for dogs and cats, current evidence suggests that concurrent CKD may place them at increased risk for sustaining additional renal injury or developing complications associated with elevated blood pressure.[18,107–109] Findings in two studies suggested that ocular lesions associated with elevated blood pressure occurred in cats with systolic blood pressure values exceeding about 160 mm Hg. Similarly, in a study in dogs with naturally occurring CKD, the risk for uremic crises and increased mortality was reported to be increased in a group of dogs with systolic blood pressure values above 160 mm Hg.[18] However, this cut off point was arbitrarily chosen in this study and therefore should not be interpreted as defining the lower limit of hypertension.

260.4.8.3 General Goals and Guidelines for Treatment

The optimum endpoint for antihypertensive therapy has not been established for dogs and cats with CKD. In the absence of such information, treatment for arterial hypertension should be initiated cautiously with the goal of reducing blood pressure to at least below 160/100 mm Hg. Except in patients with acute, severe ocular or neurologic lesions, rapid reduction in blood pressure is not necessary. Particularly in dogs, it may take weeks to months to achieve satisfactory blood pressure control.

ACE inhibitors, such as enalapril and benazepril, and calcium channel blocking (CCB) drugs, such as amlodipine, have potential renoprotecitve benefits and are therefore appropriate options for renal patients with hypertension.[111] ACE inhibitors generally produce a relatively small reduction in blood pressure.[112,113] However, because of their beneficial role in altering intraglomerular hemodynamics, proteinuria, and the profibrotic effects of the intrarenal renin-angiotensin system, ACE inhibitors may have renoprotective effects even in absence achieving adequate blood pressure control. In a recent study the ACE inhibitor, enalapril, reduced the severity of renal lesions that develop in dogs with surgically reduced renal mass.[112] Further, in dogs with naturally occurring glomerulopathies, enalapril significantly reduced proteinuria and may have been beneficial in stabilizing renal function.[22] Based on this, they appear to be the preferred antihypertensive agent for dogs with CKD. However, the role of the renin-angiotensin-aldosterone system (RAAS) and ACE inhibitor therapy in cats with CKD and hypertension is more controversial.[114–117] Evidence that activation of the RAAS is consistently central to the genesis of hypertension in cats is contradictory, and ACE inhibitors have not been found to be consistently effective in lowering blood pressure in cats with CKD. Therapy using either benazepril or enalapril may be initiated in dogs or cats with CKD at a dose of 0.5 mg/kg given orally every 24 hours.

Calcium channel blockers preferentially antagonize preglomerular vasoconstriction, which theoretically, should not reduce glomerular hypertension. However, CCBs appear to have additional renoprotective

properties.[111] They may prevent renal injury by limiting renal growth, by reducing mesangial entrapment of macromolecules, and by attenuating the mitogenic effects of diverse cytokines and growth factors (e.g., PDGF, platelet-activating factor). In addition, amlodipine inhibits the *in vitro* proliferation of mesangial cells. However, clinical trials in humans have provided conflicting results as to the renoprotective effect of CCB beyond their antihypertensive effects. Controlled studies on the renoprotective effects of amlodipine in dogs and cats have not been published. In the authors' clinical experience, CCBs have been effective antihypertensive agents in dogs and cats with CKD. Because it is usually highly effective, has few side effects, and has a relative rapid onset, the long-acting dihydropyridine calcium antagonist amlodipine is the antihypertensive of choice for most cats with CKD. Amlodipine is prescribed at a dose of 0.625 mg for cats less than 4 kg and 1.25 mg for cats greater than 4 kg. In cats with CKD, amlodipine typically reduces systolic blood pressure by about 30 to 50 mm Hg within the first 1 to 2 months of therapy.[107,118] General principles of management of hypertension are described in Chapter 130, Hypertension.

260.4.9 Treatment of Anemia of Chronic Renal Failure

260.4.9.1 General Guidelines for Minimizing Anemia

An obvious but often overlooked consideration is minimizing iatrogenic blood loss. Iatrogenic loss is especially likely to occur in hospitalized cats and small dogs because of repeated sampling for diagnostic tests and monitoring. Therefore the quantities of blood collected from these patients should be recorded and monitored.

Chronic low-grade GI blood loss can also result in moderate to severe anemia in patients with CKD that would otherwise have sufficient endogenous erythropoietin production to maintain their hematocrit values in the low-normal range. These patients may lack overt GI signs or melena. Iron deficiency, microcytosis and an elevation in BUN/creatinine ratio above what is expected in context of the patient's diet may provide indirect evidence of occult GI blood loss. Because of difficulty in confirming GI hemorrhage, a therapeutic course with histamine H_2-receptor antagonists and sucralfate may be considered. Improvements in hematocrit, appetite, or both indicate a positive response.

Iron deficiency is a relatively common problem in dogs and cats with CRF. In a recent study, the serum iron concentrations of 3 of 6 CRF dogs and 3 of 7 CRF cats were below the reference range (transferrin saturations less than 20%).[119] Whether this is related primarily to inadequate intake and absorption of iron or increased losses of iron due to GI blood loss is unclear. Unfortunately, iron status can be difficult to assess in dogs and cats. Serum iron levels can be used to screen for both iron deficiency and anemia of chronic inflammatory disease as contributing factors in the diagnostic evaluation of anemia. In dogs, serum iron levels may not reflect body iron stores in that normal values can occur in patients with iron deficiency. However, determining stainable iron content in bone marrow is helpful in assessing body iron stores and may detect problems not identified by serum iron levels or transferrin saturation. When low serum iron levels reflect true iron deficiency, bone marrow stainable iron levels will be low; in those with anemia of chronic inflammatory disease, bone marrow levels will be normal or high reflecting sequestration. The distinction is important because anemia of chronic inflammatory disease will not improve in response to iron supplements and may even result in iron overload. It is necessary to identify and remove the concurrent inflammatory disease to treat anemia of chronic inflammatory disease. Transferrin saturation (estimated by dividing serum iron by total iron binding capacity) may be useful for assessing the ability of the mobilizable iron stores (perhaps independent of total tissue iron stores) to meet the demands of

erythropoiesis and, thus is particularly useful in evaluating patients during periods of increased erythropoiesis such as during recombinant human erythropoietin (rHuEPO) therapy.

Oral supplementation with ferrous sulfate is the preferred therapy for treatment of iron deficiency anemia and also for prevention of iron-deficient erythropoiesis in patients starting erythropoietin replacement therapy. Alternatively, iron dextran may be administered by intramuscular injection. However, parenteral administration of iron is associated with a small risk of anaphylaxis, shunting of iron to reticuloendothelial storage, and iron overload. Although serum iron levels and transferrin saturation should be monitored to adjust therapy, starting doses of iron sulfate of 50 to 100 mg/day for cats and 100 to 300 mg/day for dogs have been recommended. Oral iron supplements may be associated with GI upset and diarrhea, so small divided doses may be preferable.

In addition to iron deficiency, other nutritional abnormalities may contribute to anemia in patients with CKD. Protein malnutrition and its attendant changes in plasma amino acid and hormone concentrations is known to cause suboptimal erythropoiesis and anemia. Similar changes occur in human patients and may reflect mild protein/calorie malnutrition commonly present in advanced CKD. Although they have not been examined in dogs and cats, deficiencies in riboflavin (vitamin B_2), cobalamin (vitamin B_{12}), folate, niacin, or pyridoxine (vitamin B_6) might theoretically induce nutritional anemia. Vitamin status cannot be easily determined in dogs and cats; however, deficiencies should be suspected in patients with persistent anorexia, protein and calorie malnutrition, or GI malabsorption. In addition, some drugs may predispose the patient to nutritional anemia even when dietary intake is normal. For example, therapy with trimethoprim or methotrexate may interfere with cellular folate metabolism. Hypersegmentation of the polymorphonuclear leukocytes may provide a clinical indication of vitamin B_{12} or folate deficiency.

Risk of nutritional deficiencies can be minimized through timely initiation of proper diet modifications and, if necessary, use of dietary supplements. In addition to minimizing renal anemia, preventing protein and calorie malnutrition may reduce morbidity. B vitamins, folate, and niacin can be provided as an oral supplement often with iron.[33] Care must be taken with multivitamins not to oversupplement the fat-soluble vitamins A and D.

1781

1782

RBC life span is decreased in advanced CKD. Proposed mechanisms for this mild hemolytic tendency include a malfunctioning of the membrane Na+-K+-ATPase pump and impaired regeneration of reduced glutathione needed to prevent hemoglobin oxidation. Cat hemoglobin appears to be especially prone to oxidative stress as evidenced by the frequent observation of Heinz bodies in their RBCs. Cats with CKD having large numbers of Heinz bodies tend to be more anemic. Drugs and foods (e.g., onions, propylene glycol, methylene blue, sulfonamides) that promote formation of Heinz bodies should be avoided in uremic pets whenever possible.

PTH has been postulated to play a role in the pathogenesis of anemia of CRF. PTH inhibits growth of all bone marrow cell lines *in vitro*. However, leukopenia and thrombocytopenia are not characteristic of CKD, arguing against an important role for PTH-induced bone marrow suppression. In a clinical series of canine CKD patients with anemia, the authors found no correlation between PTH levels and the degree of anemia.[34]

It has been postulated that increased serum phosphorus leads to increased intracellular red cell phosphorus. This in turn increases red cell 2,3 DPG levels, a noteworthy finding in anemic CRF patients.[34] Increased 2,3 DPG levels cause a rightward shift in the oxyhemoglobin dissociation curve, improving tissue oxygenation and decreasing the stimulus for erythropoietin synthesis.

260.4.9.2 Anabolic Steroids

Anabolic steroids were at one time the mainstay of therapy for anemia associated with CKD. Although controlled safety and efficacy studies in dogs and cats are lacking, clinical experience with anabolic steroids has been disappointing. With the advent of rHuEPO therapy, androgens have largely fallen out of favor for treatment of renal anemia in human and veterinary medicine. Based on studies in human patients and clinical experience with veterinary patients, androgens appear to work in only a small percentage of patients (usually those mildly affected), have a long delay to onset of action, and may be associated with undesirable side effects. Administration of anabolic steroids for treatment of dogs and cats with anemia of CKD should probably be limited to those patients with symptomatic anemia in which all other factors adversely affecting erythropoiesis (nutritional deficiencies, blood loss, hemolysis, concurrent disease) have been eliminated and other treatment options (erythropoietin, transfusion) are unavailable or have been exhausted.

260.4.9.3 Blood Transfusion

Transfusions of packed RBCs or whole blood may be indicated for anemic CKD patients who need rapid correction of their anemia, as in preparation for surgery. For some patients, repeated transfusions can be used for long-term maintenance of hematocrit. However, several drawbacks have limited the use of this therapy in dogs and cats, including lack of availability and expense of blood products, increasing risk of transfusion reactions with multiple transfusions, risk of immunosuppression, risk of transfer of infectious agents, and decreased life span of transfused cells in uremic patients. Even for the first transfusion, only compatible blood products (as determined by cross-matching) should be used in both dogs and cats. The post-transfusion target hematocrit should be the low end of the normal range. This should be adequate to reverse the anorexia and fatigue associated with the anemia while minimizing the complications of too rapid an increase in blood volume and viscosity such as circulatory overload, hypertension, and seizures.

260.4.9.4 Hormone Replacement Therapy

Hormone replacement therapy using rHuEPO has become the treatment of choice for anemia of CKD in cats and dogs when hematocrit values decline below about 20% and clinical signs are attributable to the anemia. Administration of rHuEPO causes a dose-dependent increase in hematocrit.[119] Correction of hematocrit to low normal takes approximately 2 to 8 weeks, depending on the starting hematocrit and dose given. As the anemia is corrected, most clients report that their pets show increases in appetite, body weight, energy level, and sociability.[119] Initially, erythropoietin is usually administered at a dose of 50 to 150 U/kg subcutaneously three times weekly. Most dogs and cats should be started at 100 U/kg administered three times weekly. Hematocrit is monitored weekly or biweekly until a target hematocrit of approximately 30% to 40% for cats and 37% to 45% for dogs is achieved.[119] When anemia is severe (hematocrit < 14%) but does not require transfusion, daily therapy with 150 U/kg may be preferred for the first week. In the presence of hypertension or when anemia is not severe, a dose of 50 U/kg three times per week may help to prevent increases in blood pressure and iron-deficient erythropoiesis. When a hematocrit at the low end of the target range is reached, the dosing interval should be decreased to twice weekly. Most animals require 50 to 100 U/kg two to three times weekly to maintain their hematocrit in the target range; however, the dose and dosing interval required to maintain individual patients in the normal range is highly variable.

Ongoing monitoring of hematocrit will be necessary to allow adjustments in dose and dosing interval. Animals requiring more than 150 U/kg three times weekly should be evaluated for erythropoietin resistance. Because of the lag time between dose adjustment and effect on hematocrit, patience must be exercised so as not to adjust the dose too frequently. Frequent dose adjustments will result in rapid, unpredictable changes in hematocrit and an inability to find a stable dosing regimen. In general, dose should not be changed any more often than once monthly. Avoiding iatrogenic polycythemia is especially important.

The basis for individual differences in response to rHuEPO is incompletely understood. Several causes of blunted response or failure to resolve renal anemia with rHuEPO therapy have been identified, including functional or absolute iron deficiency, anti-rHuEPO antibody formation, ongoing GI blood loss or hemolysis, concurrent inflammatory or malignant disease, and aluminum overload (not documented in veterinary patients). Owner errors related to drug storage, handling, or administration may account for some instances of poor response to rHuEPO therapy.

The demand for iron associated with stimulated erythropoiesis is high, and human patients without pre-existing iron overload will exhaust iron storage during rHuEPO therapy. The same appears true of dogs and cats. Iron supplementation is therefore recommended for all patients receiving rHuEPO therapy.

Adverse effects related to rHuEPO therapy in dogs and cats may include systemic hypertension, seizures, local reactions at the injection site, and development of antibodies directed at erythropoietin.[119] Hypertension may develop or increase in severity with rHuEPO therapy. Increased peripheral vascular resistance secondary to improved oxygen delivery and reversal of the vasodilation induced by chronic hypoxia may contribute to this effect. Increased blood viscosity associated with the increased hematocrit is thought to be only a minor contributor. Seizures have been observed in human, canine, and feline patients being treated with rHuEPO that have no prior history of a seizure disorder.[119] In dogs and cats, they have been reported in the setting of moderate to severe azotemia. Although hypertension, anemia, and uremic encephalopathy may be contributory, in humans, seizures are thought to be related to compensatory adaptations to increases in RBC mass. Seizures are not thought to be directly related to rHuEPO.

1782

1783

Allergic reactions, including cutaneous or mucocutaneous reactions or cellulitis sometimes with fever and arthralgia, were uncommonly observed in both dogs and cats early in the course of rHuEPO therapy.[119] Lesions generally resolved within a few days and some did not recur when therapy was reinstated.

The most important complication associated with use of rHuEPO is refractory anemia and hypoplasia of the erythroid bone marrow associated with formation of neutralizing anti-rHuEPO antibodies.[119] In some affected patients, the severity of anemia was worse than before initiation of rHuEPO treatment. This observation suggested that the anti-rHuEPO antibodies were effective in interfering with the erythropoietin effects of rHuEPO and endogenous erythropoietin. The rHuEPO protein appears to be immunogenic in many, but not all, dogs and cats with antibody titers developing at variable times from several weeks to months after the onset of therapy. After cessation of therapy, antibody titers declined. In the absence of a widely available anti-EPO antibody assay, bone marrow myeloid/erythroid ratios provide the best method to ascertain if rHuEPO resistance is due to antibody formation. After therapy is stopped and antibody titers decline, suppressed erythropoiesis may be reversible and pretreatment levels of erythropoiesis are attained.

The relatively high prevalence of anti-rHuEPO antibody production prompts the question of when to initiate rHuEPO therapy. Premature initiation of erythropoietin therapy with subsequent development of

antierythropoietin antibodies may deprive the patient of the clinical benefits of this therapy when clinical signs of anemia eventually do develop and rHuEPO can be of greatest clinical benefit. When hematocrit values are below 20%, anemia likely contributes to adverse clinical signs characteristic of uremia. In addition, degree of azotemia, expected rate of progression of kidney failure, appetite and willingness to eat therapeutic diets, and rate of progression of anemia must all be considered in the risk-benefit analysis of when to start therapy. The advantages and disadvantages of rHuEPO therapy should be discussed with the owners when anemia appears to be contributing to the patient's deteriorating quality of life. Many pet owners may consider quality of life to be as or more important than quantity of life.

260.4.9.5 Future Treatment Directions

Future options for treatment of anemia of CKD may include development of species-specific erythropoietin and gene therapy.[120] Although not commerci-ally available, recombinant canine and feline erythropoietin have been developed.[121] They offer the hope of erythropoietin replacement therapy in dogs and cats without concern for antierythropoietin antibody formation. If concern for antibody formation can be eliminated, erythropoietin therapy could be initiated earlier in the course of chronic renal insufficiency and failure. It also has been demonstrated that gene therapy can be used to induce extrarenal production of erythropoietin in cats.[122]

260.4.10 Calcitriol Therapy

260.4.10.1 Rationale for Calcitriol Therapy

An undesirable consequence of reduced renal production of calcitriol is renal secondary hyperparathyroidism. Calcitriol (1,25-dihydroxyvitamin D), the most active metabolite of vitamin D, results from renal hydroxylation of 25-hydroxyvitamin D. Normally, calcitriol inhibits PTH synthesis and release and parathyroid gland growth, an effect mediated by the vitamin D receptor in the parathyroid gland. As functioning renal mass declines, renal production of calcitriol declines. In addition, phosphorus retention also inhibits renal hydroxylation of 25-hydroxyvitamin D to calcitriol and directly stimulates PTH release. By reducing PTH levels, calcitriol therapy minimizes abnormalities associated with renal secondary hyperparathyroidism. The effectiveness of calcitriol therapy in reducing PTH levels in dogs and cats with CKD is well established.[39] Although PTH has been proposed as a potential uremic toxin responsible for many constitutional signs or uremia, the clinical benefits of reducing PTH levels have not been conclusively documented. Nagode and colleagues[39] published results of a survey of veterinarians that use calcitriol in management of dogs and cats with CKD. Results of this survey reveal a high level of enthusiasm for calcitriol among veterinarians using the drug. Clinical impressions concerning use of calcitriol in dogs and cats suggest that patients seem (1) to be brighter and more alert and interactive with owners, (2) to have an improvement in appetite, (3) to be more physically active than before treatment, and (4) to have longer life spans. Further, these authors provide pathophysiologic support for the purported benefits of calcitriol therapy through referenced studies from multiple species. In contrast, Finco and colleagues,[123] using parathyroidectomy combined with an experimental model of renal failure, concluded that increased PTH levels do not contribute importantly to clinical signs of uremia in dogs. However, this study was not designed to directly address the effectiveness of calcitriol therapy in managing clinical signs of dogs and cats with CKD.

Despite reported favorable impressions concerning use of calcitriol, its role in managing dogs and cats with CKD should be confirmed by randomized, controlled clinical trials. Routine clinical practice is never *blind*, because owners and veterinarians know when active treatment is being received. Interpretation of uncontrolled studies is confounded by the desire of pet owners and clinicians for success, as well as the placebo effect, which can cause both parties to overestimate efficacy. In addition, calcitriol has the potential to promote hypercalcemia and renal injury if improperly used. A recommendation for or against routine use of calcitriol awaits results of properly designed controlled clinical trials.

260.4.10.2 Guidelines for Using Calcitriol

The primary goal of calcitriol therapy is to prevent or correct renal secondary hyperparathyroidism and its consequences. However, the decision to use calcitriol must be made with caution because hypercalcemia is a potentially serious complication. Sustained calcitriol-induced hypercalcemia will likely result in reversible or irreversible reduction in GFR. Although hypercalcemia reportedly occurs in 30% to 57% of humans treated with calcitriol, hypercalcemia appears to be an uncommon side effect in dogs treated with doses in the range of 2.5 to 3.5 ng/kg/day.[44] Hypercalcemia is likely to occur when calcitriol therapy is combined with calcium-containing phosphorus-binding agents, particularly calcium carbonate.

Serum phosphorus concentrations must be reduced to 6.0 mg/dL or lower before initiating calcitriol therapy (see discussion of management of hyperphosphatemia in this chapter). Serum phosphorus concentrations greater than 6.0 mg/dL may inhibit the effectiveness of calcitriol therapy and enhance the tendency for calcitriol to promote renal mineralization and injury. In addition, phosphorus restriction and calcitriol therapy are likely additive in reducing plasma PTH activities. Thus serum calcium and phosphorus concentrations should be carefully monitored in patients receiving calcitriol.

Calcitriol rapidly and effectively suppresses renal secondary hyperparathyroidism. An important advantage of calcitriol over other forms of vitamin D therapy in CKD is that calcitriol does not require renal activation for maximum efficacy. Dogs and cats appear to require much lower doses of calcitriol than those recommended for humans calculated on the basis of body weight.[39] Nagode and colleagues[39] have recommended a dose of 2.5 to 3.5 ng/kg body weight per day given orally to dogs and cats with CKD. The optimum maintenance dose for calcitriol must be determined for each patient based on serial evaluation of serum calcium and phosphorus and plasma PTH concentrations. The recommended endpoint of calcitriol therapy is normalization of PTH activity in absence of hypercalcemia. When the dose of calcitriol necessary to normalize PTH levels is associated with hypercalcemia, the daily dose may be doubled and given every other day. This approach is thought to be less likely to induce hypercalcemia because the effect of calcitriol on intestinal calcium absorption is related to the duration of exposure of intestinal cells to calcitriol.

1783
1784

When plasma PTH concentration is markedly elevated or when standard therapy with calcitriol fails to normalize plasma PTH levels, pulse calcitriol therapy has been recommended.[39] In this approach, patients are given 20 ng/kg of calcitriol twice per week in the evening on an empty stomach. Pulse therapy is usually used no longer than 1 to 2 months to suppress resistant hyperparathyroidism. If successful, calcitriol is then given at the standard daily dose. Because it enhances intestinal absorption of calcium and phosphorus, calcitriol should not be given with meals. Custom-made capsules or liquid preparations containing appropriate doses of calcitriol for use in dogs and cats are available from compounding pharmacies. Compounded calcitriol preparations should contain appropriate preservatives to prevent oxidation.

Early detection of hypercalcemia is indicated to limit the extent of renal injury. However, the onset of hypercalcemia after initiation of vitamin D therapy is unpredictable (i.e., it may occur after days to months of treatment). Therefore continued monitoring of serum calcium, phosphorus, and creatinine concentrations is necessary to detect hypercalcemia, hyperphosphatemia, or deteriorating renal function before irreversible renal damage ensues. Serum calcium, phosphorus, urea nitrogen, and creatinine concentrations should be monitored 1 week and 1 month after initiating calcitriol therapy, and monthly to bimonthly thereafter. The product of serum calcium and phosphorus concentrations should not exceed 60; the goal is to attain values between 42 and 52.[48] Calcitriol's rapid onset (about 1 day) and short duration of action (half-life less than 1 day) permits rapid control of unwanted hypercalcemia. If hypercalcemia develops, it is advisable to stop treatment completely rather than reduce the dose. Therapy may be reinstituted with a reduced dose when serum calcium concentration returns to normal and serum phosphorus concentration is less than 6.0 mg/dL.

260.4.11 Minimizing Progression of Renal Failure

All patients with CKD are at risk for progressive kidney disease. Progression may occur as a consequence of their primary renal disease, in association with a variety of secondary factors that may promote progressive renal disease, or both. An important therapeutic goal for managing patients with CKD is to minimize or prevent progressive loss of renal function. Treatment designed to limit progression of kidney disease may involve a variety of interventions including diet therapy, controlling hypertension, minimizing proteinuria, and modulating the renin-angiotensin-aldosterone system.

Clinical and experimental evidence indicates that dietary intervention may be effective in preserving renal structure and function and prolonging survival. In a randomized controlled clinical trial in dogs with naturally occurring CKD, dietary intervention significantly prolonged survival and slowed decline in renal function.[1] Dogs consuming the renal diet survived an average 593 days, whereas dogs consuming a maintenance diet survived an average 188 days. This beneficial effect applied over a range of serum creatinine values encompassing both stages 3 and 4 CKD. Renal function declined in both groups, but the decline was significantly greater in the dogs consuming the maintenance diet. The specific mechanisms underlying the beneficial effects of the diet were not determined. However, it is likely that at least dietary phosphorus restriction and omega-3 PUFA supplementation contributed to the favorable effect.[1,57,93,94] It is also likely that once the dogs progressed to a more advanced level of renal dysfunction, dietary protein restriction provided an additional period of symptomatic relief, thereby prolonging survival further.

Similarly, in a nonrandomized clinical trial, cats fed a renal diet survived significantly longer than cats that continued to consume their usual diet (633 days versus 264 days).[64] It was not possible to establish the differences between diets used in this study, but the therapeutic renal diet was reduced in protein and phosphorus content. The renal diet was shown to be beneficial in lowering serum phosphorus and PTH concentrations, and it was suggested that the beneficial effect of the diet may have been related to this effect.[99]

Treatments designed to limit hypertension and proteinuria may also be of value in slowing progression of kidney disease and kidney failure. Hypertension and proteinuria are a well-established risk factors for progression of renal disease in humans.[19,124] Similarly, studies at the University of Minnesota Veterinary Medical Center have shown that elevated blood pressure and proteinuria are risk factors for uremic crises and increased mortality in dogs with stages 3 and 4 CKD.[18] The effects of blood pressure and proteinuria on progression of feline CKD have not been established.

Experimental and clinical evidence has confirmed the beneficial effect of blood pressure control on slowing progression of diabetic and nondiabetic nephropathies in humans.[19,125] In one large clinical trial, the renoprotective effect of antihypertensive therapy was further enhanced by maintaining blood pressure below the usual target value.[126] As a consequence, the "ideal" blood pressure to attain using antihypertensive therapy in human patients with CKD remains unresolved. Patient factors such as the presence or absence of proteinuria may also influence the goals of therapy. Antihypertensive therapy was most effective in limiting progression of kidney disease in patients with proteinuria. A greater reduction in blood pressure appears to be necessary for equivalent renoprotection in patients with greater levels of proteinuria.[19,126] Further, independent of blood pressure control, reducing proteinuria has been shown to have a favorable influence on kidney disease progression.[127]

Evidence supporting the renoprotective value of antihypertensive therapy in dogs and cats with naturally occurring CKD is lacking. However, studies performed in dogs with induced CKD indicate that administration of the ACE inhibitor, enalapril, limited glomerular and systemic hypertension, proteinuria, and glomerular and tubulointerstitial lesions.[112] Interestingly, enalapril was renoprotective in this study, despite the fact that the dogs had only mild hypertension and relatively modest proteinuria. Enalapril has also been reported to ameliorate proteinuria and stabilize renal function in dogs with naturally occurring glomerulopathies with protein/creatinine ratios greater than 3.0.[22] Enalapril therapy was associated with a reduction in proteinuria of over 50%. Over the 6 months of study, serum creatinine increased by more than 0.2 mg/dL in 13 of 14 dogs receiving placebo, but only three of 16 dogs receiving enalapril. In this study, enalapril significantly reduced systolic blood pressure from a mean of 154+/–25 before therapy to 142+/-19 after 6 months of treatment.

In humans, ACE inhibitors are generally considered to be the antihypertensive drugs of choice in patients with CKD, particularly when proteinuria is evident, because they lower both systemic and intraglomerular pressures and proteinuria.[19] Further, ACE inhibitors are indicated for patients with proteinuric CKD for the purpose of reducing proteinuria, regardless of whether the patient is hypertensive. It appears appropriate to consider ACE inhibitor treatment for dogs with CKD when systolic blood pressure values are proven to remain above 160 mm Hg and when the urine protein/creatinine values exceed 1.0.

1784

1785

ACE inhibitors reduce blood pressure and proteinuria in cats; however, their unique renoprotective value has yet to be established in this species.[113] As a consequence, recommendations concerning use of ACE inhibitors in cats with CKD remain unresolved. The dihydropyridine calcium-channel blocker amlodipine is the antihypertensive drug of choice for most cats. However, in humans, dihydropyridine calcium-channel blockers appear to be associated with a greater risk of progression of kidney disease.[126] Although clinical impression suggests this is not the case in cats with CKD, the effect of amlodipine on progressive renal disease has not been critically examined in cats. It has been suggested that combining amlodipine with an ACE inhibitor might have greater renal-sparing potential. Studies into the clinical value of this drug combination are needed in cats with spontaneous renal failure.

The renoprotective effects of ACE inhibitors cannot be explained entirely by their effects on blood pressure. It is likely that renoprotection results in part from suppressing renal levels of angiotensin II. Angiotensin II may adversely affect the kidneys in several ways (Box 260-8).[125] Because of the role of angiotensin II in progression of CKD, angiotensin receptor blockers have also been considered for humans with CKD.[128] Angiotensin receptor blockers and ACE inhibitors differ in the mechanism by which they inhibit angiotensin II. The ACE inhibitors block conversion of angiotensin I to angiotensin II. However, angiotensin II formation

is not completely inhibited because it can also be generated by a nonACE-dependent pathway such as by the enzyme chymase. In addition, because bradykinin is normally degraded by ACE, ACE inhibitor therapy is associated with elevated bradykinin levels. Bradykinin is a vasodilator that may have renoprotective effects by stimulating nitric oxide production. Angiotensin receptor antagonists block the type 1 receptor but leave type 2 receptor effects unopposed, which appears to be important in vasodilation. In rats with nephropathy, angiotensin II antagonism has been reported to normalize proteinuria, eliminate inflammatory cell infiltration, and ameliorate glomerular and tubular structural changes.[129] A combination of an angiotensin receptor antagonist and ACE inhibitor has been suggested as a way to maximize blockade of the renin-angiotensin system by affecting both the bioavailability of angiotensin II and also by affecting its activity at the receptor level.[130] Each type of drug has been shown to be effective in reducing proteinuria and slowing progression of renal disease. However, in experimental models and clinical models in humans, combination therapy has proven more effective than either drug alone.[128] In humans there does not appear to be an increase in toxicity or adverse events with combination therapy.[125]

260.4.11.1 Box • 260-8 Potential Adverse Effects of Angiotensin II on the Kidneys

Glomerular hypertension

Impaired glomerular permselectivity

Mesangial cell proliferation

Induction of TGF-β, thereby increasing production of extracellular matrix

Increased aldosterone production

Macrophage activation; activation of inflammation-related transcription factors

Increased production of plasminogen activator inhibitor-1

Modified from Rosenberg ME: Chronic kidney disease: progression. NephSAP 2(3):94, 2003.

Whether combination therapy is safe, effective, and provides a therapeutic advantage needs to be determined for dogs and cats with CKD.

Blockade of the renin-angiotensin system limits both angiotensin II and aldosterone while retarding progression of renal disease. Recent studies have implicated aldosterone as an important pathogenic factor in this process.[131,132] Selective blockade of aldosterone, independent of renin-angiotensin blockade, reduces proteinuria and glomerular lesions in rats with experimental kidney disease. Where blockade of the renin-angiotensin system ameliorates proteinuria and glomerular injury, selective reinfusion of aldosterone restores proteinuria and glomerular lesions despite continued blockade of the renin-angiotensin system. This observation suggests an independent pathogenic role for aldosterone as a mediator of progressive renal disease. Aldosterone appears to promote progressive renal injury through both hemodynamic effects and direct

cellular actions.[131] It appears to have fibrogenic properties in the kidneys, perhaps in part by promoting production of the profibrotic cytokine TGF-β.[132] Experimental studies have shown that the aldosterone-receptor antagonist eplerenone may attenuate proteinuria and renal damage, independent of its effect on blood pressure. Although ACE inhibitors initially cause an acute reduction in aldosterone concentration, this effect is not sustained. It has been proposed that use of aldosterone-receptor antagonists in addition to ACE inhibitors will have additional benefits toward protecting the kidneys.[131] However, the role of this form of therapy has yet to be established.

Vasopeptidase inhibitors are agents that inhibit both ACE and neutral endopeptidase, an enzyme involved in the breakdown of natriuretic peptides, adrenomedullin, and bradykinin. They decrease angiotensin II production and increase accumulation of the previously mentioned vasodilators. In experimental renal disease, they appear to have a greater renoprotective effect than ACE inhibitors.[133] Studies on these agents have not been reported in dogs and cats with CKD.

Inflammation is a prominent feature of progressive renal diseases. Future therapies are likely to include novel inhibitors of specific profibrotic or proinflammatory cytokines and growth factors. The immunosuppressive agent mycophenolate mofetil has been shown to be renoprotective in remnant kidney rats.[134] Pirfenidone, an antifibrotic agent, has been shown to attenuate renal fibrosis.[135]

260.5 PATIENT MONITORING

Response to treatment should be monitored at appropriate intervals so that treatment can be individualized to the specific and often changing needs of the patient. The data base obtained before initiating therapy or after correcting an overt uremic crisis should be used as a baseline for comparison of the patient's progress. This evaluation should be repeated at appropriate intervals. Evaluations every 2 to 4 weeks are suggested until the initial response to therapy can be established. However, the frequency of evaluation may vary depending on severity of renal dysfunction, complications present in the patient, and response to treatment. Patients receiving therapy with erythropoietin or calcitriol require frequent, life-long monitoring. After the initial response to therapy has been established, dogs and cats in stages 1 and 2 CKD may require evaluation as infrequently as every 6 to 12 months. However, patients with substantial proteinuria may require monitoring much more frequently, depending on the course of their disease. Cats and dogs in stages 3 and 4 CKD should be re-evaluated about every 2 to 4 months, depending on the stability of their renal function. Specific recommendations for monitoring are described in the various treatment sections.

261 CHAPTER • 261 Glomerular Diseases

Shelly L. Vaden

Glomerular diseases are a leading cause of renal disease and renal failure in dogs.[1] In randomly selected dogs, the incidence of glomerular lesions is as high as 43% to 90%,[2] and the incidence appears to increase with age.[3] Glomerular diseases also occur in cats, although they are less common. It has been accepted that amyloidosis and glomerulonephritis are the most common glomerular diseases of dogs and cats (Box 261-1). However, to make progress toward improved diagnosis and management of dogs and cats with glomerular disease, veterinarians must come to consider the different forms of glomerulonephritis as specific entities: membranous glomerulopathy, membranoproliferative glomerulonephritis and proliferative glomerulonephritis (including the subclass of IgA nephropathy). The proposed pathogenesis of each entity is somewhat different; in humans this leads to different clinical features and specific treatment recommendations for each disease.[4,5] Hereditary nephritis and minimal change disease are less common glomerular diseases in dogs and cats.

261.1 NORMAL GLOMERULAR STRUCTURE AND FUNCTION

The glomerulus is a modified capillary bed that functions as a filter, across which an ultrafiltrate of the plasma is formed.[4,5] The filtration barrier is composed of three layers: the fenestrated endothelium, the glomerular basement membrane (GBM), and the visceral epithelial cells, or *podocytes* (Figure 261-1). This complex structure is freely permeable to water and small dissolved solutes but retains cells and most macromolecules, such as proteins. The major determinant of passage into the filtrate is molecular size. Small molecules, such as inulin (5000 daltons), pass freely through the filter. Substances are retained with increasing efficiency as they increase in size to approximately 60,000 to 70,000 daltons; only small amounts of substances larger than this are filtered. Although the issue currently is a matter of dispute, many believe that ionic charge also influences filtration, and that negatively charged proteins are retained to a greater extent than would be predicted by size alone.[6] The podocyte foot processes and the slit diaphragms between them, as well as the basement membrane and the endothelium, are rich in negatively charged glycoproteins, creating this charge barrier. These polyanions are believed to play an important role in the maintenance of normal glomerular permeability and visceral epithelial cell shape. Albumin, a negatively charged protein with a molecular weight of 69,000 daltons, is normally largely excluded from the filtrate.

Despite this complex filtration system, small amounts of albumin and other proteins are normally found in the filtrate. Substantial degradation of these proteins occurs, resulting in excretion only of peptide fragments, which are not detected by routine total protein assays. Proteins and peptide fragments may also undergo resorption in the nephron distal to the glomerulus.[6]

261.2 CLINICAL FINDINGS IN GLOMERULAR DISEASE

261.2.1 Signalment

Glomerular disease can develop in a dog of any age but appears to be most common in middle-aged to older dogs. The prevalence of microalbuminuria, a marker of increased glomerular permeability, increases as dogs age, with more marked increases seen beyond 6 years of age.[7] The average age of 375 dogs with a variety of glomerular diseases reported in five studies was 8.3 years.[1,8–11] Male and female dogs were equally

represented. However, the average age and gender predilection seen with specific glomerular diseases varies somewhat from the overall averages. Glomerular diseases often occur secondary to another disease process. Infectious and noninfectious inflammatory diseases may be more likely in young and middle-aged animals, whereas neoplasms are more common causes of glomerular disease in older patients. Familial glomerular diseases often are manifested at an early age. Several breeds of dogs are known to have familial glomerular diseases (Table 261-1). Labrador retrievers and golden retrievers may have a higher incidence of glomerular disease; however, the possibility that this increased representation reflects the popularity of these breeds requires further evaluation.[8,12]

261.2.2 History

The clinical signs associated with glomerular disease vary considerably, depending on the severity of proteinuria and the presence or absence of renal failure.[8,9,13] Many animals with glomerular disease are asymptomatic, and proteinuria is detected during routine health screening. Alternatively, animals may manifest specific signs related to an underlying inflammatory, infectious, or neoplastic condition (Boxes 261-2 and 261-3). Signs of glomerular disease may be nonspecific (e.g., weight loss, lethargy) or consistent with chronic renal failure or uremia (polyuria, polydipsia, anorexia, vomiting, and malodorous breath). Acute renal failure is a less common presentation for animals with glomerular disease. When urinary protein losses are severe, signs of fluid retention (e.g., abdominal enlargement consistent with ascites, peripheral edema) or thromboembolism (e.g., dyspnea, loss of limb function) may be present. Hypertensive damage to the central nervous system, eyes, or heart may induce a variety of clinical signs.

261.2.2.1 Box • 261-1 Glomerular Diseases Described in Dogs and Cats

- Amyloidosis
- Focal segmental glomerulosclerosis
- Glomerulonephritis
  - Crescentic type (rare)
  - Membranoproliferative form
    - Type I (mesangiocapillary)
    - Type II (dense deposit disease)?
  - Proliferative glomerulonephritis (mesangial and endocapillary)
- IgA nephropathy

Glomerulosclerosis

Hereditary nephritis

Lupus nephritis

Membranous glomerulopathy*

Minimal change glomerulopathy

* Membranous glomerulopathy is the most common glomerular disease in cats; other glomerular diseases appear to be uncommon in cats.

Figure 261-1 Electron micrograph of a glomerular capillary wall showing the filtration barrier composed of the fenestrated endothelium, the glomerular basement membrane, and the visceral epithelial cell (podocyte). (Courtesy J.C. Jennette, Chapel Hill, NC, School of Medicine, University of North Carolina.)

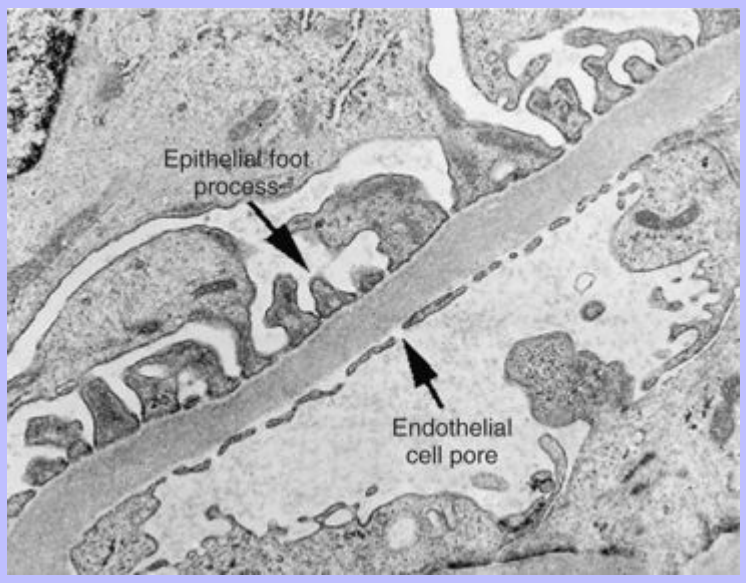

Table • 261-1 Breeds of Dogs with Familial Glomerulopathies

BREED	GLOMERULAR DISEASE
Beagle	Amyloidosis
Bernese mountain dog	Mesangiocapillary glomerulonephritis
Bull terrier	Hereditary nephritis
Cocker spaniel (especially English)	Hereditary nephritis
Dalmatian	Hereditary nephritis
Doberman pinscher	Glomerulosclerosis, cystic glomerular atrophy
English foxhound	Amyloidosis
Greyhound	Glomerular vasculopathy and necrosis
Newfoundland	Glomerulosclerosis
Rottweiler	Atrophic glomerulopathy
Samoyed (rare)	Hereditary nephritis
Shar Pei	Amyloidosis
Soft-coated wheaten terrier	Proliferative and sclerosing glomerulonephritis

261.2.3 Physical Examination Findings

The physical examination is often unremarkable in dogs with glomerular disease.[8,9,13] Nonspecific evidence of systemic disease may be present, such as poor body condition or poor haircoat. Dogs with advanced renal failure may have oral ulcerations, pale mucous membranes, or dehydration. Subcutaneous edema or ascites, or both, is sometimes noted. Occasionally dogs have physical evidence of thromboembolic disease, such as dyspnea or a decreased or absent peripheral pulse. Evidence of a predisposing inflammatory, infectious, or neoplastic process may be detected during the physical examination. The kidneys of affected animals are variable in size. Animals with chronic renal failure often have small, firm, irregularly shaped kidneys, whereas those with milder disease often have normal-sized or, occasionally, enlarged kidneys.

261.2.4 Clinicopathologic and Imaging Findings

Proteinuria is the hallmark of glomerular disease and is discussed in Chapter 32. A urine protein to creatinine ratio (UPC) greater than 0.5 in a urine sample free of evidence of inflammation and macroscopic hematuria is abnormal. With respect to the UPC, no magic number or range of numbers is diagnostic for any one renal disease, and the overlap in expected ranges is too broad to be clinically reliable. In general, dogs with amyloidosis or membranous nephropathy have the highest UPCs, and those with tubulointerstitial disease have lower values.[14] Glomerular lesions have been identified in dogs without proteinuria.[15,16] In three studies of urine albumin in canine models of glomerular disease, microalbuminuria was detected prior to increases in the UPC, and the magnitude of microalbuminuria increased over time in dogs that eventually developed an increased UPC.[17–19] It therefore seems reasonable to conclude that a dog with persistent microalbuminuria of increasing magnitude should be assessed as having an injurious process to the glomerular filtration barrier and may eventually develop overt proteinuria.

Isosthenuria is a variable finding in dogs and cats with glomerular disease. In one study of dogs with glomerulonephritis, 37% had urine specific gravities in excess of 1.035, and isosthenuria was detected in only 29%.[9] However, dilute urine (i.e., a urine specific gravity less than 1.016) was more common in dogs with amyloidosis, occurring in 63% of dogs, whereas only 5.1% were able to concentrate above 1.035.[13] The presence of renal azotemia and an intact concentrating ability, called *glomerulotubular imbalance,* is indicative of glomerular disease. Cylindruria is common in dogs with glomerular disease; casts are most often hyaline but can be granular, waxy, or fatty. It is believed that proteins are packaged into casts to protect the renal tubular epithelium from their damaging effects. Renal hematuria develops with glomerular injury in humans and is more common in specific diseases (e.g., IgA nephropathy, mesangial proliferative glomerulonephritis), but it appears to be less common in dogs with glomerulopathies.[5] Erythrocytes that have passed through the abnormal glomerular capillary bed are often misshapen; the morphology of urine erythrocytes can be used to differentiate hematuria of glomerular origin from that due to other causes.

Hypoproteinemia due to hypoalbuminemia develops in many dogs and cats with glomerular disease and is more likely in animals with heavy proteinuria. Hypoalbuminemia occurred in 60% and 70% of dogs with glomerulonephritis or amyloidosis, respectively.[9,13] Azotemia, hyperphosphatemia, and metabolic acidosis, consistent with renal failure, may be present in dogs with severe disease. Of dogs with glomerulonephritis or amyloidosis, 53% and 26% respectively, were not azotemic.[9,13] Nonregenerative anemia that develops secondary to renal failure or to a systemic disease is observed in many affected animals. Other hematologic abnormalities also may reflect concurrent and possibly underlying systemic diseases. Thrombocytosis and hyperfibrinogenemia are common findings in dogs with glomerular disease.

The nephrotic syndrome of hypoalbuminemia, proteinuria, hypercholesterolemia, and edema, although pathognomonic for glomerular disease, was present in only 15% of dogs with glomerulonephritis in one study.[9] Incomplete nephrotic syndrome (i.e., without edema or ascites) was more common, occurring in 49% of the dogs.[9] Nephrotic syndrome is expected to occur more commonly in dogs with amyloidosis, membranous nephropathy, hereditary nephritis, and minimal change disease because of the heavy proteinuria associated with these diseases.[5,14]

On abdominal radiographs, the kidneys may appear normal or small and irregular. Some animals may actually have enlarged kidneys. Similar changes in shape and size can be seen with ultrasonographic scans, on which increased echogenicity of the cortex and loss of corticomedullary distinction may also be noted. The renal pelvis may be mildly dilated if polyuria is present or if fluids are being administered.

Dogs and cats with proteinuria should be thoroughly evaluated for underlying infectious, inflammatory, or neoplastic diseases (see Boxes 261-2 and 261-3). This evaluation should include a thorough physical examination, and diseases of the oral cavity and skin should not be overlooked as potential underlying diseases. Aspiration cytology should be performed on all cutaneous and subcutaneous masses. Serologic testing for regional infectious diseases, as well as antinuclear antibody testing, should be performed. During radiographic or ultrasonographic evaluation of the abdomen, attention should be given to other organs to detect any other disease process. Thoracic radiographs should also be evaluated in middle-aged to older dogs.

1788

1789

261.2.5 Histologic Diagnoses

Renal biopsy provides a definitive diagnosis of glomerular disease but may not be needed if treatment of a potential underlying disease leads to resolution of the proteinuria or if end-stage renal disease is already

present. When evaluated appropriately, renal biopsy specimens can provide important clinical information about the type and severity of lesions in dogs and cats with glomerular disease. In fact, obtaining an accurate histologic diagnosis may be one of the more important factors in successful management of the dog or cat with glomerular disease. Clinical decisions regarding the diagnosis, treatment, and prognosis can be made from the information obtained through renal biopsy.

261.2.5.1 Procurement and Processing of the Renal Biopsy Specimen

The procedure used to obtain a renal biopsy specimen is discussed in Chapter 84. When a specimen is to be used for evaluation of glomerular disease, only cortical tissue should be obtained, because biopsy of the medulla is not needed and is associated with a greater risk of hemorrhage, infarction, and fibrosis. The use of general anesthesia is associated with an ability to obtain better quality specimens. An adequate sample of cortex has a minimum of five glomeruli when examined by light microscopy, although one glomerulus may be all that is needed to make a definitive diagnosis.

If a percutaneous method is used to obtain a renal biopsy specimen from a patient with glomerular disease, at least two quality samples of renal cortex should be obtained, using either a 16-or 18-gauge needle. A dissecting microscope can be used to verify that two adequate biopsy samples have been obtained. One sample should be placed in formalin, and the other should be divided into two smaller pieces containing glomeruli. One piece is put into a fixative suitable for electron microscopy (EM) (e.g., 4% formalin plus 1% glutaraldehyde in sodium phosphate buffer), and the other piece is frozen for immunofluorescent microscopy (IFM). An alternative to freezing is to immerse the tissue in ammonium sulfate-N-ethylmaleimide fixative (i.e., Michel's solution), which preserves tissue-fixed immunoglobulins. Wedge biopsies should be divided in a similar fashion; tissue for EM should be minced appropriately.

Thin sections (2 to 4 μm) of paraffin-embedded tissue should be used for light microscopy because standard sections of 5 to 6 μm are too thick for adequate assessment of glomerular cellularity and capillary loop thickness.[4] Hematoxylin and eosin staining can be used for initial assessment of the general appearance of the specimen. However, periodic acid–Schiff (PAS), which stains glycoproteins, is the preferred stain of many nephropathologists and is particularly useful for demonstration of interstitial and glomerular scarring and for assessment of the GBM. Methenamine silver specifically stains the basement membrane of the tubules, glomeruli, and Bowman's capsule. Trichrome is useful for evaluation of the mesangium and is also the best light microscopic stain for visualization of immunoglobulins. Congo red can be used to demonstrate the presence of amyloid.

EM of renal biopsy specimens has not been used frequently enough in dogs and cats to determine the diagnostic merit in groups of patients with varying presentations; however, in humans, EM appears to be most helpful in the evaluation of individuals with renal hematuria, a familial history of renal disease, or proteinuria with normal renal excretory function. Nevertheless, a sample should be collected for EM in nearly all dogs and cats undergoing renal biopsy, because the exact diagnosis is most likely unknown. IFM or immunohistochemistry should include at a minimum stains for immunoglobulin M (IgM), IgG, IgA, and C3.

261.2.5.2 Evaluation of the Renal Biopsy Specimen

Whenever possible, specimens should be evaluated by a pathologist with expertise in nephropathology. Renal biopsy specimens from proteinuric dogs and cats should be evaluated by light microscopy, EM, and IFM. Limiting the evaluation to light microscopy alone often allows for only a subjective interpretation of

the glomerular lesion, leaving too much room for error. Although many reports have described glomerular lesions in dogs and cats, the use of different nomenclature and different morphologic criteria among pathologists sometimes makes interpretation and comparison of the data difficult at best. A standard classification system for the characterization of glomerular lesions in dogs and cats needs to be embraced. The World Health Organization (WHO) criteria for the classification of human glomerulopathies have proved to be applicable to glomerular diseases in dogs.[11] General acceptance of this system would lead to a better understanding of the natural history, pathogenesis, and response to treatment in the various glomerular diseases in dogs and cats.

The normal glomerulus contains four to eight lobules, each composed of capillaries supported on a centrilobular core of mesangial matrix (Figure 261-2).[4,5] The GBM is thin, delicate, PAS-positive, and argyrophilic. The glomerular capillary lumen is normally widely patent and lined with eosinophilic endothelial cell cytoplasm (Figure 261-3). There should be only one or two nuclei per mesangial cell region. Parietal epithelial cells, visceral epithelial cells, endothelial cells, and mesangial cells comprise the normal glomerulus and can easily be identified by EM (see Figure 261-1). The flattened parietal epithelial cells line the inner surface of Bowman's capsule. The visceral epithelial cells (podocytes) line the outer surface of the capillary loops and rest on the GBM. The podocytes, which are characterized by their foot processes, form the outermost layer of the capillary wall. The endothelial cells line the inner surface of the capillary loops, with the nuclei disposed centrilobularly, toward the mesangium. The fenestrations of the endothelial cell cytoplasm can be visualized easily. The normal GBM should be approximately the same thickness as the base of a foot process turned 90 degrees.

1789

1790

Figure 261-2 Schematic diagram showing the composition of each lobule in a normal capillary. (Courtesy J.C. Jennette, Chapel Hill, NC, School of Medicine, University of North Carolina.)

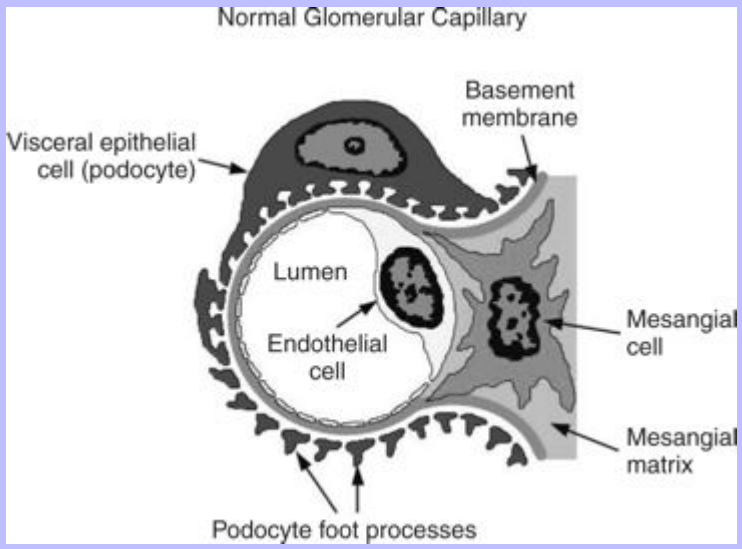

Figure 261-3 Normal glomerulus from a dog. Note that the capillary lumens are widely patent and the capillary loops are thin, often appearing discontinuous. Hypercellularity is not present.

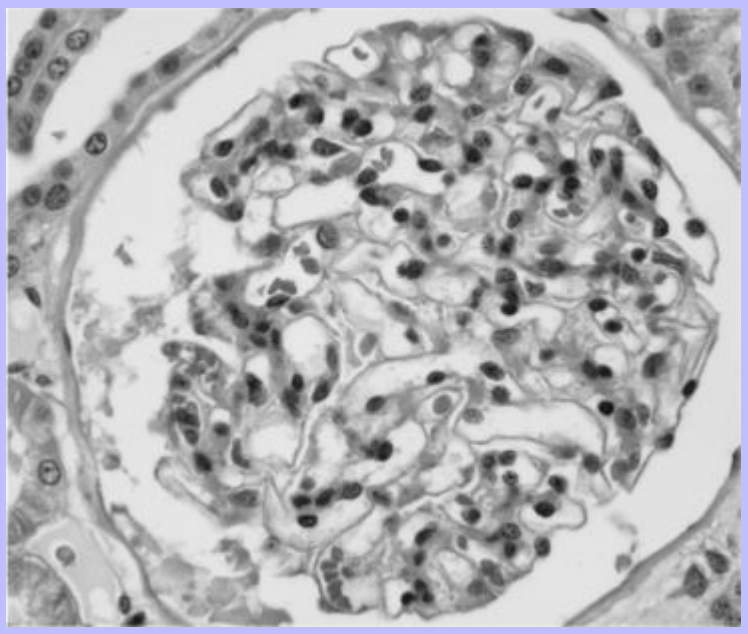


When glomerular lesions are present, if nearly all of the glomeruli are affected, the disorder is *generalized*. The disorder is *focal* if less than half of the glomeruli are affected. When evaluating individual glomeruli, if the entire glomerulus is affected, the pattern is *diffuse,* or *global*. The lesion is *segmental* or *local* if only a few lobules within affected glomeruli are involved. Descriptions of each of the pathologic findings in the varying glomerular diseases are provided below. Lupus nephritis can be associated with several glomerular lesions and, when active, may have an interstitial infiltrate of mixed inflammatory cells and acute damage to the tubules.[5] *Crescents* can loosely be defined as two or more layers of cells in Bowman's space and are suggestive of severe injury. Crescentic glomerulonephritis, which is diagnosed when crescents are present in 50% or more of the glomeruli, appears to be uncommon in dogs and cats.

Immunofluorescent staining should be positive in dogs or cats with either *in situ* immune complex formation, as is believed to occur with primary membranous glomerulopathy, or with deposition of circulating complexes, as may occur with type I membranoproliferative glomerulonephritis and proliferative glomerulonephritis.[4,5] Because true anti-GBM GN has not been documented in the dog or cat, the expected immunostaining pattern is discontinuous, occurring either in the capillary loops or in the mesangium. The mesangium plays a role in the clearance of macromolecular debris from the glomerular capillary wall. As such, it is possible that some of the immunoglobulin present in the glomeruli of some dogs is not specific in nature and not associated with clinically relevant immunologic injury. Therefore the prevalence and relevance of positive immunofluorescent staining in dogs without glomerular disease needs further investigation.

261.3 GLOMERULAR DISEASES

Many glomerular diseases affect dogs; fewer appear to affect cats. Many of these diseases historically have been lumped under the umbrella of "glomerulonephritis" (see Box 261-1). As a profession, veterinary medicine needs to move beyond this generalization and begin to characterize each disease as a separate entity. The historical approach of combining diseases characterized as glomerulonephritis into one group has led to limited information on the natural history and effective treatment of the individual diseases in dogs and cats. In human medicine, the characterization of each glomerular disease as a specific entity has led to an advanced understanding of the pathogenic events leading to the specific glomerular disease. This enhanced understanding is forging the way to the development of optimized and specific therapeutic approaches for the individual glomerular diseases and to more clearly defined prognoses.[4,5] This section outlines what is known about the individual diseases in dogs and cats, with additional information garnered from the wealth of knowledge on these diseases in humans.

Acquired glomerular injury is the result of damage sustained after immune complex formation or deposition (e.g., membranous nephropathy, membranoproliferative glomerulonephritis, proliferative glomerulonephritis) or of damage caused by systemic factors that affect the glomerulus (e.g., amyloidosis, focal segmental glomerulosclerosis, minimal change disease). Although the effects of systemic factors vary, some general statements can be made regarding the pathogenesis of the immune complex–mediated glomerulonephropathies.[20] Immune complexes that are deposited in the glomerulus or that form *in situ* initiate glomerular damage. Cell-mediated immune mechanisms also take part in the pathogenesis of glomerular inflammation. Once glomerular damage has been initiated, other processes contribute to glomerular injury, including activation of complement and of the coagulation cascade and resident cells; influx of neutrophils, monocytes, and platelets; release of proteolytic enzymes; synthesis of cytokines or other growth factors; generation of proinflammatory lipid mediators; and alteration of hemodynamic factors. The mechanisms that determine whether progressive renal damage or resolution of the process occurs are unclear.

261.3.1 Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN) may be the most common glomerular disease in dogs, accounting for 20% to 60% of dogs in various studies.[1,21] However, glomerular lesions are most likely to be called MPGN when they have not undergone thorough evaluation, including the use IFM and EM; the incidence of MPGN is most certainly overestimated in dogs. On the other hand, MPGN is more common in humans living in underdeveloped countries, where exposure to harmful environmental agents, including infectious disease, may be greater than in those living in developed countries.[5] MPGN therefore may be the glomerular lesion expected to be most common in dogs, but it probably is less common than currently reported.

261.3.1.1 Clinical Features

The mean age of dogs with MPGN in one study was 10.5 years.[11] Males and females appear to be equally affected. Even though the disease is common, no thorough study of MPGN as a distinct glomerular disease has been done in dogs. In humans the disease is characterized by a slowly progressive course, and about 50% of those affected develop nephrotic syndrome.

MPGN has been identified as a familial disease in Bernese mountain dogs. A unique, rapidly progressive form of MPGN that is accompanied by tubular necrosis and interstitial inflammation and is uniformly fatal

has been reported in association with *Borrelia burgdorferi* infection in dogs.[12] The average age of affected dogs was only 5.6 years. Labrador retrievers and golden retrievers were significantly predisposed to developing this lesion.

1790

1791

261.3.1.2 Pathogenesis

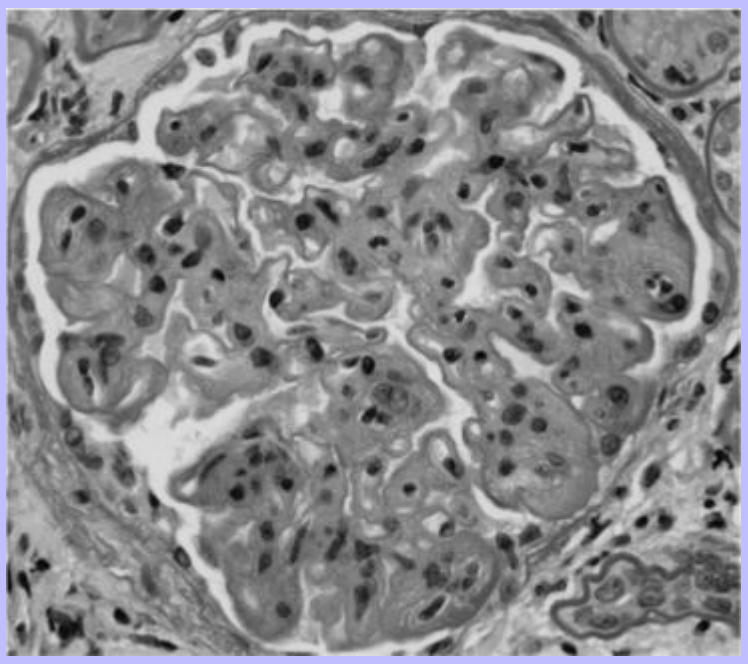
There are two types of MPGN.[4,5] Type I MPGN, also called mesangiocapillary GN, is often induced by infectious diseases and is characterized by immune complex accumulation on the subendothelial side of the GBM. The intramembranous dense deposits that characterize type II MPGN, also called *dense deposit disease,* are not immune deposits but are of undefined origin; type II MPGN is not associated with infectious diseases and seems to be uncommon in dogs. Renal lesions appearing to be type I MPGN have been associated with a variety of infectious diseases in dogs (see Box 261-2 and Box 261-3). The accumulation of immune complexes or dense deposits leads to cytokine-mediated activation and expansion of the mesangium and an inflow of leukocytes. In type II MPGN, activation of the alternate pathway of complement predominates, whereas in type I MPGN activation of the classic pathway occurs.

In humans with MPGN, hypocomplementemia is so common that this disease is sometimes called *hypocomplementemic GN*. Hypocomplementemia appears to develop either from increased consumption secondary to immune complex activation of the classic pathway or from the presence of anticomplement autoantibodies known as *nephritic factors*. Interestingly, type I MPGN also occurs in Brittany spaniels and in humans with congenital C3 deficiency.[15] The pathogenic role of hypocomplementemia is not understood.

261.3.1.3 Histopathologic Characterization

MPGN is diagnosed when both thickened capillary loops and mesangial hypercellularity (more than three nuclei per mesangial region) are present (Figure 261-4).[4,5,11] The glomerulus may become enlarged and segmented or lobular in appearance. The activated mesangium expands the capillary walls and extends into the subendothelial space, causing the double contour, or “railroad,” appearance of the GBM that can be seen with light microscopy. With IFM, immune complex deposition can be identified in type I MPGN as granular deposits of C3 in combination with IgG, IgM, or IgA, or combinations thereof, in the GBM or mesangium or both. With EM, type II MPGN can be differentiated from type I by the identification of intramembranous dense deposits. EM also is used to identify the immune deposits in type I MPGN.

Figure 261-4 Glomerulus from a dog with membranoproliferative (mesangiocapillary) glomerulonephritis. Note the thickened capillary loops and the mesangial hypercellularity, which result in the segmented and lobular appearance.



261.3.1.4 Specific Treatment

Effective treatment of the underlying infectious, inflammatory, or neoplastic disease is the cornerstone of management of patients with MPGN. Because activation of platelets appears to be involved in the pathogenesis of this disease, antiplatelet drugs also should be given.[5]

261.3.1.5 Prognosis

Specific data regarding the prognosis of MPGN in dogs is lacking. In people, azotemia, severe proteinuria, systemic hypertension and marked tubulointerstitial lesions at presentation are the most significant predictors of an unfavorable outcome.[5]

261.3.2 Membranous Nephropathy

Membranous nephropathy (MN) is probably the second most common glomerular disease in dogs, accounting for up to 10% to 45% of reported cases.[2,11,22–24] It is the most common glomerular disease of cats, in which other forms of glomerular disease are uncommon.[25,26] Because there is rarely evidence of an inflammatory

response in the glomeruli or interstitium, the disease is more correctly called a glomerulopathy or nephropathy, rather than glomerulonephritis.

261.3.2.1 Clinical Features

As in humans, MN appears to be more common in male dogs and cats (approximate male to female ratios are 1.75:1 in dogs and 6:1 in cats). The mean age of affected dogs from four studies was 8 years, but there was considerable range (1 to 14 years). The disease is more common in younger cats, with an approximate mean age of only 3.6 years (range, 1 to 7 years).[25] There does not appear to be any breed predilection, although a preponderance of Doberman pinschers was seen in one report. Interestingly, four of five of these Dobermans were 3 years of age or younger, which may suggest a familial pattern.[23]

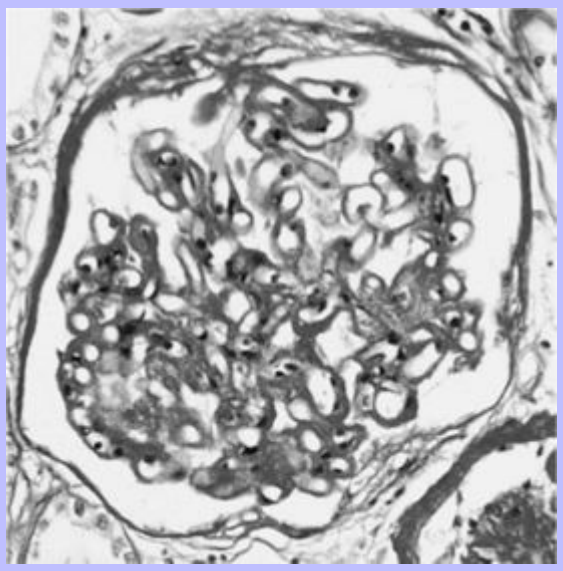
Proteinuria in animals with MN may be massive, often as high or higher than that which occurs in dogs with amyloidosis.[14] Because of this heavy proteinuria, many animals present with nephrotic syndrome. Microhematuria is reported in 30% to 40% of humans with MN but has not been systematically studied in dogs and cats.[5] Cats and dogs with MN may present with signs of renal failure. Many cats have normal to enlarged kidneys at presentation.

Membranous nephropathy has four ultrastructural stages that correlate with the temporal evolution of the disease and the clinical presentation in dogs, cats, and humans.[4,5,23,25] There is some suggestion that these stages also correlate with therapeutic outcomes in humans with MN, in that people may be more likely to respond to appropriate management if they are in one of the first two stages. More advanced stages in cats and dogs have been shown to correlate with more severe azotemia, whereas animals with milder disease were more likely to have nephrotic syndrome.[23,25]

261.3.2.2 Pathogenesis

In humans, MN is considered to be either primary (i.e., idiopathic) or to occur secondary to another disease process; primary disease is most common.[5] In primary MN, immune complexes are found mainly in the subepithelial spaces of the capillary loops. Secondary MN can be distinguished from the primary form by the presence of immune complexes in the mesangium or subendothelial space (or both) and in the subepithelial space. The finding of antibodies on the subepithelial side is unique to MN and suggests that 1791
binding occurs on the urinary side of the GBM. The subsequent activation of complement and cytokine 1792
responses may be reduced, because the site of reaction is distant to the circulation, which contributes to the lack of inflammation associated with MN.

Figure 261-5 Glomerulus from a dog with membranous nephropathy. Note the thickened, rigid-appearing capillary loops and the lack of hypercellularity. (Courtesy of J.L. Robertson, Blacksburg, VA, Virginia Maryland Regional College of Veterinary Medicine.)



Although the exact pathogenesis of this disorder is unknown, it is considered to be an immune complex–mediated disease. There is evidence to support both *in situ* formation of immune complexes and trapping of circulating immune complexes. However, in humans with primary MN, the weight of evidence supports the *in situ* reaction of unbound antibody with fixed antigens, perhaps intrinsic GBM or glomerular visceral epithelial cells antigens. In this regard, primary disease may be a true autoimmune disorder.

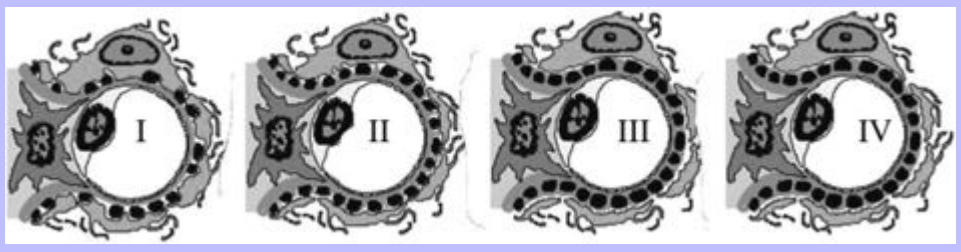
Circulating immune complexes most likely play a larger role in patients with secondary disease. Proteinuria probably develops through a complement-dependent mechanism, independent of inflammatory cells. The terminal complement complex (C5b-9 membrane attack complex) has been implicated in the pathogenesis of this disease. Increased urinary concentrations of the membrane attack complex have been demonstrated in some, although not all, individuals with MN. Demonstration of this complex may be more likely early in the disease process, when active immune deposit formation occurs. Myriad immune system irregularities have been reported in association with MN in humans (e.g., altered CD4+ to CD8+ ratio, Fc receptor dysfunction, and impaired lymphocyte and suppressor cell function), which supports a pathogenic role for an underlying immunologic defect. These irregularities are perhaps based on a genetic susceptibility, a theory supported by familial clustering of MN in humans.[4,5]

261.3.2.3 Histopathologic Characterization

The normally lacey-appearing GBM becomes uniformly thickened and more rigid as a result of the deposition of immune complexes in the subepithelial spaces in MN (Figure 261-5).[4,11] New basement membrane material accumulates around the immune deposits. Because the deposits do not become

impregnated with silver, “spikes” may be identified on the outside of the GBM when an appropriate silver stain is used. Advanced cases may show irregular thickening and distortion of the capillary walls with occasional widening of the mesangium. Immunofluorescent microscopy is useful in determining the site of immune complex deposition. Staining of the immune complexes produces a beaded appearance along the GBM and can be so heavy that it may be difficult to differentiate from a linear pattern. In secondary cases, the mesangial spaces are also positive. In dogs with MN, IgG and C3 have most commonly been identified, although there have also been reports of finding IgM and IgA.[11,21] Several studies have reported affected dogs and cats in which positive staining was identified only in the glomerular capillary loops, which suggests the presence of primary, or idiopathic, disease in these animals.[21–23,25]

Figure 261-6 Ultrastructural stages in the progression of membranous nephropathy. (Courtesy J.C. Jennette, Chapel Hill, NC, School of Medicine, University of North Carolina.)



Electron microscopy should be used to confirm the location of the immune deposits and to characterize the stage of disease progression (Figure 261-6).[4,23,25] Deposition of immune complexes, progressive engulfment of the complexes by the surrounding GBM, and eventual resolution of the deposits characterize the stages. Stage I is characterized by subepithelial dense immune deposits without adjacent projections of basement membrane material and only minimal thickening of the GBM. Projections of adjacent GBM material, or spikes, are identified in stage II. In stage III, these projections surround the immune deposits. In stage IV, the GBM is markedly thickened, and electron-lucent zones have replaced some or all of the electron-dense deposits. In advanced stage IV disease, sometimes referred to as stage V, there is variable thickening of the GBM and apparent resolution of the electron-dense deposits. In some affected animals, staging is difficult because several stages of disease may be present simultaneously.

261.3.2.4 Specific Treatment

In addition to identification of potentially inciting disease processes and nonspecific management of proteinuria, immunosuppressive therapy may be warranted in dogs or cats with persistent proteinuria caused by MN, particularly if they appear to have idiopathic, or primary, disease and are not azotemic. Affected humans with similar clinical pictures may respond to immunosuppressive therapy with corticosteroids combined with an alkylating agent (i.e., cyclophosphamide or chlorambucil).[5] The approach that has proven most beneficial is alternation of methylprednisolone and chlorambucil every other day for 6 months. Cyclosporine is considered a valid therapeutic option for patients not responding to corticosteroids and alkylating agents. Even when treatment is effective, relapses may occur. The use of immunosuppressive therapy in dogs and cats with membranous nephropathy needs to be studied more carefully.

261.3.2.5 Prognosis

Although MN appears to be progressive in some dogs and cats, the progression may be slow enough that many animals can lead relatively normal lives. In a study of 24 cats with MN, four (17%) survived 4 to 10 months and eight (33%) had long-term survival of 2.5 to 6 years; clinical remission occurred in seven (29%) of the cats. Corticosteroids were administered to three of the eight long-term survivors. However, 11 cats (46%) died or were euthanized due to nephrotic syndrome or renal failure shortly after diagnosis.[26] Long-term survivors had only IgG deposition, C3 deposition, or both; cats that also had deposition of IgM or IgA had a shorter survival period. Stage III and stage IV disease, defined by the presence of intramembranous deposits, was associated with a poorer prognosis.[26]

1792

1793

Survival data for dogs is more difficult to extract from prior reports, although it appears to be similar to what has been reported in cats. Survival in dogs has ranged from 4 days to greater than 3 years.[23] Spontaneous remissions have been reported. Spontaneous remission occurs in 20% to 30% of humans with MN, whereas 20% to 40% of cases progress to renal failure.[5] The risk of progression in humans appears to correlate with the magnitude of proteinuria and renal function impairment; patients with the highest degree of proteinuria and azotemia are more likely to have more rapid progression compared with other patients.

261.3.3 Proliferative Glomerulonephritis

Proliferative glomerulonephritis, caused by endocapillary or mesangial proliferation, accounted for 2% to 16% of glomerular lesions in dogs in two studies.[11,21] In humans a complete pathologic diagnosis requires both a morphologic description (e.g., focal mesangial proliferative glomerulonephritis) and a specific disease designation (e.g., IgA nephropathy, lupus glomerulonephritis).[4,5] With the exception of IgA nephropathy, proliferative glomerulonephritis in dogs has not included the specific disease designation.[27,28] It therefore is difficult to correlate the diseases that have been described in dogs with the wealth of information regarding pathogenesis and treatment known for the specific diseases in humans.

261.3.3.1 Clinical Features

Dogs with proliferative glomerulonephritis reported in two studies were on average between 7 and 9 years of age.[11,10] Proteinuria and renal failure are the most common presenting signs in affected dogs. Renal failure may be mild or moderate and acute or chronic. Humans with mesangial proliferative glomerulonephritis often have microscopic or macroscopic hematuria; the presence of hematuria has not been thoroughly evaluated in dogs.[5]

261.3.3.2 Pathogenesis

Proliferative glomerulonephritis is an immune complex–mediated disease. Anti-GBM disease causes proliferative glomerulonephritis in humans but has not been described in the dog or cat. Postinfectious glomerulonephritis of humans, characterized by endocapillary proliferation, most commonly occurs after a streptococcal infection but has also been identified with other infections (e.g., staphylococcal infection).[5] Interestingly, this pattern of disease is usually caused by infections of limited duration that often have

resolved prior to the emergence of clinical signs of glomerular disease. Persistent infections are more likely to cause MPGN or MN.[4]

261.3.3.3 Histopathologic Characterization

Mesangial proliferative glomerulonephritis is characterized by mesangial cell hyperplasia, defined as four or more cells per mesangial area.[4,11] This is often accompanied by an increase in mesangial matrix (Figure 261-7). Endocapillary proliferative glomerulonephritis occurs with a proliferation of glomerular endothelial cells and may be accompanied by an increase in mesangial cellularity. An influx of mononuclear cells accounts for some of the increase in cellularity. Evaluation by IFM reveals fine granular deposits of IgG or IgM or both in the GBM and mesangium. EM can be used to characterize further the location of the immune complexes. Because the proliferative glomerulonephropathies often develop secondary to systemic diseases, immune complexes are often identified in the mesangium, although some complexes may be found in the capillary walls. Subepithelial “humps” can be identified in humans with postinfectious glomerulonephritis.[4]

261.3.3.4 Specific Treatment

Because this category probably encompasses several disease entities, there are no specific treatment recommendations. The potential source of immune complexes should be removed, and nonspecific management of glomerular diseases should be followed.

261.3.3.5 Prognosis

The prognosis for this specific group of diseases has not been evaluated in dogs. The presence of chronic renal failure or the formation of crescents, or both, is most likely associated with a poorer prognosis.

1793

261.3.3.6 Immunoglobulin A Nephropathy

In several studies of canine glomerular disease, IFM has demonstrated mild to moderate frequency of IgA positivity, suggestive of IgA nephropathy.[27,28] However, because IgA is predominantly polymeric in dogs, it may be nonspecifically trapped in the mesangium, more so than monomeric IgA, the predominant form in humans. The diagnosis of IgA nephropathy requires a predominance of IgA positivity on IFM evaluation; codeposits of IgG, IgM, or C3 may be present but should be less intense than IgA. Mesangial proliferative glomerulonephritis is the expected light microscopic lesion; some humans do not have any apparent glomerular lesions. In one study of clinically normal dogs with glomerular lesions, 85% had IgA deposits.[16] In another study of 100 dogs with and without renal disease, 47 had IgA deposition, and in six dogs IgA was the only immunoglobulin detected.[28] Increased deposition of IgA was associated with increased cellular proliferation. Dogs with enteric or hepatic diseases had the highest incidence of IgA deposition. Excessive IgA immune complex formation due to enteric disease or decreased clearance of IgA complexes in association with liver disease have been proposed in the pathogenesis of secondary IgA nephropathy in humans.[5]

In people, IgA nephropathy is more common in young adults, with males outnumbering females; the prevalence varies substantially throughout the world.[5] In a report of three dogs with apparent IgA nephropathy, the dogs were male and young to middle aged (4 to 7 years).[27] The dogs had episodes of microscopic and macroscopic hematuria, as well as proteinuria and varying degrees of renal failure. Although the dogs were housed together in a blood donor facility, predisposing environmental factors were not identified. The dog most severely affected had uncontrolled hypertension and codeposits of IgG or IgM, both of which are negative prognostic indicators in humans.

Treatment of patients with secondary IgA nephropathy should be directed at treatment of the associated systemic disease. Control of hypertension should be considered a cornerstone of therapy. Fish oil rich in omega-3 fatty acids administered to affected humans resulted in slowed progression of renal disease but did not lead to a reduction in proteinuria.[5]

261.3.4 Amyloidosis

The term *amyloidosis* refers to a diverse group of diseases that have in common the extracellular deposition of fibrils formed by polymerization of proteins with a beta-pleated sheet conformation.[29] Several different proteins may be deposited to form amyloid in humans, but the number of proteins involved in domestic animals appears to be limited. Many of these proteins display specific tissue tropisms that lead to characteristic clinical syndromes. The dog is the domestic animal most commonly affected by amyloidosis. With the exception of the Chinese Shar Pei, amyloid is deposited primarily in the glomeruli of affected dogs.[13,30] In fact, amyloidosis is one of the most common glomerular diseases in dogs, accounting for 23% of dogs with glomerular disease in one study.[8]

261.3.4.1 Clinical Features

Reactive amyloidosis is the most common form of amyloidosis in dogs and cats. Renal amyloidosis is more common in older dogs. The mean age of affected dogs was 9.2 years in one study, in which 85% of affected

dogs were 7 years of age or older.[13] Females appear to be affected more often than males (the male to female ratio is 1:1.7). Beagles, collies, and Walker hounds may be at increased risk for amyloidosis.[13] Renal amyloidosis may be familial in beagles and English foxhounds.[31]

The most common clinical signs of renal amyloidosis in dogs are those common to other glomerular diseases. Because proteinuria associated with amyloidosis may be massive, many animals brought to the veterinarian are in nephrotic syndrome. In one study of proteinuria, six of seven dogs with amyloidosis had nonselective proteinuria, suggesting a marked loss of the size-selective properties of the glomerular capillary wall.[16] Although other organ systems may be involved (liver, spleen, adrenal glands, gastrointestinal tract), clinical signs associated with amyloid deposition in these organs are rare in dogs. Chronic infectious and noninfectious inflammatory diseases and neoplasia have been reported in association with reactive amyloidosis in 32% to 53% of affected dogs; however, many dogs and cats with reactive amyloidosis do not have an identifiable inflammatory process at the time of presentation.[8,13]

Renal amyloidosis in the Shar Pei develops at an earlier age (mean age 4.1 years) than in other dogs with amyloidosis, but like other breeds, the disease is more common in females (male to female ratio of 1:2.5).[13] In Shar Peis, amyloid is most commonly deposited in the renal medulla; only 64% of Shar Peis had glomerular involvement in one report.[30] As a result, as few as 25% to 43% of affected Shar Peis have proteinuria. Affected dogs may have signs of involvement of other organs, particularly the liver. Many Shar Peis have a history of recurrent fever and swelling of the tibiotarsal joints (commonly called *Shar Pei fever* or *Shar Pei swollen hock syndrome*) prior to the development of renal amyloidosis. Affected Shar Peis may be an animal model of familial Mediterranean fever in humans.

Amyloidosis is relatively uncommon in the cat, with the exception of Abyssinians and Siamese (especially the Oriental shorthair color variant).[32] In Abyssinians, amyloid is deposited primarily in the medulla, although glomerular involvement has been described. This pattern of deposition results in medullary fibrosis and papillary necrosis and leads to chronic renal failure as the most common clinical manifestation; marked proteinuria is not common. Siamese and Oriental shorthair cats have a predilection for deposition of amyloid in the liver, leading to hepatic rupture and hemorrhage. Diagnosis of renal amyloidosis in affected cats is based on a high index of suspicion and exclusion of other renal diseases or on postmortem examination; biopsy of the renal medulla is associated with too high a degree of risk to be warranted.

261.3.4.2 Pathogenesis

The primary protein involved in the formation of amyloid deposits in dogs and cats is amyloid A protein (AA), which is formed by the polymerization of the amino terminal portion of serum amyloid A protein (SAA), an acute-phase reactant.[29] SAA is synthesized and released by hepatocytes after they have been stimulated by macrophage-derived cytokines (e.g., interleukin-1 (IL-1), IL-6, tumor necrosis factor). Because of the association of amyloid A with inflammatory diseases, this form of amyloidosis has been termed *reactive,* or *secondary,* amyloidosis.

Concentrations of SAA increase 100-to 1000-fold after tissue injury. Although concentrations decrease to baseline by 36 to 48 hours after removal of the inflammatory stimulus, they remain increased if inflammation persists.[29] Chronic inflammation and persistent or prolonged increases in SAA concentrations are required for the development of reactive amyloidosis. Humans with familial Mediterranean fever, a disease similar to that reported in Shar Peis, have defective formation of pyrin, a protein involved in the

downregulation of mediators of inflammation.[33] Because only a small percentage of animals with chronic inflammation develop amyloidosis, other factors must be involved in the pathogenesis.[29] There are multiple polymorphs of SAA, and certain polymorphs perhaps are more amyloidogenic. There may be inherited and acquired variations in the ability to degrade SAA, a two-step process that involves cell surface–associated proteases contained in monocytes. A defect in the second step of this process may predispose some individuals to the development of amyloidosis. It has been demonstrated that the AA-degrading property of normal serum is decreased in humans with reactive amyloidosis. This activity correlated with serum albumin concentrations; hypoalbuminemia associated with the inflammatory process or amyloidosis may contribute to decreased AA-degrading activity. Increased concentrations of other acute-phase reactants that are protease inhibitors (e.g., antitrypsin and antichymotrypsin) also may contribute to the pathogenesis of amyloidosis.

1794

1795

SAA concentrations are increased during the predeposition phase, before the appearance of tissue amyloid deposits, but may persist during the deposition phase. Abyssinians with renal amyloidosis have increased SAA concentrations.[29] Chinese Shar Peis with renal amyloidosis have increased serum concentrations of IL-6, a cytokine that stimulates SAA synthesis and release.[34] The deposition phase, during which amyloid deposits appear in the tissue, is subdivided into two phases. The rapid phase is characterized by rapid increases in the amount of amyloid, whereas the plateau phase is a time when little net change occurs in tissue deposition.

261.3.4.3 Histopathologic Characterization

The beta-pleated conformation is responsible for the characteristic staining properties of the amyloid deposits.[4] When the kidney is evaluated by conventional light microscopy, amyloid deposits in the glomeruli appear as acellular material that expands the mesangium and glomerular basement membranes and stains homogeneously eosinophilic with hematoxylin-eosin (Figure 261-8). Glomerular deposits are most often diffuse and global but occasionally are focal and segmental. Deposits sometimes can be found in the walls of small blood vessels, tubular basement membranes, and interstitial tissues. When stained with Congo red and evaluated by conventional light microscopy, amyloid deposits take on various shades of red, depending on the amount of amyloid and the thickness of the section. Deposits stained with Congo red and evaluated by polarizing microscopy are birefringent and have an apple green color (Figure 261-9). Reactive amyloidosis can be confirmed by decolorization of the Congo red–stained amyloid deposits by potassium permanganate oxidation. Electron microscopy is not needed to confirm a diagnosis of amyloidosis.

261.3.4.4 Specific Treatment

The beta-pleated sheet configuration of amyloid fibrils leads to their insolubility and resistance to proteolysis, making specific treatment relatively ineffectual. In humans with familial Mediterranean fever, colchicine prevented the development of renal amyloidosis even in patients who continued to have recurrent febrile episodes.[33,35] This led to the recommendation that colchicine be used in the management of Shar Peis with renal amyloidosis. Ideally this drug is administered during the predeposition phase, which in Shar Peis is presumably characterized by recurrent fevers and swollen hocks. However, colchicine administration may lead to remission of proteinuria even after the appearance of amyloid deposits. No evidence supports the effectiveness of colchicine once amyloidosis has resulted in renal failure. Although the effects of the drug in the treatment of amyloidosis are not fully known, colchicine does impair the release of SAA from hepatocytes by binding to microtubules and preventing secretion. In addition,

colchicine may prevent the production of amyloid-enhancing factor. The dosage of colchicine used is 0.01 to 0.03 mg/kg given orally every 24 hours. Gastrointestinal upset is the primary side effect.

Dimethylsulfoxide (DMSO) has been shown to be beneficial in a limited number of dogs with renal amyloidosis, although the exact benefit remains controversial.[35] If given during the rapid deposition phase, DMSO leads to a decrease in SAA concentrations and resolution of tissue deposits. However, the amount of amyloid deposited in the kidneys of humans was unchanged after DMSO administration, which lends support to the current belief that DMSO does not solubilize amyloid fibrils. The anti-inflammatory effects of DMSO may account for some of the beneficial effects. Reduction of interstitial fibrosis and inflammation may lead to improved renal function and reduced proteinuria. DMSO has an unpleasant odor that may lead to poor owner compliance. Furthermore, this drug may contribute to signs of nausea and anorexia seen in some dogs. The recommended dosage is 90 mg/kg given orally or subcutaneously three times weekly. DMSO should be diluted 1:4 with sterile water before injection to limit the pain associated with injection. Neither DMSO nor colchicine is effective once the plateau phase of deposition has been reached.

261.3.4.5 Prognosis

The prognosis for dogs and cats with renal amyloidosis is generally poor. In one study of dogs with amyloidosis, 58% died or were euthanized at the time of diagnosis. In the remaining dogs, survival ranged from 2 to 20 months; survival of a year or longer was reported in only 8.5%.[29] The longest survival was observed in a dog treated with DMSO.

1795

1796

261.3.5 Hereditary Nephritis

The term *hereditary nephritis (HN)* refers to a diverse group of inherited glomerular diseases that are the result of a defect in basement membrane collagen (type IV).[36] These diseases are discussed in Chapter 264. A brief discussion of hereditary nephritis is included in this chapter because it should be considered as a differential diagnosis for any dog presenting with proteinuric renal disease, particularly if the dog is young.

261.3.5.1 Clinical Features

Hereditary nephritis has been reported in several breeds of dogs. An autosomal recessive form of the disease occurs in English cocker spaniels, whereas bull terriers and Dalmatians develop an autosomal dominant form.[36–39] An X-linked dominant form of HN has been described in Samoyeds and mixed-breed dogs; carrier females may have mild disease.[37] The report in the Samoyeds is of a single kindred; the disease is not considered to be common in this breed. HN is characterized by proteinuria, renal hematuria, and progressive glomerular disease. Concurrent hearing and ocular abnormalities, as described in humans with HN, appear to be uncommon in affected dogs, with the exception of anterior lenticonus, which occurs in some bull terriers.[38]

261.3.5.2 Pathogenesis

HN is the result of a genetic mutation or deletion in type IV collagen, the primary protein constituent of the GBM.[4,36] The presence of defective collagen leads to premature deterioration of the GBM and progressive glomerular disease.

261.3.5.3 Histopathologic Characterization

Prior to electron micrographic studies of English cocker spaniels, the renal lesions were described as renal cortical hypoplasia or membranoproliferative or sclerosing glomerulonephritis. Electron microscopy is required to make the diagnosis of HN. Multilaminar splitting and fragmentation of the GBM are seen, often with intramembranous, electron-dense deposits.

261.3.5.4 Specific Treatment

No specific treatment is available for affected dogs. Use of a diet formulated for renal failure and administration of angiotensin-converting enzyme (ACE) inhibitors have proved beneficial in affected dogs. Early detection of HN through screening of dogs of relevant breeds for microalbuminuria allows early therapeutic intervention, which may slow disease progression.[17]

261.3.5.5 Prognosis

The rate of progression is predictable in Samoyeds and English cocker spaniels, with terminal renal failure generally developing before 2 years of age.[36] However, disease progression is more variable in bull terriers and Dalmatians, with some dogs surviving for as long as 10 years.[38–39]

261.3.6 Minimal Change Disease

Although uncommonly described in dogs and cats, minimal change disease (MCD) is a common cause of nephrotic syndrome in humans, especially children.[5,40] Because EM is required for diagnosis, the disease most likely is underdiagnosed in dogs and perhaps in cats. In humans this disease is sometimes referred to as *nil disease, lipoid nephrosis,* or *idiopathic nephrotic syndrome*.

261.3.6.1 Clinical Features

There have been isolated reports of dogs that appear to have MCD; we have seen a few dogs in which we suspected this disease at North Carolina State University College of Veterinary Medicine. However, there is only one well-described case report of MCD in a dog presenting with nephrotic syndrome.[40] Proteinuria is likely to be of heavy magnitude with this disease, and nephrotic syndrome is common.

261.3.6.2 Pathogenesis

In humans, MCD is usually idiopathic, although secondary disease also occurs. Increased production of lymphokines by dysfunctional T cells is believed to be responsible for an increase in GBM permeability.[5] The primary change is loss of anionic charge in the glomerular capillary wall, leading to collapse of the podocyte foot processes. This loss of charge selectivity is the crucial event leading to proteinuria. The resultant proteinuria is highly selective; albumin is the primary protein lost.

261.3.6.3 Histopathologic Characterization

Animals with MCD have a lack of light microscopic lesions in the glomerulus.[4] Occasionally, slight hypercellularity is present, as evidenced by three or four nuclei in the mesangial region. Some lipid droplets may be present in the renal tubules, but there should not be any evidence of tubular atrophy or interstitial fibrosis. With IFM, immunoglobulin deposition is absent; however, there may be increased staining of vimentin, a marker for visceral glomerular epithelial cells. The diagnosis is confirmed with EM by identification of marked foot process effacement (Figure 261-10). MCD belongs to the WHO classification of minor glomerular abnormalities. In one study of glomerular lesions in dogs, 28 of 115 dogs fell into this classification, but only one of these dogs had MCD.[11] Therefore identification of only minor glomerular abnormalities in a dog or cat with proteinuria does not make a diagnosis of MCD.

261.3.6.4 Specific Treatment

An important reason to include MCD on the list of differential diagnoses for dogs with nephrotic syndrome is the disease's seemingly exquisite response to corticosteroids; the expected response rate in humans with MCD is 80% to 90%.[5]

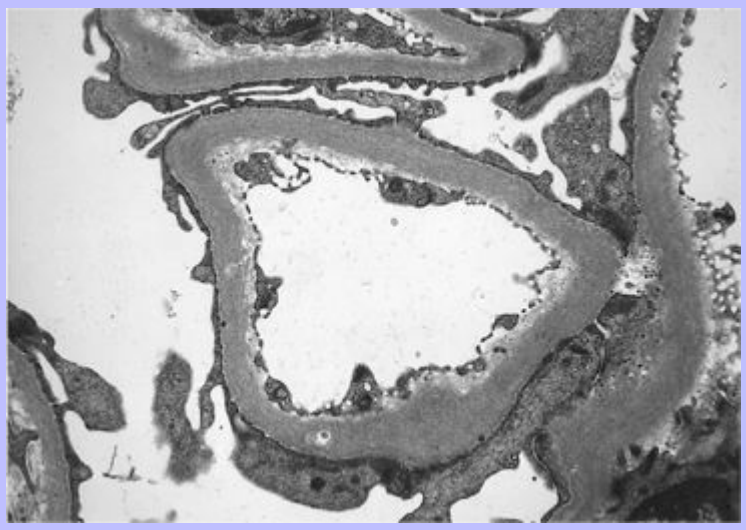
261.3.6.5 Prognosis

The prognosis for MCD in dogs is unknown. One or more relapses are seen in 75% to 85% of affected humans.[5]

261.3.7 Glomerulosclerosis

Glomerulosclerosis often develops as an end-stage lesion in response to glomerular injury.[4] Focal or global sclerosis may be a primary or concurrent lesion in animals with glomerular disease. The incidence of glomerulosclerosis increases with age, although the percentage of glomeruli expected to be sclerotic in dogs of advancing age groups has not been fully characterized. Glomerulosclerosis is a common finding in diabetic nephropathy of humans. Although glomerulosclerosis and proteinuria can develop in dogs with diabetes mellitus, the clinical relevance of this is unknown. Glomerulosclerosis can also develop after hypertensive renal damage.

Figure 261-10 Electron micrograph of a glomerular capillary loop in a dog with minimal change disease. Effacement of the foot processes has occurred.



Focal segmental glomerulosclerosis (FSGS) is a specific glomerular disease that has been identified, but poorly characterized, in dogs (Figure 261-11).[4,11] FSGS is a common glomerular disease in humans, accounting for up to 35% of nephrotic syndrome in adults. The disease is most likely underdiagnosed in dogs and often mischaracterized as MPGN. FSGS was the diagnosis rendered in 10% of dogs with glomerular disease in one study.[11] Males and females were equally represented, and the average age was 8.5 years. FSGS is diagnosed in the proteinuric patient that has segmental glomerulosclerosis in a glomerulus that is otherwise normal, without other glomerular lesions present to explain the sclerosis. IFM evaluation should be negative in affected patients; however, nonspecific trapping of immunoglobulins and C3 can occur in sclerotic areas.

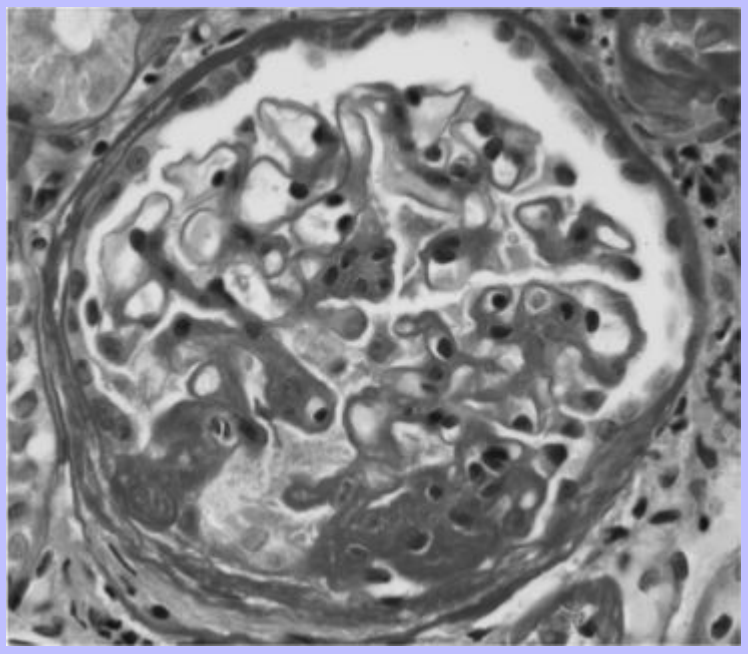
Five subtypes of this disease have been described in humans: perihilar, cellular, tip, collapsing and "not otherwise specified."[4] The clinical features of these subtypes vary somewhat, but the course is generally one of progressive proteinuria and renal failure. Permeability factor, a transferable circulating factor that promotes increased *in vitro* glomerular permeability to albumin and other plasma proteins, has been implicated in the pathogenesis of FSGS in humans.[5] Although the exact identify of this permeability factor is unknown, it is not an immunoglobulin or an immune complex. It is likely that several factors eventually will be identified that are capable of inducing increased glomerular permeability and eventual sclerotic lesions.

261.3.8 Tubulointerstitial Lesions Associated with Glomerular Disease

Proteinuria induces tubular damage, leading to progressive nephron loss.[41] Evidence in support of this includes the correlation between heavy proteinuria and a negative patient outcome in humans with various glomerular diseases; also, rodents with albumin-induced overload proteinuria develop renal injury and fibrosis, and the urine of proteinuric humans shows mediators of renal inflammation and fibrosis, some of

which are produced by renal tubules exposed to various proteins.[41] However, albumin may not be the culprit. Rodents with albumin-induced overload proteinuria develop altered glomerular permselectivity, with urinary loss of proteins in addition to albumin. Rats and humans with highly selective proteinuria appear to be at lower risk of eventual tubulointerstitial damage.

Figure 261-11 Glomerulus from a dog with a lesion resembling focal segmental glomerulosclerosis. Note the relatively normal appearance of the glomerular sections that are not sclerotic.



Some damage occurs secondary to obstruction of the tubules by protein casts.[42] However, the proteins themselves are also toxic to the tubular epithelial cells and lead to increased interstitial inflammation, fibrosis, and cell death. Proteinuria necessitates increased resorption of proteins through tubular cells by means of lysosomal processing. Ruptured lysosomes lead to cytoplasmic damage. Interstitial inflammatory cells, initially recruited in response to injury, contribute to the development of interstitial fibrosis. Other factors that may be involved in the genesis of interstitial inflammation and fibrosis induced by proteinuria include osteopontin, monocyte chemoattractant protein-1, urinary iron, endothelin-1, transforming growth factor-β, and tumor necrosis factor-alpha.[42] A direct link has not been established between proteinuria and progressive renal damage in dogs, but it probably exists to some extent. Because proteinuria may be a major factor responsible for progressive renal failure in patients with glomerular disease, aggressive management of the proteinuria should be considered a cornerstone of the treatment of dogs and cats with glomerular disease.

261.4 NONSPECIFIC MEDICAL MANAGEMENT OF GLOMERULAR DISEASE

In addition to specific management that might be implemented with the various glomerular diseases, nonspecific management is indicated. This therapy can be divided into three major categories: (1) treatment of potential

underlying diseases processes, (2) reduction of proteinuria, and (3) management of uremia and other complications of generalized renal failure (discussed in Chapter 260).

Many glomerulopathies in dogs are believed to develop secondary to a systemic infectious, inflammatory, or neoplastic disease process. However, the inciting agent may not be obvious at first presentation because the offending disease is no longer present or is occult. Continued observation and scrutiny are necessary, because the causative disease process may become obvious in the ensuing months after presentation. The initial step in the management of a persistently proteinuric dog or cat is to treat and eliminate, if possible, any potential predisposing diseases. The dog should be subsequently evaluated for resolution of the proteinuria, which may occur slowly over a period of months. If proteinuria does not resolve or worsens, a renal biopsy to determine the specific glomerular disease present may be warranted.

Enalapril significantly reduced proteinuria and delayed either the onset or the progression of azotemia in dogs with glomerulonephritis.[43] Treatment of dogs with glomerular diseases with ACE inhibitors is now considered a standard of care.[43] ACE inhibitors may reduce proteinuria and preserve renal function by several possible mechanisms. The decreased efferent glomerular arteriolar resistance effected by ACE inhibitors leads to decreased glomerular transcapillary hydraulic pressure and decreased proteinuria. Other proposed mechanisms include reduced loss of glomerular heparan sulfate, decreased size of the glomerular capillary endothelial pores, improved lipoprotein metabolism, slowed glomerular mesangial growth and proliferation, and inhibition of bradykinin degradation.[43] Typically enalapril (0.5 mg/kg given orally) is administered once a day. If no reduction in proteinuria is seen after 2 to 4 weeks, the frequency should be increased to twice daily (approximately half of the dogs may eventually need twice daily administration).[43] Although the serum creatinine concentration should be monitored, it is uncommon for dogs to have worsening of azotemia due to enalapril administration alone. Adequate blood pressure control of hypertensive dogs may also lead to a reduction in proteinuria and slow the progression of disease. Because ACE inhibitors are relatively weak antihypertensive agents, additional antihypertensive agents (e.g., amlodipine) may be needed if hypertension (i.e., systolic blood pressure greater than 170 mm Hg) persists after the initiation of ACE inhibitor therapy.

1797 1798

Platelets and thromboxane may play an important role in the pathogenesis of glomerulonephritis. Thromboxane is an inducer of platelet aggregation and a chemotactic factor for neutrophils. Neutrophils induce damage to the GBM through release of proteolytic enzymes. Thromboxane release may lead to a reduction in the glomerular filtration rate by inducing vasoconstriction and mesangial cell contraction. Thromboxane synthetase inhibitors have been shown to decrease proteinuria in dogs with experimentally induced glomerulonephritis.[44] Aspirin is a nonspecific cyclo-oxygenase inhibitor that may be used to reduce glomerular inflammation and inhibit platelet aggregation, which may have an added benefit of preventing thromboembolism. In theory, very low doses of aspirin (0.5 mg/kg given orally once or twice daily) may selectively inhibit platelet cyclo-oxygenase without preventing the beneficial effects of prostacyclin formation.

Dietary protein restriction may be useful in the management of dogs with glomerulopathies. Humans and rats with glomerular disease demonstrate a reduction in proteinuria without a change in serum albumin concentrations with restriction of dietary protein. Diets should not be supplemented with protein, because this aggravates urinary protein losses. The enhanced omega-3 to omega-6 polyunsaturated fatty acid ratio and restriction in salt and phosphorus found in canine renal diets may also be of benefit to dogs with glomerulopathies. Omega-3 fatty acid supplementation has been shown to be renoprotective in dogs with renal failure and to mitigate hypertension and reduce serum triglyceride and cholesterol concentrations in humans with nephrotic syndrome.[45] These positive effects are in part mediated through generation of the 3-series prostaglandins. Sodium restriction is beneficial in the control of hypertension and fluid retention. Provision of adequate exercise may help reduce the formation of

edema or ascites. Because plasma volume is often reduced in animals with hypoalbuminemia and edema, the use of diuretics should be avoided unless these drugs are needed to control respiratory distress.

The use of immunosuppressive drugs in the treatment of both dogs and humans with glomerular disease is controversial. No controlled study has been done on the use of corticosteroids in dogs with glomerular diseases. Proteinuria has been demonstrated in dogs with corticosteroid excess and may induce glomerular lesions.[9,46] Furthermore, prednisolone administration was shown to reversibly increase proteinuria in dogs with hereditary nephritis.[47] The use of immunosuppressive agents is generally limited to dogs that have developed glomerulonephritis secondary to a steroid-responsive disease, such as systemic lupus erythematosus, but it should also be considered in animals with primary membranous nephropathy or MCD. Cyclosporine, the only drug that has been studied prospectively in dogs with glomerular disease, was found to be of no benefit.[48] However, dogs with idiopathic disease were included in this study regardless of which specific glomerular disease they had. In the future, the use of immunosuppressive drugs needs to be systematically studied in dogs with primary membranous nephropathy, MCD, or lupus nephritis. Until the results of such a study are available, immunosuppressive agents should be used only with caution and careful patient monitoring.

The UPC, urinalysis, body weight, body condition score, and serum albumin and creatinine concentrations should be evaluated monthly whenever modifications in the therapeutic plan are being made, or every 3 to 6 months if the dog's clinical signs are stable and therapeutic changes are not being made. Slight day-to-day variations in the UPC can occur; changing proteinuria is most accurately measured by assessing trends in the UPC over time. The systemic blood pressure should be measured at least every 3 to 6 months and more frequently if hypertension is unregulated. If the dog no longer has the ability to produce concentrated urine, a urine sample should be submitted for bacterial culture and susceptibility testing every 6 months. Because histologic lesions do not necessarily resolve even though renal function may improve, repeat biopsies generally are not needed. A reduction in proteinuria (ideally greater than 50%) as measured by the UPC without an increase in the serum creatinine concentration indicates improvement or response to therapy.

261.5 COMPLICATIONS OF GLOMERULAR DISEASE

Complications of severe proteinuria include edema formation, systemic hypertension, hypercoagulability and thromboembolism, hyperlipidemia, increased risk for infection, altered pharmacokinetics, malnutrition, muscle wasting, and endocrine abnormalities.[42] Edema formation, systemic hypertension, and hypercoagulability are the complications most frequently recognized in dogs, and less commonly in cats, with glomerular disease.

261.5.1 Edema Formation

Several factors contribute to the formation of edema in patients with nephrotic syndrome.[42] In severe forms of nephrotic syndrome, decreases in the plasma oncotic pressure allow for transudation of fluid into the interstitial spaces. The resultant decrease in effective plasma volume leads to increased renin-angiotensin-aldosterone activity and retention of water and sodium and worsening of edema. However, most humans with nephrotic syndrome do not have reduced blood volumes or increased plasma renin or aldosterone activities. Thus primary sodium retention must also be involved in the pathogenesis of edema in these patients. Proposed mechanisms in primary renal sodium retention include a reduced single nephron glomerular filtration rate with enhanced proximal tubular resorption and cytokine-induced modification of distal resorption, leading to resistance to natriuretic factors, including atrial natriuretic peptide. In humans it is believed that mechanisms of primary renal sodium retention are the most important determinants of edema formation until the serum albumin concentration decreases below 2 g/dL. Below this concentration, the plasma

oncotic pressure is sufficiently reduced to allow for transudation of fluid from the vascular compartment into the interstitial space.[42] Dogs may be more resistant to the formation of edema, which does not generally occur until the serum albumin concentration is below 1.5 g/dL. Plasma volume may be reduced at this point, making the use of diuretics in the management of edema relatively ineffective and also dangerous because of the increased risk of acute renal failure and thromboembolism.[42]

1798

1799

261.5.2 Hypertension

Systemic hypertension has been reported in up to 80% of dogs with glomerular disease. The frequency of hypertension in each form of glomerular disease has not been established in dogs but does vary in humans. Hypertension appears to be most common in people with FSGS and membranoproliferative glomerulonephritis, whereas it is uncommon in association with MCD and does not occur higher than control populations in humans with membranous nephropathy.[5] The primary mechanism of hypertension in association with nephrotic syndrome is believed to be expansion of the plasma volume in association with primary renal sodium retention. However, generation of several vasoactive factors (e.g., renin, angiotensin II, endothelin) is increased in human patients with nephrotic syndrome and may contribute to hypertension. Nitric oxide deficiency may also play an important role in the development of hypertension.[42]

Target organs of hypertensive injury include the kidneys, the central nervous system, the eyes, and the heart. Blindness may be the presenting complaint in animals with hypertension, most commonly due to retinal detachment. However, retinal hemorrhage, edema, vessel tortuosity, and degeneration; hyphema; and secondary glaucoma may also occur. Hypertensive encephalopathy may be manifested as lethargy, altered mentation, altered behavior, seizures, or balance disturbances. Cardiac changes in dogs and cats with hypertension include systolic murmurs, gallop rhythms, and left ventricular hypertrophy. The blood pressure should be measured in all dogs and cats with glomerular disease, because uncontrolled hypertension is a risk factor for progressive renal injury.

261.5.3 Thromboembolism

Thromboembolism, perhaps the most serious complication of glomerular disease, was reported in 5% of dogs with glomerulonephritis, 14% of dogs with amyloidosis, and 13% of dogs with all forms of glomerular disease.[8,9,13] Because emboli may be difficult to detect, the prevalence of thromboembolism in dogs with glomerular disease may be higher than indicated by these studies. The risk of thromboembolism is highest in dogs with diseases most likely to cause nephrotic-range proteinuria (e.g., membranous nephropathy, amyloidosis). Pulmonary thromboembolism is most common, but emboli may also lodge in other arteries (e.g., mesenteric, renal, iliac, brachial, coronary) or the portal vein.

Although urinary loss of antithrombin III (AT III) has gained the most attention in veterinary medicine, the pathogenesis of the hypercoagulable state is multifactorial.[42] AT III is a serine protease inhibitor that modulates fibrin generation; heparin catalyses these reactions. AT III (65,000 daltons) is similar in charge and size to albumin (69,000 daltons); serum AT III activity closely correlates with the serum albumin concentration. This close correlation allows one to predict an increased risk of thromboembolism in patients with a serum albumin concentration less than 2 g/dL, when serum AT III activity would be expected to be less than 75% of normal.[8] However, AT III activity levels do not always correlate with the development of thromboembolism; other factors are involved.

Albumin binds to arachidonic acid, which, if unbound, would stimulate platelet aggregation through the generation of prostaglandins (i.e., thromboxane B_2); hypoalbuminemia is associated with increased platelet aggregation.[42] Hypercholesterolemia contributes to platelet hypersensitivity by influencing the membrane-associated enzyme and receptor activity through alteration of the membrane composition. The role of platelet hypersensitivity in the development of hypercoagulability may be enhanced by thrombocytosis, which occurs in many animals with glomerular disease. Increased fibrinogen concentrations (i.e., above 300 mg/dL), which are often present in patients with nephrotic syndrome, lead to increased fibrin complex formation and platelet hyperaggregation. The risk of thromboembolism may be further enhanced by increased concentrations of alpha$_2$ macroglobulin; alpha$_2$ antiplasmin; procoagulant cytokines; coagulation factors V, VII, VIII, and X; increased plasma viscosity and interstitial pressure; decreased plasma plasminogen concentrations; decreased plasma volume and blood flow; endothelial injury; and infections.[42]

Coumadins and aspirin have been used in the prevention of thromboembolism in at-risk dogs. However, warfarin is highly protein bound. It is very difficult to titrate the dose adequately to prolong the prothrombin time appropriately (i.e., 150% of baseline) in dogs with hypoalbuminemia, and its use is not recommended. Alternatively, low-dose aspirin is inexpensive, easy to administer, and has the added benefit of potentially reducing proteinuria.

261.5.4 Hyperlipidemia

Hypercholesterolemia was reported in 79% of dogs with glomerulonephritis and 86% of dogs with amyloidosis.[9,13] Cholesterol concentrations as high as 749 mg/dL have been reported, although the mean concentration was 312 mg/dL in 69 dogs with glomerulonephritis and 350 mg/dL in 23 dogs with amyloidosis.[8,9] Increases in total plasma cholesterol, very-low-density lipoprotein (VLDL), and low-density lipoprotein (LDL) occur.[49] Hyperlipidemia is variably seen in humans with nephrotic syndrome and has not been fully studied in dogs. The pathogenesis of hyperlipidemia in association with nephrotic syndrome is complex.[49] Hypoalbuminemia stimulates hepatic protein synthesis, including the synthesis of lipoproteins, leading to hypercholesterolemia.[42] The serum albumin concentration and plasma oncotic pressure inversely correlate with the magnitude of hypercholesterolemia. It is unclear whether hypoalbuminemia or the decreased plasma oncotic pressure, or both, induce the increased synthesis. Alterations in lipid catabolism also contribute to the development of hyperlipidemia. Orosomucoid, which plays an important role in the maintenance of glomerular permselectivity, is lost in the urine of patients with glomerular disease. Urinary losses of orosomucoid exacerbate proteinuria but also contribute to hyperlipidemia by indirectly causing decreased hepatic production of heparin sulfate, a cofactor needed in normal lipoprotein lipase function.[49]

Some evidence supports the theory that uncontrolled hyperlipidemia contributes to glomerular and tubulointerstitial injury. LDL and oxidized LDL may alter mesangial cell function and increase the synthesis of mesangial matrix, thereby accelerating the formation of glomerulosclerosis.[42] Glomerular and tubulointerstitial lipoprotein deposition and lipoprotein-induced cytotoxicity also contribute to renal injury. Interestingly, glomerular lesions have been identified in cats with lipoprotein lipase deficiency and in miniature schnauzers with hyperlipidemia.[50]

261.6 PROGNOSIS FOR GLOMERULAR DISEASE

The prognosis for dogs and cats with glomerular disease is variable and probably based on a combination of factors. The prognosis is expected to differ with the various diseases, as discussed earlier in the chapter. Although progressive disease can be expected to occur in a large percentage of animals with glomerular disease, spontaneous remission and response to specific therapy can also be expected. Furthermore, disease progression can be slow enough for the animals to lead relatively normal lives, especially when the diagnosis is established early in the disease process. In humans, azotemia, severe proteinuria, systemic hypertension, and marked tubulointerstitial lesions at presentation are the most significant predictors of an unfavorable outcome in most forms of glomerular disease. Clinical impressions would suggest that these same variables affect the prognosis in dogs and cats.

1799

1800

Dogs with glomerulonephritis that were azotemic at first evaluation survived less than 3 months.[9] The median survival of 53 dogs with glomerulonephritis and amyloidosis that were not dead or euthanized shortly after presentation was only 28 days, although individual dogs survived for more than 3 years; survival times did not correlate with any biochemical parameter in these dogs.[8] Both of these studies are inherently biased toward death by the inclusion of dogs from which renal tissue samples were collected during postmortem examination. More study is needed to characterize the natural history and prognosis of the various glomerular diseases in dogs and cats.

262 CHAPTER • 262 Urinary Tract Infections

Joseph W. Bartges

A urinary tract infection (UTI) develops when a breach (either temporary or permanent) occurs in host defense mechanisms and a virulent microbe in sufficient numbers is allowed to adhere, multiply, and persist in a portion of the urinary tract. UTIs typically involve bacteria, although fungi and viruses also may infect the urinary tract. Infection may predominate at a single site, such as the kidney (pyelonephritis), ureter (ureteritis), bladder (cystitis), urethra (urethritis), prostate (prostatitis), or vagina (vaginitis), or it may be present at two or more of these sites. Because a UTI may involve more than one location, it may be relevant to identify the infection anatomically; that is, upper urinary tract (kidneys and ureters) or lower urinary tract (bladder, urethra, and prostate or vagina). UTIs may or may not produce clinical signs.

The reported incidence of bacterial UTI in dogs and cats is variable. Bacterial UTI is estimated to affect 14% of all dogs during their lifetime,[1] and it is more common in females.[2–5] In cats, bacterial UTIs occur more often in animals older than 10 years, and the incidence increases with age.[6–9] Fungal UTI is believed to be uncommon.[10–13] The incidence of viral UTI is unknown, but viruses have been implicated as a cause of lower urinary tract disease in cats (see Chapter 266).[14–18]

The pathogenesis of urinary tract infections represents a balance between uropathogenic infectious agents and host resistance. UTIs should be treated with antimicrobial agents; however, the status of host defense mechanisms is important in the development, treatment, and prevention of these infections.

262.1 DEFINITION OF CONCEPTS AND TERMS

262.1.1 Urinary Tract Infection

A *urinary tract infection* is defined as adherence, multiplication, and persistence of an infectious agent in the urogenital system. Infections often involve a bacterial organism that is present normally in the distal urogenital tract.

262.1.2 Microburia

Microburia refers to the presence of microbes, typically bacteria, in the urine.

262.1.3 Bacteriuria

Bacteriuria refers to the presence of bacteria in the urine. However, identification of bacteria in the urine is not synonymous with UTI. The presence of bacteria may represent contamination of a urine sample, particularly if the sample was collected by voiding or catheterization. Bacteria in the distal urogenital tract may appear in urine collected by these methods, or the urine may be contaminated after collection. *Significant bacteriuria* is the term used to describe bacteriuria that represents a UTI. A high bacterial number in a properly collected and cultured urine sample is indicative of a bacterial UTI. Small numbers of bacteria obtained from untreated pets usually indicate contamination. *Asymptomatic bacteriuria* refers to significant bacteriuria that is not associated with clinical signs of UTI. This often occurs in animals with compromised

host defenses, such as those with glucocorticoid excess, diabetes mellitus, or feline immunodeficiency virus infection.

262.1.4 Funguria

Funguria refers to the presence of fungi in the urine. Fungi are not normally present in the urogenital system, and identification of these organisms indicates the presence of an infection, regardless of whether clinical signs are seen.

262.1.5 Pyuria

Pyuria refers to the presence of white blood cells (WBCs) in the urine. Pyuria is defined as (1) more than 3 to 5 WBCs (neutrophils) per high-power field in urine sediment prepared from a 5 mL aliquot of urine collected by cystocentesis, or (2) more than 5 to 10 WBCs per high-power field in urine sediment prepared from a 5 mL aliquot of urine collected by catheterization or voiding. Pyuria is not synonymous with UTI; it only implies inflammation.

262.1.6 Inflammation versus Infection

The presence of inflammation is not synonymous with UTI. Many disease processes result in urinary system inflammation, characterized by hematuria, pyuria, and/or proteinuria. The presence of one or more of these conditions does not indicate the etiology or location of the disease process in the urogenital system. To identify the etiology of the inflammation, additional testing must be performed, such as imaging studies, urine culture, renal function tests, endoscopy, urodynamic studies, or biopsy.

262.2 ETIOPATHOGENESIS

262.2.1 Normal Host Defenses

Most UTIs are the result of ascending migration of pathogens from the distal urogenital tract into otherwise normally sterile locations. A resident population of bacteria that is normally present in the lower urogenital tract may decrease establishment of an uropathogen or may emerge as a uropathogen if normal host defenses are altered (Table 262-1).

Although the urinary tract communicates with the microbe-laden external environment, most of the urinary tract is normally sterile, and all of it is resistant to infection. Mechanisms of host resistance to UTIs may be divided into two categories: (1) natural inherent resistance factors and (2) acquired or induced resistance factors activated by the onset of a UTI (Box 262-1). Systemic host defenses play a role in the prevention of hematogenous spread of pathogens to and from the urinary tract; however, local host defense mechanisms are the initial defense in the prevention of ascending infection (Box 262-1).[19] There also appears to be a difference in host defense mechanisms between the upper and lower urinary tracts. For example, induction of diuresis is beneficial for preventing experimental induction of bacterial pyelonephritis in rats[20]; however, dilute urine appears to increase the susceptibility of animals to bacterial infection of the lower urinary tact.[7,21]

Table • 262-1 Bacteria Detected in the Urogenital Tract of Normal Male and Female Dogs

Box • 262-1 Natural and Acquired Host Defenses of the Urinary Tract

1. Normal micturition
    a. Adequate urine volume
    b. Frequent voiding
    c. Complete voiding
2. Anatomic structures
    a. Urethral high-pressure zones
    b. Surface characteristics of urothelium
    c. Urethral peristalsis
    d. Prostatic secretions (antibacterial fraction and immunoglobulins)
    e. Length of urethra
    f. Ureterovesical flap valves

g. Ureteral peristalsis

h. Glomerular mesangial cells (?)

i. Extensive renal blood supply and flow

j. Others (?)

3. Mucosal defense barriers

a. Antibody production

b. Surface layer of glycosaminoglycans

c. Intrinsic mucosal antimicrobial properties

d. Exfoliation of urothelial cells

e. Bacterial interference by commensal microbes of distal urogenital tract

f. Others (?)

4. Antimicrobial properties of urine

a. Extreme high and low of urine pH

b. Hyperosmolality

c. High concentration of urea

d. Organic acids

e. Low-molecular-weight carbohydrates

f. Tamm-Horsfall mucoproteins

g. Others (?)

5. Systemic immunocompetence

a. Cell-mediated immunity

b. Humoral-mediated immunity

From Osborne CA, Lees GE: Bacterial infections of the canine and feline urinary tract. *In* Osborne CA, Finco DR (eds): Canine and feline nephrology and urology. Baltimore, Williams & Wilkins, 1995, pp 759–797.

262.2.2 Microbial Factors

Not all microbes, particularly bacteria, are pathogenic. For example, of the more than several hundred serotypes of *Escherichia coli,* fewer than 20 account for most bacterial UTIs.[22] Because *E. coli* is the most common bacterial uropathogen in humans, dogs, and cats, its virulence (uropathogenicity) has been studied extensively.[22–33] Less is known about the uropathogenicity of other pathogens (Box 262-2). Uropathogens typically have more than one virulence factor, therefore the absence of one factor does not necessarily result in loss of uropathogenicity. Likewise, bacteria that are nonpathogenic in a normal pet may become pathogenic in one with altered host defenses.

262.2.3 Microbial Isolates

The bacteria that commonly cause UTIs are similar in dogs and cats. Infections caused by *E. coli* are most common, and this pathogen accounts for one third to one half of all organisms isolated from urine. Gram-positive cocci are the second major group of uropathogens. Staphylococci, streptococci, and enterococci account for one fourth to one third of isolates recovered. Bacteria that cause the remaining one fourth to one third of bacterial UTIs include *Proteus, Klebsiella, Pasteurella, Pseudomonas, Corynebacterium,* and *Mycoplasma* spp.; however, infection caused by any of these bacteria is uncommon.[6,7,11,34–37]

1801

1802

262.2.3.1 Box • 262-2 Some Factors That May Enhance the Virulence (Uropathogenicity) of Bacteria Causing Urinary Tract Infection

1. *Escherichia coli*
    a. Certain O (somatic) antigens
        i. Outer polysaccharide portion of bacterial envelope
        ii Smooth colony morphology on culture plate
        iii Indirect marker of virulence (human studies)
    b. Certain K (capsular) antigens
        i. Capsule surrounds bacterium.
        ii May inhibit phagocytosis and complementmediated bactericidal activity
        iii Increased resistance to inflammation favors persistence of bacteria in tissue.
    c. Adhesive fimbriae (pili)
        i. Proteinaceous filamentous organelles that protrude from the surface of the bacterium
        ii Specific types of fimbriae (p-fimbriae) enhance the ability of a bacterium to remain adherent to uroepithelium despite cleansing action of urinary system.
    d. Hemolysin

i. Increases amount of free iron available for bacterial growth

ii May cause tissue damage

e. Aerobactin

i. Iron-binding protein

ii Facilitates bacterial growth

f. R-plasmids

i. Promote resistance to antimicrobial agents

g. Resistance to serum bactericidal activity

h. Short generation time in urine

2. *Proteus, Staphylococcus*, and some *Klebsiella* spp.

a. Adherence factors

b. Urease

i. Bacterial enzyme that hydrolyzes urea to ammonia

ii Ammonia directly injures uroepithelium.

iii Urease fosters production of magnesium ammonium phosphatase uroliths.

c. R-plasmids

3. *Pseudomonas* sp.

a. Heavy mucoid polysaccharide capsule

i. Prevents antibody coating

b. R-plasmids

Approximately 75% of bacterial UTIs in dogs are caused by a single species of pathogen, approximately 20% are caused by two species, and approximately 5% are caused by three species.[11] A similar pattern is found in cats.[7,8]

262.2.4 Routes of Infection

The majority of UTI occur as a consequence of ascending migration of pathogens through the genital tract and urethra to the bladder, ureters, and one or both kidneys. Rectal, perineal, and genital bacteria serve as the principal reservoirs for infection.[38–42] Although the intrinsic motility of some bacteria, including *E. coli* and *Proteus* spp., may aid their retrograde migration from the distal urogenital tract, brownian movement is the

primary mechanism for ascending infection.[41] In addition to gaining access to the urinary tract, microbes must adhere to and colonize the urothelial surface. Thus the establishment of a UTI depends on the number and virulence of microbes and their interaction with host defenses.

The upper urinary tract is most commonly infected by ascending microbes rather than through hematogenous seeding caused by systemic infection.[44–46] Because blood must pass through glomerular capillaries in the renal cortex before it reaches the medulla, most hematogenous bacteria do not reach the renal medulla. Apparently, renal cortical tissue is more resistant to infection than medullary tissue. Urinary tract obstruction or trauma increases the risk of hematogenous seeding of the urinary tract by interfering with the renal microcirculation.[47]

262.3 CLINICAL FINDINGS

262.3.1 Historical Information and Physical Examination Findings

Dogs and cats with UTI may or may not be symptomatic. Clinical signs associated with UTI are variable and depend on the interaction of (1) the virulence and numbers of the uropathogen, (2) the presence or absence of predisposing causes, (3) the body's compensatory response to infection, (4) the duration of infection, and (5) the site or sites of infection (Table 262-2). Pollakiuria, stranguria, dysuria, and inappropriate urination may be observed with lower urinary tract infections. Animals with upper urinary tract infections may show pain localized to one or both kidneys, hematuria, septicemia, or renal failure (with resultant clinical signs if both kidneys are infected). If the UTI is associated with a predisposing condition (e.g., diabetes mellitus, hyperadrenocorticism, or bladder neoplasia), clinical signs associated with that condition usually predominate. Female dogs with abnormalities of the vulva, perivulvar dermatitis, or vaginal stenosis may have an increased risk for UTI.[48] Male cats with perineal urethrostomies also have an increased risk for UTI.[49] Some animals may have infection of both the upper and lower urinary tracts, especially if renal failure is present.

262.3.2 Laboratory Results

Unless septicemia or renal failure is present, the results of complete blood cell counts are normal. If septicemia is present, leukocytosis and a left shift may be seen. Lower urinary tract infection does not cause changes in blood work unless another disease process is present. With upper urinary tract infections, serum biochemical analysis may be normal or may indicate renal failure (if both kidneys are diseased). If the UTI is associated with another disease, changes in laboratory parameters may reflect the associated condition. In cats, feline leukemia virus and feline immunodeficiency virus infections increase the risk of UTI.[7]

262.3.3 Results of Imaging Studies and Endoscopy

In many dogs and cats with a UTI, the results of imaging studies are normal. Survey abdominal radiography may reveal uroliths, renomegaly, or small kidneys, or other defects that may predispose the animal to the development of a UTI. Some dogs may have pelvic displacement of the urinary bladder (so-called pelvic bladder), which can be associated with urinary incontinence and UTI, although it also is observed in dogs without disease.[50] If no abnormalities are found by survey abdominal radiography, ultrasonography or contrast radiography should be performed. The upper urinary tract may be evaluated by excretory urography, and the lower urinary tract may be evaluated by contrast cystourethrography, double contrast cystography, and contrast vaginourethrography. A potential complication of contrast radiography of the lower urinary tract is

induction of a UTI. Ultrasonography is a noninvasive technique that is useful for evaluating the echotexture and architecture of the urinary tract except for the distal urethra. In humans, nuclear scintigraphy using technetium-99m–labeled dimercaptosuccinic acid (DMSA) may be useful for evaluating for pyelonephritis; however, this diagnostic aid has not been used in dogs.[51,52]

Table • 262-2 Abnormalities that Help Localize Urinary Tract Infections

SITE OF INFECTION	HISTORY	PHYSICAL EXAMINATION FINDINGS	LABORATORY FINDINGS	IMAGING STUDIES
Lower urinary tract	Dysuria, pollakiuria	Small, painful, thickened bladder	*Complete blood count (CBC):*	Normal kidneys
	Urge incontinence	Palpable masses in urethra or bladder	Normal Urinalysis: Pyuria, hematuria, proteinuria, bacteriuria	Structural abnormalitiesof lower urinary tract
	Signs of abnormal detrusor reflex (overflow incontinence, large residual volume)	Flaccid bladder wall, large residual volume	Urine culture: Significant bacteriuria	± Urocystoliths and/orurethroliths
	Gross hematuria at end of micturition	Abnormal micturition reflex ± Palpation of uroliths		± Thickening of bladder wall and rregularity of mucosa
	Cloudy urine with abnormal odor			Rarely, intraluminal gas formation (emphysematous cystitis)
	No systemic signs			
	Recent catheterization or urethrostomy			
Upper urinary tract	Polyuria, polydipsia	± Detectable abnormalities	CBC:± Leukocytosis	Renomegaly
	± Signs of systemic infection	± Fever and other signs of systemicinfection	Urinalysis: Pyuria, hematuria, proteinuria, bacteriuria, white	± Abnormal kidney shape
	± Renal failure	± Abdominal (renal) pain	blood cell or granular castsImpaired urine concentration	± Nephroliths, ureteroliths
		Kidney(s) normal or increased in size	± Azotemia and other findingsof renal failure	± Dilated renal pelves, dilated pelvicdiverticula

Chronic prostatitis	Recurrent urinary tract infections	Often no detectable abnormalities	CBC: Normal	± Prostatomegaly
	Urethral discharge independent of urination	± Prostatomegaly or asymmetric prostate	Urinalysis: Pyuria, hematuria, proteinuria, bacteriuria	± Prostatic cysts
	± Dysuria			± Prostatic mineralization

Endoscopy of the lower urinary tract may be useful for identifying mucosal and intraluminal lesions that may predispose an animal to UTI. In one cat, a urolith not visible by survey radiography was visualized by cystoscopy.[53] Disadvantages of cystourethroscopy include induction of anesthesia to perform the procedure, contamination of and trauma to the lower urogenital tract, and difficulty performing the procedure in male cats.

262.4 DIAGNOSIS

262.4.1 Urinalysis

A urinalysis should be performed as a routine part of a minimum database. A complete urinalysis involves determination of the urine specific gravity (USG) using a refractometer, chemical analysis using analytic test pads on dipsticks, and sediment examination. Cystocentesis is the best method of collecting urine when evaluating a dog or cat for UTI. If infectious prostatitis or vaginitis is suspected, these anatomic areas should be evaluated using different techniques (see Chapters 253 and 263).

With urinary tract infection the USG is variable, depending on whether the infection involves the upper urinary tract or an associated disease. Dipstick analysis often, but not always, reveals hematuria and proteinuria. Leukocyte esterase (WBCs) and nitrite (bacteria) test pads are not reliable in dogs and cats and should not be used.[54]

Examination of urine sediment should be a routine part of a complete urinalysis. The presence of a significant number of WBCs (more than 0 to 5 per high-power field) associated with hematuria and proteinuria in a properly collected urine sample suggests inflammation. Detection of significant microburia with pyuria indicates active inflammation associated with an infection. Bacteria and fungi may be difficult to identify in dilute urine, making a diagnosis of UTI problematic. UTI, especially a bacterial UTI, may be present without concurrent inflammation if host defenses are compromised (e.g., as in hyperadrenocorticism or feline leukemia virus infection).[7,12,55–59]

Rod-shaped bacteria may be identified in unstained preparations of urine sediment if more than 10,000 bacteria/mL are present, but they may not be consistently detected if present in fewer numbers. Cocci are difficult to detect in urine sediment if their numbers are less than 100,000 bacteria/mL.[2] Although detection of bacteria on urine sediment examination suggests bacterial UTI, this finding should be verified by urine culture. Urine sediment may be stained with Gram's stain or new methylene blue to aid in detection of microbes; however, urine culture is the gold standard for confirmation of UTI. Failure to detect bacteria on examination of urine sediment does not exclude their presence or rule out a UTI.

262.4.2 Urine Collection

For urine culture, urine should be collected by cystocentesis. With lower urinary tract disease, collection of a sample by this method may be difficult, and it may be necessary to collect urine by catheterization or, less desirably, voiding. These techniques require cleansing of the pet's external genitalia, and the perivulvar fur may require clipping to prevent contamination. Although urinary catheterization of dogs is usually accomplished without chemical restraint, cats require sedation or anesthesia. A sterile catheter and collection container (a syringe or a collection cup with a tight-fitting lid) are used. If the results of quantitative culture of urine samples obtained by catheterization or midstream voiding are equivocal after serial cultures, urine should be collected by cystocentesis.

The presence of bacteria, even in low numbers, in urine collected aseptically by cystocentesis indicates a UTI; however, false-positive results may occur if a loop of intestine is penetrated with the hypodermic needle during the procedure or if the sample is contaminated during handling. Contamination usually involves recovery of more than one organism.

262.4.3 Urine Culture

As mentioned previously, urine culture is the gold standard for diagnosis of a UTI. A diagnosis of UTI based only on clinical signs, hematuria, and/or urinary tract inflammation is a misdiagnosis that may result in inadequate or inappropriate treatment. Under some circumstances, antimicrobial therapy may be initiated without first obtaining the results of urine culture (see Empiric Antimicrobial Treatment, below); however, samples for urine culture should be collected before drug therapy is started. If antimicrobial therapy has been started, it should be discontinued for 3 to 5 days prior to performance of a urine culture to minimize inhibition of microbial growth.

A urine culture is the most definitive means of diagnosing a bacterial UTI. Fungal culture should be considered when yeast or fungi are identified on urine sediment examination. Care must be taken to collect, preserve, and transport the urine sample so as to avoid contamination, proliferation, or bacterial death.[60] Urine specimens for aerobic bacterial culture should be transported and stored in sealed, sterilized containers, and processing should begin as soon as possible. If laboratory processing is delayed by more than 30 minutes, the specimen should be refrigerated at 4°C.[61] At room temperature, bacterial counts may double every 20 to 45 minutes. Multiplication or destruction of bacteria may occur within 1 hour of collection.

If samples cannot be processed immediately for urine culture, several alternatives are available. Blood agar and MacConkey's agar plates may be inoculated and incubated for 24 hours. A calibrated bacteriologic loop or a microliter mechanical pipette that delivers exactly 0.01 or 0.001 mL of urine to the culture plates should be used. The urine is streaked over the plates by conventional methods. Blood agar supports the growth of most aerobic uropathogens, and MacConkey's agar provides information that aids the identification of bacteria and prevents “swarming” of *Proteus* spp. The plates are incubated or placed under an incandescent light.[62] If bacterial growth occurs on the plate after 24 hours, the plates may be submitted for identification and determination of antimicrobial sensitivities, or antimicrobial susceptibility may be determined using the agar disk diffusion method.[62,63] If no growth occurs after 24 hours, the plates may be discarded.

Commercially available urine culture collection tubes containing preservative, combined with refrigeration, may be used to preserve specimens for up to 72 hours.[64] More recently, in-house urine culture and susceptibility kits have become available (IndicatoRx; IDEXX Laboratories, Westbrook, Maine).

1804
1805

262.4.3.1 Qualitative urine culture

A qualitative urine culture involves the isolation and identification of bacteria in urine; it does not include quantification of bacterial numbers. Although urine in the bladder is normally sterile, urine that passes through the distal urogenital tract often becomes contaminated with resident flora (see Table 262-1). Therefore the presence of bacteria in urine collected by catheterization or voiding is often difficult to interpret, even with quantification of bacteria (Table 262-3). For this reason, a diagnostic urine culture should include quantitation of bacterial numbers in addition to identification of the organism and antimicrobial susceptibility.

262.4.3.2 Quantitative urine culture

A quantitative urine culture includes isolation and identification of the organism and determination of the number of bacteria (i.e., colony-forming units [cfu] per unit volume). Quantitation allows interpretation of the significance of bacteria present in a urine sample. However, caution should be exercised in the interpretation of quantitative urine cultures obtained by midstream voiding or manual expression of the bladder. Although urine obtained from most dogs without a UTI is either sterile or contains less than 10,000 cfu/mL (see Table 262-3), counts of 100,000 cfu/mL or higher have occurred with sufficient frequency to make collection of urine by midstream voiding or manual expression unsatisfactory.[65] The definition of significant bacteriuria in cats involves lower numbers of organisms, because cats appear to be more resistant to UTI than dogs.

262.4.4 Antimicrobial Susceptibility Testing

Administration of antimicrobial agents is the cornerstone of treatment for UTI. The antimicrobial agent selected should be (1) easy to administer, (2) associated with few, if any, side effects, (3) inexpensive, (4) able to attain tissue or urine concentrations that exceed the minimum inhibitory concentration (MIC) for the uropathogen by at least fourfold, and (5) unlikely to affect the pet's intestinal flora adversely.[2] The antimicrobial agent chosen should be based on antimicrobial susceptibility testing.

262.4.4.1 Agar disk diffusion technique

Antimicrobial susceptibility testing is often done using agar disk diffusion (Kirby-Bauer technique),[66] which is adequate for most bacterial UTIs. The agar disk diffusion method consists of Mueller-Hinton agar plates that have been inoculated with a standardized suspension of a single uropathogen. Paper disks impregnated with different antimicrobial drugs are placed on the plate. After 18 to 24 hours' inoculation at 38° C, antimicrobial susceptibility is estimated by measuring zones of inhibition of bacterial growth surrounding each disk. The zones of inhibition are then interpreted in light of established standards and recorded as resistant, susceptible, or intermediately susceptible. Because of differences in the ability of various antimicrobials to diffuse through agar, the antimicrobial disk surrounded by the largest zone of inhibition is not necessarily the drug most likely to be effective. Also, because the concentration of antimicrobial (except nitrofurantoin) in the paper disks is comparable to the typical serum concentration of the drug, drugs that are found to be resistant by the agar disk diffusion method may be effective in the urinary tract if they are excreted in high concentrations in urine (e.g., ampicillin and cephalexin).

Table • 262-3 Interpretation of Quantitative Urine Cultures in Dogs and Cats*

	SIGNIFICANT		SUSPICIOUS		CONTAMINANT	
SAMPLE TYPE	DOGS	CATS	DOGS	CATS	DOGS	CATS
Cystocentesis	≥1000	≥1000	100 to 1000	100 to 1000	≤100	≤100
Catheterization	≥10,000	≥1000	1000 to 10,000	100 to 1000	≤1000	≤100
Midstream voiding	≥100,000†	≥10,000	10,000 to 90,000	1000 to 10,000	≤10,000	≤1000
Manual compression	≥100,000†	≥10,000	10,000 to 90,000	1000 to 10,000	≤10,000	≤1000

From Lulich JP, Osborne CA: Bacterial urinary tract infections. *In* Ettinger SJ, Feldman EC (eds): Textbook of Veterinary Internal Medicine, 4th ed. Philadelphia, WB Saunders, 1999, pp 1775–1788.

* Values are given in colony-forming units per milliliter of urine (cfu/mL). Data represent generalities. Occasionally, bacterial UTI may be detected with fewer organisms (i.e., false-negative results).

† Because the contamination level of midstream samples may be 10,000 cfu/mL or higher (i.e., false-positive result), these samples should not be used for routine diagnostic culture.

262.4.4.2 Antimicrobial dilution technique

Antimicrobial dilution susceptibility tests are designed to determine the minimum concentration of an antimicrobial drug that will inhibit the growth of the uropathogen (i.e., the MIC). After inoculation and incubation of uropathogens into wells containing serial twofold dilutions of antimicrobial drugs at concentrations achievable in tissues and urine, the MIC is defined as the lowest antimicrobial concentration (or highest dilution) that allows no visible bacterial growth. The MIC is several dilutions lower than the minimum bactericidal concentration of drugs. In general, the antimicrobial agent is likely to be effective if it can achieve a concentration four times that of the MIC (Table 262-4). Many antimicrobial drugs that are excreted through the kidneys reach concentrations in urine that are 10 to 100 times greater than the serum concentration.

262.5 TREATMENT

262.5.1 Prevention

Normal host defense mechanisms are effective in preventing UTIs; however, they are not impenetrable. For example, normal host defenses may be overwhelmed if large quantities of a virulent uropathogen are introduced into the urinary tract during diagnostic and therapeutic procedures. Iatrogenic UTI is a common complication of indwelling urinary catheters, especially if an open-ended system is used. Bacterial UTI developed in 20% of healthy adult female dogs after intermittent catheterization; in 33% of male dogs during repeated catheterization; and in 65% of healthy male cats within 3 to 5 days of open indwelling catheterization. In a clinical study, bacterial UTI developed in 52% of dogs and cats with indwelling urinary catheters; the risk of UTI increased with the duration of catheterization.[67] The use of indwelling urinary catheters during diuresis or corticosteroid administration is particularly dangerous, and the problem is compounded if the dog or cat has preexisting urinary tract disease.

Table • 262-4 Average Canine Urine Concentrations of Some Antimicrobial Agents

DRUG	DAILY DOSAGE (mg/kg)	ROUTE OF ADMINISTRATION	MEAN URINE CONCENTRATION (SD)
Amikacin	5	SQ	342 ± 143 µg/mL
Amoxicillin	11	PO	202 ± 93 µg/mL
Ampicillin	26	PO	309 ± 55 µg/mL
Cephalexin	18	PO	500 µg/mL
Chloramphenicol	33	PO	124 ± 40 µg/mL
Enrofloxacin	5	PO	40 10 µg/mL
Gentamicin	2	SQ	107 ± 33 µg/mL
Hetacillin	26	PO	300 ± 156 µg/mL
Kanamycin	4	SQ	530 ± 151 µg/mL
Nitrofurantoin	4.4	PO	100 µg/mL
Penicillin G	36,700 U/kg	PO	295 ± 211 µg/mL
Penicillin V	26	PO	148 ± 99 µg/mL
Sulfisoxazole	22	PO	1466 ± 832 µg/mL
Tetracycline	18	PO	139 ± 65 µg/mL
Trimethoprim/sulfadiazine	13	PO	55 ± 19 µg/mL
Tobramycin	2.2	SQ	66 ± 39 µg/mL

From Ling GV: Therapeutic strategies involving antimicrobial treatment of the canine urinary tract. J Am Vet Med Assoc 185(10):1162–1164, 1984; and Lulich JP, Osborne CA: Bacterial urinary tract infections. *In* Ettinger SJ, Feldman EC (eds): Textbook of Veterinary Internal Medicine, 4th ed. Philadelphia, WB Saunders, 1999, pp 1775–1788.
SD, Standard deviation; *SQ,* subcutaneous; *PO,* per os (by mouth).

Iatrogenic UTI may be prevented by (1) avoiding indiscriminate use of urinary catheters, (2) using a closed collection system for indwelling urinary catheters, (3) using indwelling urinary catheters cautiously when pets are undergoing diuresis, (4) avoiding the use of indwelling catheters in immunosuppressed pets or those receiving immunosuppressive medications (e.g., glucocorticoids), (5) appropriately using antimicrobials with urinary catheterization, and (6) using diagnostic and therapeutic techniques that minimize trauma and microbial contamination of the urinary tract.[2] Although it would seem logical to administer antimicrobial agents while an indwelling urinary catheter is in place so as to decrease the chance of iatrogenic UTI, the practice is discouraged. Concomitant oral or parenteral administration of antimicrobial agents during indwelling urethral catheterization reduces the frequency of development of a bacterial UTI; however, it promotes the development of UTI caused by multidrug-resistant bacteria.[67]

262.5.2 Eradication of Underlying Causes

Although antimicrobial agents are the cornerstone of treatment of UTI, they should be used in a logical fashion. Overuse and misuse of antimicrobial agents may result in the emergence of resistant organisms, a situation that has implications for veterinary and human health. A UTI occurs in association with compromise of host defense mechanisms, which may be transient or permanent. Transient compromise often results in the development of a simple, uncomplicated UTI; however, permanent compromise results in the development of complicated UTI. Evaluation for and correction or control of the compromise or compromises in host defense mechanisms are important in the treatment of UTI, especially if these infections are recurrent (Figure 262-1). For example, recurrent bacterial UTI may occur in female dogs with a recessed vulva; vulvoplasty may help prevent future infections.[68,69]

262.5.2.1 Bacterial Urinary Tract Infection

262.5.2.1.1 Uncomplicated UTI

Uncomplicated UTIs are those in which no underlying structural, neurologic, or functional abnormality is identified. Dogs and cats with an uncomplicated UTI are usually successfully treated with a 10-to 14-day course of an appropriate antimicrobial agent (see Figure 262-1). If the proper antimicrobial is chosen and administered at the appropriate dosage and frequency, clinical signs should resolve within 48 hours. Also, the results of a complete urinalysis should improve within this same time frame. If possible, a urine culture should be performed 5 to 7 days after cessation of antimicrobial therapy.

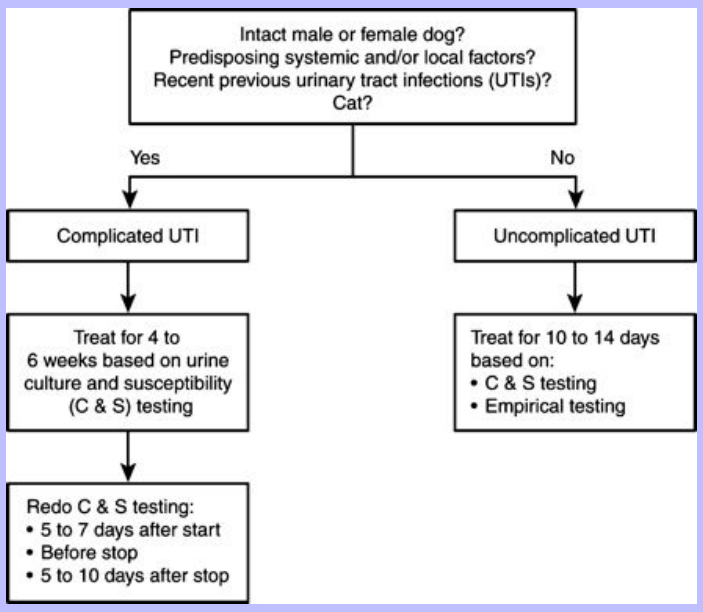
262.5.2.1.2 Empiric antimicrobial treatment

Treatment of uncomplicated bacterial UTI of acute onset may be undertaken without the results of antimicrobial susceptibility testing, provided (1) that the dog or cat has not been given antimicrobial agents within the last 4 to 6 weeks and (2) that this is an initial or infrequent occurrence. In such situations, the antimicrobial should be chosen for its known properties and with knowledge of bacteria that commonly cause UTI (Table 262-5). Identification of bacteria on examination of urine sediment, especially if Gram's staining is performed, increases the likelihood of empirically choosing an appropriate antimicrobial. For example, *E. coli* is the most common cause of bacterial UTI in dogs and cats and is a gram-negative rod associated with aciduria. Staphylococci, on the other hand, are gram-positive cocci associated with alkaluria because they produce urease, which metabolizes urea to ammonia, resulting in an alkaline urine pH.

1806

1807

Figure 262-1 Algorithm for treatment of urinary tract infection (UTI) in dogs and cats. *C & S,* Urine culture and susceptibility testing.



The use of fluoroquinolones for empiric treatment of bacterial UTI is discouraged because of the inherent resistance of many gram-positive organisms and the developing resistance of many gram-negative organisms, especially *E. coli*, to this class of antimicrobials.[26,70]

Table • 262-5 Estimate of Susceptibility of Uropathogens to Commonly Used Antimicrobial Agents

UROPATHOGEN	DRUGS OF CHOICE	ALTERNATIVES
Enterobacter spp.	Trimethoprim-sulfadiazine	Cephalosporins (first and second generation), gentamicin, nitrofurantoin
*Escherichia coli**	Trimethoprim-sulfadiazine	Cephalosporins (first and second generation), fluoroquinolones, gentamicin
Klebsiella spp.*	Cephalosporins (first generation)	Amikacin, gentamicin, trimethoprim-sulfadiazine, cephalosporins (second and third generation)
Mycoplasma,* *Ureaplasma*	Fluoroquinolones	Tetracyclines
Proteus spp.*	Amoxicillin, ampicillin, amoxicillin-clavulanate	Cephalosporins (first and second generation), gentamicin, nitrofurantoin, trimethoprim-sulfadiazine
*Pseudomonas aeruginosa**	Fluoroquinolones	Tetracyclines, gentamicin, cephalosporins (first, second, and third generation)
Staphylococcus spp.*	Amoxicillin, ampicillin, amoxicillin-clavulanate	Cephalosporins (first generation), nitrofurantoin, trimethoprim-sulfadiazine
Streptococcus spp., *Enterococcus* spp.	Amoxicillin, ampicillin, amoxicillin-clavulanate	Cephalosporins (first generation), nitrofurantoin, trimethoprim-sulfadiazine

* Prior treatment with antimicrobials may alter the susceptibility of uropathogens to these drugs.

262.5.2.1.3 Complicated UTI

Reproductively intact dogs, all cats, and animals with identifiable predisposing causes for UTI (e.g., renal failure, hyperadrenocorticism, and diabetes mellitus) should be considered to have a complicated UTI (see Figure 262-1). Pyelonephritis and prostatitis are examples of complicated UTI. Treatment with antimicrobials for longer than the routine 10 to 14 days may be indicated, and the drugs are usually administered for 4 to 6 weeks. The urine should be evaluated in the first week of treatment for response to therapy and also before discontinuation of therapy. Prophylactic antibiotic treatment may be necessary to control bacterial UTIs that are difficult to eradicate or that recur frequently.

1807

1808

262.5.2.1.4 Recurrent UTI

262.5.2.1.4.1 Relapse

A *relapse* is defined as recurrence of a UTI caused by the same organism. Relapses usually occur within days to weeks of discontinuation of antimicrobial therapy. Possible causes of relapse include use of an inappropriate antimicrobial agent; administration of an appropriate antimicrobial agent at an inappropriate dosage, frequency, or duration; and complicating factors. A urine culture should be

evaluated prior to reinstitution of antimicrobial therapy, and further diagnostic evaluation for predisposing causes is indicated.

262.5.2.1.4.2

Reinfection

Reinfection is defined as infection with a different organism than that initially present. Reinfections usually occur some time after cessation of antimicrobial therapy. Although predisposing risk factors may be present, many animals that become reinfected do not have identifiable risk factors. If reinfection occurs infrequently, each episode may be treated as an uncomplicated UTI. However, if reinfection occurs more often than three times a year, the animal should be treated as having a complicated UTI. Additionally, prophylactic antimicrobial therapy may be indicated.

262.5.2.1.4.3

Superinfection

A *superinfection* occurs when a second bacterial organism is isolated while an animal is receiving antimicrobial therapy. This organism often displays a high degree of antibiotic resistance. A UTI that occurs in animals receiving antimicrobial therapy that also have an indwelling urethral catheter is an example of a superinfection.[67]

262.5.2.1.4.4

Prophylactic antimicrobial treatment

No good studies have evaluated prophylactic antimicrobial therapy in animals that have frequent reinfections. When prophylactic therapy is undertaken, urine culture and susceptibility testing should be done to ensure that the bacterial UTI has been eradicated. A drug should be selected that is excreted in high concentration in the urine and that is unlikely to cause adverse effects. Often a fluoroquinolone, cephalosporin, or beta-lactam antimicrobial is chosen. The antimicrobial should be given at approximately one third the therapeutic daily dose immediately after the pet has voided, and when the drug and its metabolites will be retained in the urinary tract for 6 to 8 hours. This is typically done at night. The drug is administered for a minimum of 6 months. Urine samples are collected, preferably by cystocentesis (not by catheterization, because this may induce a bacterial UTI) every 4 to 8 weeks for urinalysis and quantitative urine culture. If no evidence of bacterial UTI is found, prophylactic therapy is continued. If a bacterial UTI is identified, the active (break-through) infection is treated as a complicated bacterial UTI. If a break-through bacterial UTI does not occur after 6 months of prophylactic antimicrobial therapy, the therapy may be discontinued and the pet monitored for reinfection.[71,72]

262.5.2.1.4.5

Ancillary therapy

Many forms of ancillary therapy have been developed to aid in the treatment of UTI. Ancillary therapy includes urinary acidifiers, urinary antiseptics, local instillation of antimicrobial agents into the urinary bladder, alteration of urine volume, and the use of pharmacologic agents to affect the storage and voiding phases of micturition. Although the activity of antimicrobial agents is affected by the urine pH, rarely is alteration of the urine pH undertaken in an effort to increase activity. An exception is induction of aciduria when methenamine, a urinary antiseptic, is used.

Instillation of antimicrobial agents into the urinary bladder is ineffective and may be associated with complications. For example, instillation of gentamicin into a compromised urinary bladder may result

in absorption and attainment of toxic serum levels. If antimicrobial therapy is required, antimicrobials should be administered orally or parenterally. An instance when instillation of a pharmacologic agent into the urinary bladder may be beneficial is the use of a cystostomy catheter. A cystostomy catheter is inserted directly into the urinary bladder and exits the ventral abdominal wall. Instillation of Tris-EDTA through the cystostomy catheter into the urinary bladder after the bladder has been emptied of urine may decrease the incidence of bacterial UTI.[74]

262.5.2.2 Fungal Urinary Tract Infection

Fungal UTIs are rare in dogs and cats. They often are associated with glucosuria of diabetes mellitus but may also occur in animals that do not have diabetes. In one study of 20 dogs and cats with *Candida* spp. UTI, concurrent diseases or nonantifungal drugs administered within 1 month of isolation included antibiotics, corticosteroids, diabetes mellitus, nonurogenital neoplasia, and noncandidal urogenital disease. All animals had sources of local or systemic immune compromise that likely predisposed to infection.[12] Treatment of animals with a fungal UTI involves correction or control of the predisposing cause or causes, urinary alkalization, and administration of antifungal drugs. In animals without clinical signs, administration of urinary alkalinizing agents (e.g., potassium citrate or sodium bicarbonate) or the use of diets that induce alkaluria may result in successful eradication of the fungal UTI.[10] Fungal growth is inhibited in an alkaline medium. In animals with active disease, however, antifungal drugs that are excreted renally in an active form should be administered. Although amphotericin B is renally excreted and achieves high concentration in urine, it is not often used because it is parenterally administered and is nephrotoxic. Fluconazole is a good choice and is orally administered. Itraconazole may also be a good choice, but it has not been evaluated for the treatment of fungal UTIs in dogs and cats. Antifungal agents must be administered for several months in association with induction of alkaluria. Correction and/or control of the predisposing underlying disease is paramount in the treatment and prevention of fungal UTI.

262.5.2.3 Viral Urinary Tract Infection

Although viruses are associated with urinary tract disease in humans, their role in urinary tract disease in dogs and cats is unknown.[75,76] Viral infection of the lower urinary tract may be a cause of lower urinary tract disease in cats.[15,16]

263 CHAPTER • 263 Prostatic Diseases

Michelle A. Kutzler

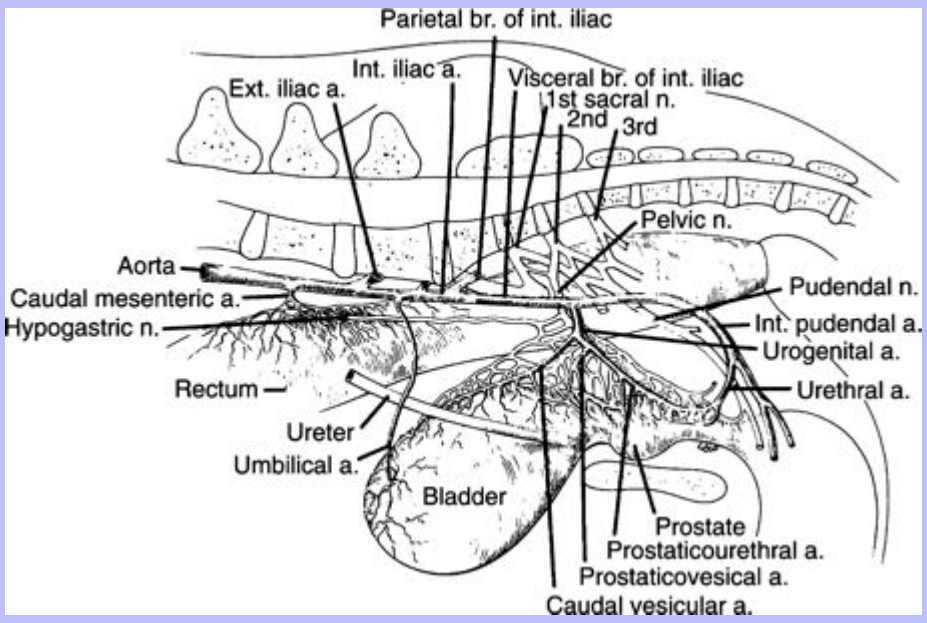
Amy Yeager

263.1 DEVELOPMENT AND ANATOMY

The embryologic development of the prostate begins from multiple outgrowths of the urethral epithelium.[1] During fetal development, testosterone secreted from the testes is reduced to dihydrotestosterone (DHT) in cells in the urogenital sinus, stimulating the formation of the prostatic lobes in the retroperitoneal space caudal to the urinary bladder (Figure 263-1).[2,3] Age, androgenic stimulus, disease, and the degree of urinary bladder distention affect the prostate's position. The gland is intra-abdominal in fetuses and pups less than 2 months old because of the urachal attachment that maintains the bladder in a cranioventral position.[4] The urachal remnant breaks down at about 2 months of age, at which time the prostate moves into an intrapelvic position.[3] Beginning about 8 months of age, androgenic stimulation arising from sexual maturity results in prostatic enlargement; the prostate is repositioned cranially over the pelvic brim as it increases in size, to a total or partial intra-abdominal position.[4] After castration, the prostate atrophies and returns to the intrapelvic position. The degree of urinary bladder distention also affects the prostate's position; specifically, a full bladder displaces the prostate intra-abdominally, whereas an empty bladder facilitates an intrapelvic position.[5]

The prostate is a bilobed, musculoglandular organ that completely encircles the proximal urethra between the membranous portion of the urethra and the neck of the urinary bladder. A capsule surrounds the prostate, and a prominent median septum divides the gland into two ovoid lobes that are dorsally flattened, with the ventral surface covered in a layer of fat.[3] Well-developed arrays of smooth muscle fibers from the capsule extend down into the parenchyma to blend with the smooth muscle of the urethra.[6] Numerous ducts open into the prostatic urethra at the colliculus seminalis, a central portion of the dorsal longitudinal urethral crest.[1] The deferent ducts enter the craniodorsal surface of the prostate and continue caudoventrally to open on each side of the colliculus seminalis.[1]

Figure 263-1 Diagram of the normal anatomic relationship of the prostate to other structures in the caudal abdomen. (Adapted from Miller ME et al: Anatomy of the Dog. Philadelphia, WB Saunders, 1964.)



The urogenital artery, a branch of the internal pudendal artery, supplies blood to the prostate via several prostatic branches through the dorsolateral surfaces (see Figure 263-1).[7] Several prostatic branches originate from the urogenital artery and enter the prostate gland at the dorsolateral surfaces. These branches tunnel beneath the capsule and further divide into smaller parenchymal arteries.[7] Venous drainage occurs via the urethral vein that accompanies the urethra or through small venules that follow the capsular arteries.[7] Lymphatic drainage is to the middle iliac lymph nodes.[3] The hypogastric and pelvic nerves provide sympathetic and parasympathetic innervation to the prostate (see Figure 263-1).[3] Parasympathetic stimulation during erection increases the rate of prostatic fluid production, and sympathetic stimulation during ejaculation ejects the fluid into the prostatic urethra.[8]

263.2 PHYSIOLOGY

In the dog, the prostate is the only accessory sex gland, and its secretory function is androgen dependent. Although both testosterone and DHT stimulate prostatic glandular activity, DHT is far more biologically active in that it binds to the androgen receptor with two times the affinity of testosterone and has a fivefold slower rate of dissociation.[9] In sexually mature dogs, the prostate comprises the compound tubular alveolar glands that radiate from the urethral duct openings.[10] In castrated and sexually immature dogs, the prostate comprises a branching ductular system with poor alveolar development.[10] Elimination of the androgenic stimulus, either pharmacologically or by castration, results in glandular and parenchymal atrophy of the prostate.[11] In addition to

1809 1810

androgens, locally produced growth factors (i.e., endothelin-1, basic fibroblast growth factor, transforming growth factor-beta, interleukin-6, and interleukin-8) act to modulate prostatic alveolar development and function.[12]

Prostatic fluid makes up the first and third fractions of the ejaculate; it increases the volume of the ejaculate and possibly aids in sperm transport.[1] Prostatic fluid accounts for greater than 97% of the total ejaculate volume.[13] When neither micturition nor ejaculation is occurring, prostatic fluid is constitutively secreted and expelled into the prostatic urethra, from which it drains into the urinary bladder. Normal prostatic fluid is thin and clear. The major secretory product of the prostate is arginine esterase, which constitutes greater than 90% of the protein in the seminal plasma.[14] Prostate-specific antigen (PSA), the major seminal plasma protein in humans, is not detectable in canine serum or seminal plasma.[15] However, arginine esterase and PSA are both serine proteases and have similar molecular weights and hormonal regulation.[16] The canine prostate also secretes prostatic acid phosphatase.[15]

263.3 SIGNALMENT AND CLINICAL SIGNS

Most prostatic diseases are associated with prostatomegaly. Prostatic size correlates with body weight and age[17] (Table 263-1) as well as breed.[18] Scottish terriers are reported to have prostates four times larger than those of dogs of other breeds of similar weight and age.[18] Doberman pinschers and German shepherds were the breeds most commonly represented in a review of 177 cases of prostatic disease.[19]

Clinical signs associated with prostatic disease vary, depending on the degree of prostatomegaly and the specific disorder. Prostatic enlargement is common in dogs more than 5 years old. The most common clinical signs associated with prostatic disease are urethral discharge, hematuria, and tenesmus. However, patients with prostatic disease may be asymptomatic. The urethral discharge may be clear, purulent, or hemorrhagic. In a 14-year retrospective study of prostatic disease, hemorrhagic urethral discharge, which could be exacerbated by sexual arousal, was the only clinical sign observed in 23% of cases.[20] The source of the hemorrhage may be dilated prostatic urethral veins, which can be visualized with cystoscopy.[21] Greatly increased vascularity associated with hyperplasia, infection, or neoplasia in the prostatic parenchyma may be an additional source of hemorrhage.[22] Although widely described as a clinical sign associated with prostatic disease, tenesmus is present only when the prostate is morbidly enlarged. In one report, constipation developed after mineralization of a grossly enlarged paraprostatic cyst.[23] Additional clinical signs associated with prostatic disease include fever, cachexia, abnormal hindlimb gait, and caudal abdominal pain.

Table • 263-1 Formula for Calculation of Maximum Prostatic Measurements from Ultrasonographic Examination of Healthy Male Intact Dogs

DIMENSION	DEFINITION	FORMULA
Length	Diameter along urethral axis	(0.055 ×BW) +(0.143 ×A) +3.31
Width	Diameter perpendicular to axis of height^{T}	(0.047 ×BW) +(0.089 ×A) +3.45
Height^{S} (H^{S})*	Diameter perpendicular to axis of length	(0.046 ×BW) +(0.069 ×A) +2.68
Height^{T} (H^{T})†	Diameter along line separating two lobes	(0.044 ×BW) +(0.083 ×A) +2.25
Volume	[1/2.6 ×(Length ×Width ×[(H^{S} +H^{T})/2])] +1.8 cm^{3}	(0.867 ×BW) +(1.885 ×A) +15.88

Modified from Ruel Y et al: Vet Radiol Ultrasound 39:212, 1998; and from Kamolpatana K et al: Vet Radiol Ultrasound 41:73, 2000.
BW, Body weight; *A*, age.

* Height as measured from the sagittal view.

† Height as measured from the transverse view.

263.4 EXAMINATION OF THE PROSTATE AND PROSTATIC FLUID

263.4.1 Prostate

A cursory examination of the prostate can be performed by concomitant rectal and abdominal palpation. Rectal palpation permits examination of only the dorsal or dorsocaudal aspect of the prostate.[24] Concomitant abdominal palpation not only allows examination of the cranial aspects of the prostate, it also facilitates better palpation per rectum because the prostate can be pushed into or near the pelvic canal.[1] During palpation, the prostate should be evaluated for size, symmetry, surface contour, movability, and pain. The normal prostate is bilobed, symmetric, smooth, movable, and pain free.

Transabdominal ultrasonography is the best imaging modality for evaluation of the prostate because it is a safe, noninvasive method that allows for precise measurements as well as evaluation of the prostatic parenchyma. Dogs can be imaged in dorsal, dorsal oblique, or lateral recumbency. Because the haircoat is thin in the suprapubic area, clipping usually is not necessary. However, hair may be clipped from the ventral abdomen between the cranial aspect of the prepuce and pubic bone from the midline to the inguinal fold to facilitate imaging. Alcohol and/or coupling gel is applied to the skin to improve contact. A 5 to 10 MHz convex or sector transducer is recommended because of its 90-degree or greater field of view and because the transducer head can follow the body contour of the caudal abdomen better than that of a linear array transducer. To image the prostate, the transducer is placed against the ventral abdominal wall cranial to the pubis. The prostate should be imaged in both the sagittal (longitudinal) and transverse planes to ensure that all areas of the prostate are visualized. The true sagittal plane can be confirmed by observation of the hypoechoic urethral tract.

Prostate dimensions should be measured on both the sagittal and transverse planes (Figure 263-2). Prostate length and height should be measured on the sagittal images. Length is defined as the maximum prostatic diameter along the urethral axis, and height is defined as the maximum prostatic diameter perpendicular to the axis of the length. The transverse image of the prostate is then obtained by rotating the transducer 90 degrees. From the transverse image, height is defined as the prostatic diameter separating the two lobes, and width is defined as the maximum prostatic diameter perpendicular to the axis of the height. In a study of 100 healthy, intact male dogs, the maximum prostatic dimensions were reported, and the maximum predicted values of

prostate size were found to vary by age and body weight.[25] Formulas for calculating the maximum prostatic dimension in a normal, intact dog are presented in Table 263-1. Normal prostatic height on sagittal plane views for a dog castrated before 1 year of age is about 1 cm (Figure 263-3).

Figure 263-2 Sagittal **(A)** and transverse **(B)** ultrasonographic images of a normal prostate from an intact dog. The prostatic parenchyma is uniformly of medium texture and is moderately hyperechoic compared with surrounding structures, and the prostatic urethra *(U)* is hypoechoic. Note the anechoic bladder neck *(B)* and pubic bone shadow *(S)* on the sagittal image.

The ultrasonographic appearance of a prostate from a normal, intact dog should be uniformly fine-medium texture and moderately hyperechoic, an appearance similar to that of the spleen, with a capsule that is echoic and has smooth margins.[26] The urethra, which runs lengthwise through the middle of the two lobes, generally is hypoechoic compared with the prostatic parenchyma. In contrast, the ultrasonographic appearance of a

prostate from a castrated dog is slightly hypoechoic compared with surrounding fat and adjacent structures, such that the urethra is more difficult to visualize (see Figure 263-3). The echogenicity within the prostate should be assessed for focal, multifocal, or diffuse changes in echotexture. Increased echogenicity and coarse echotexture is associated with hyperplasia, inflammation, infection, and neoplasia. A more echogenic, butterfly-shaped hilar region may be imaged in the center of the prostate in the intact male dog (see Figure 263-2); this corresponds to collagen and epithelial tissue in the wall of the prostatic urethra and periurethral ducts.[27] The hilar echo may be masked by increased echogenicity caused by hyperplasia, inflammation, infection, and neoplasia. However, imaging of the hilar echo may be unreliable because of technical artifact.

Figure 263-3 Sagittal ultrasonographic image of a normal prostate from a castrated dog. Note the small size of the prostate (0.92 cm) and the slightly hypoechoic parenchyma compared with adjacent structures.

Ultrasonography also allows the examiner to determine whether cysts are present (or absent) in the prostate. The size, number, and location of the cysts should be characterized. The relative echogenicity of the luminal contents of the cysts should be characterized as hypoechoic or anechoic. Parenchymal mineralization may also be observed and is frequently associated with neoplasia. However, mineralization occasionally may develop with chronic inflammation.

Although ultrasonography can detect enlargement and changes in the internal prostatic architecture, these features are not pathognomonic for a specific disease. The ultrasonographic appearance of the prostate does not correlate well with culture results, nor does the presence and number of cysts factor into the incidence or type of infection encountered.[28] However, compared with radiography, ultrasonographic imaging is more sensitive for assessing focal or regional parenchymal disease.[29,30] Ultrasonography has also proved to be a useful technique for evaluating the response to pharmacologically induced prostatic involution.[31]

Ultrasonographic evaluation for prostatic disease should include evaluation of adjacent structures, including the urethra and urinary bladder. Primary urinary tract disease (e.g., infection, calculi, transitional cell carcinoma) may complicate or mimic prostatic disease. The sublumbar (medial iliac and hypogastric) lymph nodes should be evaluated. Enlargement and/or altered echogenicity may represent extension of prostatic disease into the regional lymph nodes. In addition, the smooth contour of the caudal lumbar vertebrae may

become irregular with metastasis of prostatic neoplasia, which may be more accurately diagnosed with a radiograph. In rare cases, when prostatic disease extends beyond the capsule, adjacent fat may become hyperechoic from edema, inflammation, fibrosis, or necrosis. Peritoneal fluid may be visible, and if so, analysis of the fluid may aid in the diagnosis of treatment.

1811

The location, size, and contour of the prostate can be evaluated with caudal abdominal radiography. A normal prostate does not displace the colon and bladder from their normal positions. Radiographically, the prostate has a soft tissue opacity, and its identification is influenced by the differential subject opacity of surrounding tissues. Radiographic diagnosis of prostatomegaly can be made when the prostate dimensions exceed 70% of the pubic-promontory distance on a lateral radiograph (Figure 263-4)[30] or 50% of the width of the pelvic inlet on a ventrodorsal radiograph.[32] However, neither of these methods accounts for the effects of age on prostate size. Often the exact dimensions of the prostate cannot be determined because of superposition of osseous structures or because of lack of abdominal serosal detail as a result of lack of fat, the presence of ascites, or focal peritonitis associated with prostatitis.[33] The ability of radiography to identify parenchymal changes associated with disease is limited to identification of mineralization, which may be insignificant or may be indicative of neoplasia or, less frequently, chronic inflammation. With caudal abdominal radiography, enlargement of sublumbar lymph nodes (medial iliac and hypogastric lymph nodes) may be observed, because it would cause ventral displacement of the colon. In addition, obvious lytic bone lesions involving the lumbar vertebral bodies and pelvic bones may be identified (Figure 263-5).

1812

Figure 263-4 Lateral radiograph of the caudal abdomen of a dog with marked prostatomegaly. The bladder is indicated by the cranial arrows and the prostate by the caudal arrows. (From Barsanti JA, Finco DR: Canine prostatic diseases. *In* Ettinger SJ [ed]: Textbook of Veterinary Internal Medicine, 3rd ed. Philadelphia, WB Saunders, 1989, p 1864.)

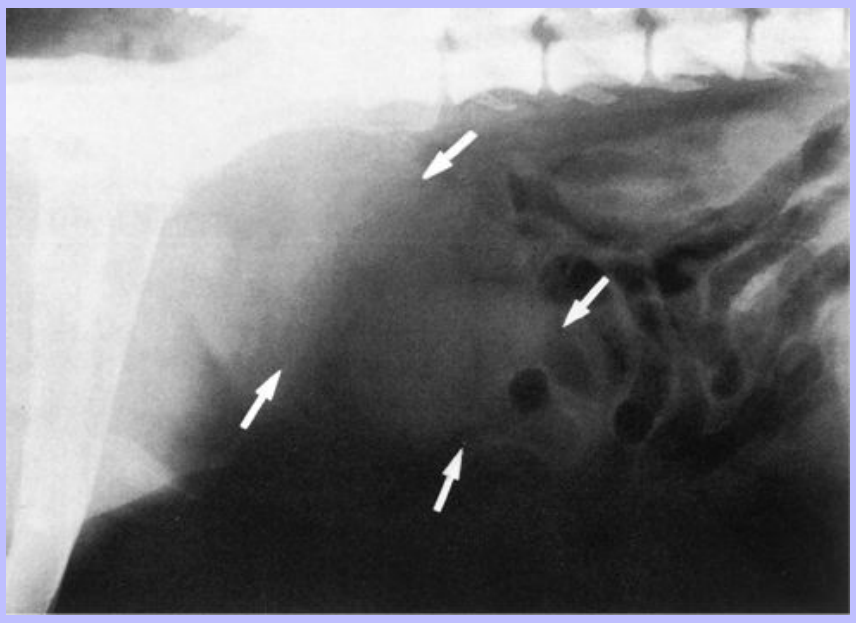


Figure 263-5 Early radiographic changes caused by prostatic adenocarcinoma. Proliferative changes *(arrows)* are indicative of early metastasis (L5-L7). (From Greiner TP, Johnson RG: Diseases of the prostate gland. *In* Ettinger SJ [ed]: Textbook of Veterinary Internal Medicine, 2nd ed. Philadelphia, WB Saunders, 1983, p 1474.)

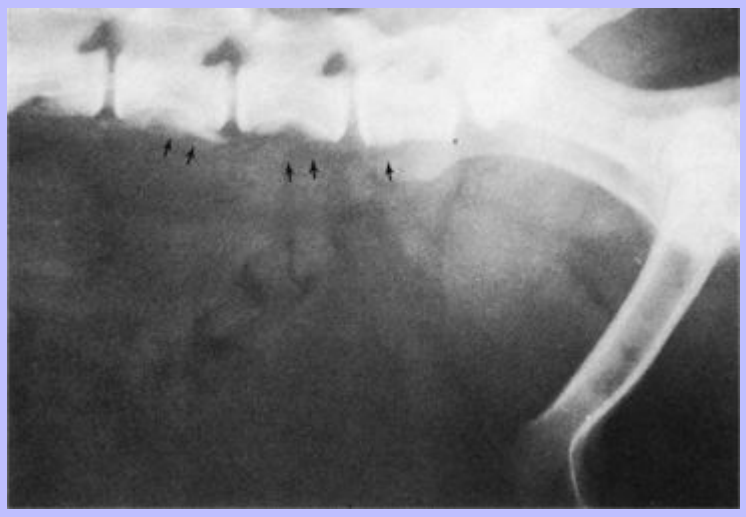
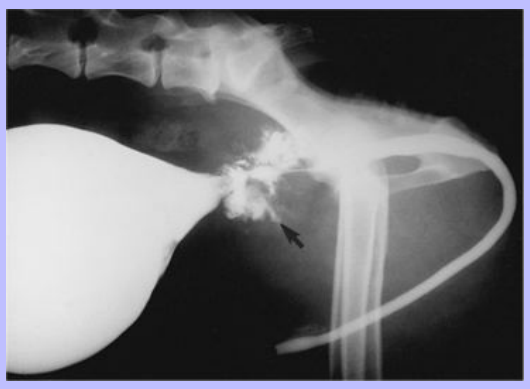


Distention retrograde contrast urethrocystography (DRCU) has been described as a method for determining prostatic integrity. In a normal prostate, minimal positive contrast is identified in the prostatic parenchyma near the urethra (urethroprostatic reflux) (Figure 263-6).[34] However, accumulation of larger volumes of contrast material in the prostatic parenchyma (intraprostatic reflux) has been reported with all types of prostate diseases.[1] Irregularity or an undulant pattern to the prostatic urethral surface has been associated with benign prostatic hyperplasia, chronic bacterial prostatitis, and neoplasia (Figure 263-7).[30] Narrowing of the prostatic urethral diameter during DRCU has been reported to occur in association with benign prostatic hyperplasia, prostatic abscessation, and neoplasia.[30] Because the prostatic urethral diameter varies among normal dogs with the degree of bladder distention, changes in prostatic diameter must be interpreted cautiously.[35] In addition, the absence of positive results on contrast studies does not rule out the presence of prostatic disease.[30] In most cases, ultrasonography is a better method than DRCU for imaging prostatic integrity.

Figure 263-6 Distention retrograde contrast urethrocytogram from a normal dog. Note the small quantity of urethroprostatic reflux *(arrow)*. (From Root Kustritz MV, Klausner JS: Prostatic diseases. *In* Ettinger SJ, Feldman EC [eds]: Textbook of Veterinary Internal Medicine, 5th ed. Philadelphia, WB Saunders, 2000, p 1689.)

Figure 263-7 Distention retrograde contrast urethrocytogram from a dog with adenocarcinoma. Note the prostatomegaly and intraprostatic reflux of contrast agent (arrow). (From Root Kustritz MV, Klausner JS: Prostatic diseases. *In* Ettinger SJ, Feldman EC [eds]: Textbook of Veterinary Internal Medicine, 5th ed. Philadelphia, WB Saunders, 2000, p 1695.)

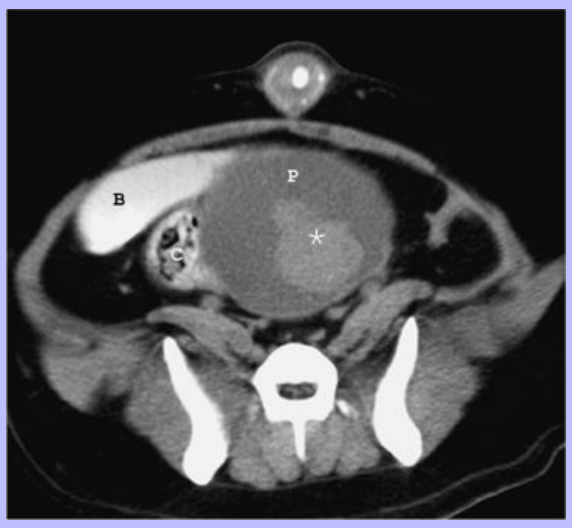


Computed tomography (CT) (Figure 263-8) and magnetic resonance imaging (MRI) are excellent modalities for imaging both the prostate and adjacent structures, where metastasis may be a concern. In humans, MRI is an accurate means of assessing changes in prostatic volume that is highly correlated with the weight of the excised prostate.[36] However, the veterinary literature has little information about the value of CT or MRI in the diagnosis of prostatic disease in the dog. Both of these imaging modalities are expensive, and both require immobilization of the dog with general anesthesia. Bone scintigraphy may be helpful for imaging osseous metastatic lesions before they can be identified by radiography.[37]

263.4.2 Prostatic Fluid

With any dog suspected of having prostatic disease, the prostatic fluid should be assessed by cytologic evaluation and quantitative bacterial culture. Prostatic fluid may be obtained either by ejaculation (collection of the third fraction) or by prostatic wash; the former method is preferred, especially when bacterial infection and concomitant cystitis are suspected. To ejaculate a dog, the prepuce is retracted caudally, and digital pressure is applied to the base of the penis, proximal to the bulbus glandis (Figure 263-9). Intense pelvic thrusting occurs with ejaculation. Prostatic fluid can be collected aseptically by ejaculation as long as care is taken (1) to change collection containers after the combined first and second fractions have been collected and (2) to ensure that the tip of the penis does not touch the inside of the sterile collection container. The combined first and second fraction sample should be saved for semen evaluation if indicated. Cytologic evaluation of the prostatic fluid aids in the determination of whether contamination occurred during ejaculation; specifically, the presence of squamous epithelial cells with gram-positive cocci in conjunction with an absence of neutrophils indicates that contamination occurred during collection.[38]

Figure 263-8 Transverse computed tomograph of the caudal abdomen of a dog with profound prostatomegaly *(P)* displacing the colon *(C)* and bladder *(B)*. Positive contrast was introduced into the bladder prior to examination. Note the irregular, high attenuating mass in the prostate *(*)*.



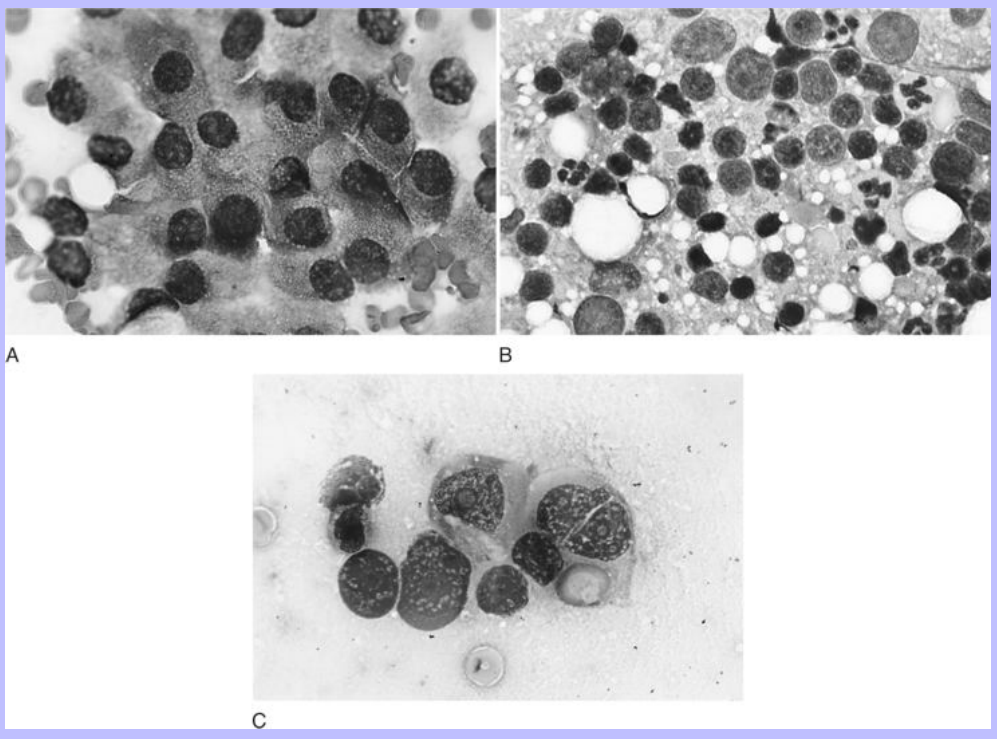
If the dog will not ejaculate, a prostatic wash should be performed (see Chapter 84). Using aseptic technique, the bladder is catheterized, and urine is removed. The bladder then is flushed with 5 mL of sterile saline, and this sample is saved (PM-1).[38] The catheter subsequently is retracted so that the tip is distal to the prostate. The prostate then is massaged per rectum for about 1 minute to express a quantity of prostatic fluid into the urethra, where it can be collected with a urinary catheter. Sterile saline (5 mL) is slowly injected while the urethral orifice is occluded. The catheter is advanced into the bladder as aspiration is performed, and the sample (PM-2) is collected. The prostatic wash sample should be fixed on a glass slide, stained with hematoxylin-eosin, and evaluated for cellularity (Figure 263-10). Comparison of the cytologic examination and quantitative bacterial culture results from both prostatic wash specimens (PM-1 and PM-2) allows the precise location of the problem to be determined.[1] If lower urinary tract infection is present, before the prostatic wash is performed, the dog should be treated with an appropriate antibiotic (e.g., ampicillin) that does not penetrate the prostate. After the infection has been successfully treated, the wash may be performed. Prostatic massage is not with-out risks. In cases of acute prostatitis or prostatic abscess, there is a risk of creating a septicemia by forcing bacterial organisms into the blood stream or of causing peritonitis.[1] Also, uncertainty exists as to whether prostatic fluid has been expressed.

Figure 263-9 Collection of prostatic fluid (third fraction) by means of ejaculation.

Fine needle aspiration may also be used for collecting prostatic fluid samples.[1] For this technique, the skin surface through which the needle is to be inserted should be clipped and surgically scrubbed. Once the needle enters the prostate, aspiration should be performed as the needle is redirected several times within the gland. Negative pressure is then slowly released, and the needle is withdrawn. In some cases, fine needle aspirate samples are nondiagnostic. If prostatic neoplasia is suspected, a prostatic biopsy, rather than a fine needle aspirate, may be necessary.[39] In one study, complications associated with fine needle aspiration included hematuria and periprostatic hemorrhage.[38,40] In another report, a sterile intraprostatic cyst was aspirated and

developed into a prostatic abscess.[41] Fine needle aspiration therefore may pose an increased risk of complications in febrile animals or those with leukocytosis or before examination of prostatic fluid obtained by ejaculation or prostatic massage.[1]

Figure 263-10 Prostatic wash samples from a normal dog **(A)**, a dog with adenocarcinoma **(B)**, and a dog with transitional cell carcinoma **(C)**. (×100 magnification.)



Cytologic examination of prostatic fluid can identify inflammation but cannot be used in place of bacterial culture to identify infection.[42] Low numbers of neutrophils (fewer than 5 per high-power field) can normally be found in voided urine and in an ejaculate.[1] Prostatic inflammation and infection are well correlated with the appearance of macrophages in prostatic fluid.[42] However, the severity of inflammatory infiltrate is well correlated with the type or number of bacteria present.[28] Quantitative bacterial cultures yielding equal to or greater than 2 $\log_{10}$ of one or more bacterial species in prostatic fluid samples, compared with the number of colonies of the same species in paired urethral or urine samples, is indicative of prostatic infection.[43] Urine bacterial culture results are well correlated with prostatic fluid culture results, such that cystocentesis is a safer alternative than fine needle aspiration of the prostate if prostatic fluid cannot be collected by ejaculation or prostatic wash.[42]

1814

1815

The prostatic fluid pH in dogs with experimental prostatic infection (pH 6.3) did not significantly differ from that in dogs without infection (pH 6.25).[42] It is unclear whether prostatic fluid arginine esterase levels would

be useful in the diagnosis prostatic disease. In one study, serum arginine esterase levels were significantly higher in dogs with benign prostatic hyperplasia compared with normal dogs, dogs with bacterial prostatitis, and dogs with prostatic neoplasia.[44] In another study, although dogs with benign prostatic hyperplasia had higher arginine esterase levels than normal dogs, the levels were not significantly different from those in dogs with bacterial prostatitis or prostatic neoplasia.[15] Serum and seminal acid phosphatase levels showed no difference when normal dogs were compared with those with prostatic diseases or among different prostatic disorders.[15]

Careful selection and preparation of dogs for biopsy are essential. Prostatic biopsies are not recommended if bacterial prostatitis is suspected unless neoplasia is also suspected or the existence of chronic bacterial prostatitis can not be confirmed by other tests.[1] Antibiotics should be started 48 hours before a prostatic biopsy is performed if bacterial infection is suspected. A fluid-or air-filled urethral catheter can be passed before prostatic biopsy samples are taken to avoid damage to the prostatic urethra.[40] The biopsy site should be clipped and prepared aseptically. “Blind” prostatic biopsies are not recommended. Ultrasonographic guidance should be used for a prostatic biopsy because it provides continuous, real-time imaging of biopsy instrument placement; this reduces the risk of postbiopsy complications (hematuria, dissemination of infection, laceration of major blood vessels, urethral fistulation, orchitis, inadvertent puncture of adjacent organs).[1] In addition, ultrasonographic guidance increases the diagnostic yield of the biopsy sample, because the needle can be directed into what appears to be diseased tissue. The ultrasound transducer should be covered with a sterile sleeve, and sterile acoustic coupling gel should be used (Figure 263-11). The biopsy instrument can be introduced with a clip-on ultrasound guide or by freehand. The clip-on guide ensures that the needle remains in the plane of the sound beam. However, the guide limits the maneuverability of the biopsy instrument and may itself be awkward. The biopsy instrument should be directed tangentially to avoid the central prostatic urethra.[45] We prefer to use the spring-loaded Tru-Cut biopsy instrument.

Figure 263-11 Ultrasonographic guidance during biopsy minimizes the risk of complications and maximizes the diagnostic value of the sample.

263.5 BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is the most common prostate abnormality in intact male dogs and is estimated to occur in 100% of old, intact dogs.[6] Androgens are essential for the development and maintenance of BPH. However, with age, a modest decrease in the serum testosterone concentration, combined with no change in the serum estradiol-17-beta concentration, results in a relative decrease in the serum androgen to estrogen ratio.[10] This altered hormonal milieu is believed to contribute to the pathogenesis of BPH by increasing androgen receptor expression.

Histologic evidence of BPH develops at an early age. In a study of beagles, 16% had evidence of BPH at 2 years of age, and 50% had evidence of BPH at 4.1 to 5 years of age.[46] Electron microscopic analyses revealed that the volume densities of rough endoplasmic reticulum and secretory granules were significantly lower in the prostatic epithelial cells from dogs less than 1.5 years of age compared with older dogs.[47] After 4 years of age, intraparenchymal cyst formation may accompany BPH as a result of obstruction of parenchymal ducts that causes accumulation of prostatic secretions. In intact male dogs with no clinical evidence of urologic problems, the prevalence of intraparenchymal cyst formation is 14%.[25,48] The histologic pattern of BPH with intraparenchymal cyst formation shows areas of glandular hyperplasia, foci of atrophy, and chronic inflammation (lymphocytes and plasmocytes) in the stroma.[10] Intraparencymal cyst formation may predispose the prostate to bacterial infection.

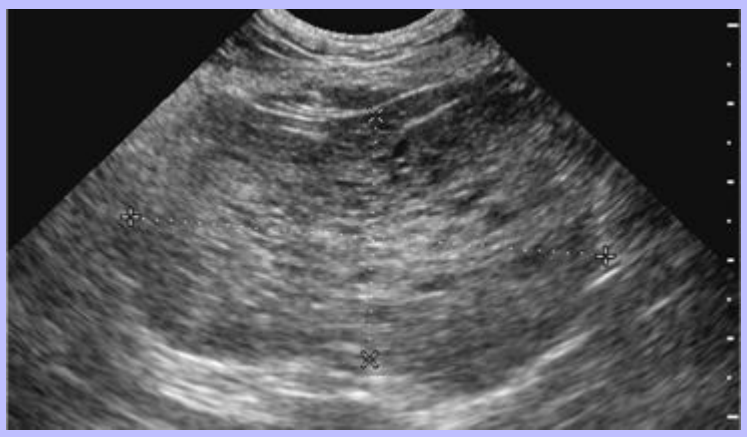
The diagnosis of BPH is made indirectly by elimination of other types of prostatic disease. A definitive diagnosis of BPH requires histopathologic confirmation.[19] However, it is difficult to justify a prostatic biopsy when the results of less invasive methods strongly support the diagnosis of BPH and the absence of more sinister prostatic diseases.[38] A presumptive diagnosis of BPH is based on the history, clinical signs, prostatic imaging, and prostatic fluid cytology and culture. Clinical signs associated with BPH include hemorrhagic urethral discharge, hematuria, hemospermia, and tenesmus. In one study in which hemorrhagic urethral discharge was the only sign of prostatic disease, 95% of the dogs had only BPH.[20] However, it is important to mention many dogs with BPH show no clinical signs. In a study on prostatic disease in 177 dogs, nearly half of the histologically confirmed cases of BPH had no clinical signs.[19] BPH may only become a clinical problem once it results in pressure on the colon or if it encroaches on the muscles and nerves in the pelvic canal.

On palpation, BPH produces a symmetrically enlarged prostate with a normal contour, although intraparenchymal cyst formation may result in some degree of asymmetry.[49,50] The ultrasonographic appearance of a prostate from a dog with BPH typically is moderately enlarged with symmetric, smooth margins and normal to slightly increased echogenicity.[51] The central hilar echo may be absent, and small, anechoic cysts in the parenchyma may be present.[52] (See Figure 243-12.) Cytologic evaluation of prostatic fluid from dogs with BPH reveals epithelial dysplasia without significant inflammation or any neoplastic changes.[53] If inflammatory cells are present, most of them (greater than 80%) are mononuclear cells (lymphocytes and plasmocytes).[54] Quantitative bacterial culture from prostatic fluid should be fewer than 100 bacteria per milliliter.[15]

For nonbreeding males, the recommended treatment for BPH is castration. Prostatic size significantly decreases within 7 to 10 days after castration.[55] Medical treatments are not as effective as castration in reducing prostatic size,[20,56] but they do offer an alternative for owners who decline surgery. Finasteride (Proscar®, Merck), a

5-alpha-reductase inhibitor, prevents conversion of testosterone to DHT[57,58] and produces a dose-dependent regression in prostate size.[59] At a daily oral dose of 0.1 to 0.5 mg/kg (5 mg of Proscar® per 10 to 50 kg body weight), finasteride reduces prostatic volume and secretory function by 43% in 16 weeks without adversely affecting semen quality.[60] However, the effects of finasteride are reversible within less than 8 weeks of discontinuation of treatment.[61] Finasteride is potentially teratogenic to male fetuses if pregnant females are exposed to the drug during the first third of gestation.

Figure 263-12 Transverse ultrasonographic image of a prostate with benign hyperplasia. Note the enlarged size, absence of hilar echo, and presence of many small cysts (too numerous to count) with anechoic luminal contents.



Several antiandrogenic drugs (chloradinone acetate,[58] osaterone acetate,[62] delmadinone acetate,[53] flutamide,[31] and megestrol acetate[50,63]) are effective at reducing prostatic size but can adversely affect gonadal function and are not recommended for use in breeding animals. Estrogens have also been used to treat BPH; however, because of the risk of myelosuppression and prostatic abscess formation, they are no longer a recommended treatment. The liposterolic extract of saw palmetto plant berries or the American dwarf palm tree *(Serenoa repens)* reportedly improves urinary flow rates in humans with BPH. However, treatment with *S. repens* for 91 days had little effect (positive or negative) in dogs.[64] In humans, BPH originates from the transition zone, a unique inner region of the prostate to this species, where its growth can impinge upon the urethra.[65] This differs from dogs, in which BPH is a diffuse process that develops from the peripheral terminal glands, expanding away from the urethra,[66] which may explain the differences observed with *S. repens* therapy.

263.6 CHRONIC BACTERIAL PROSTATITIS

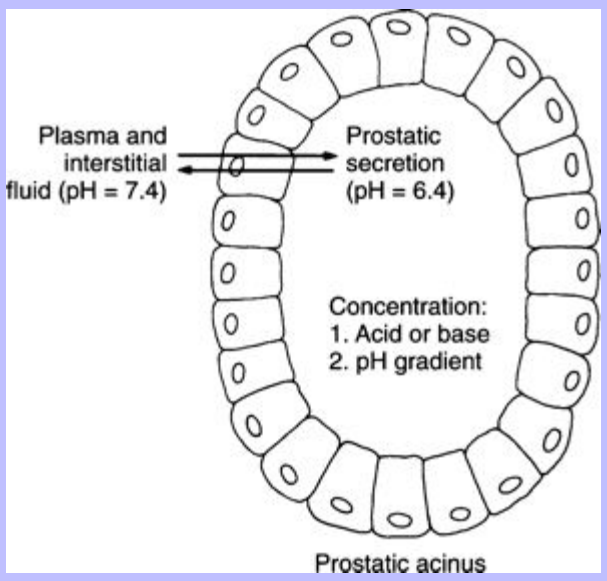
Chronic bacterial prostatitis (CBP) is the second most common prostate disorder in intact male dogs. It often occurs in conjunction with BPH. Bacterial infection of the prostate may arise by extension of bacteria from the urethra or by a hematogenous route. The pathogenic agent is usually common to the distal urinary tract (e.g., *Escherichia coli, Pseudomonas* and *Proteus* spp., staphylococci, and streptococci). *Brucella canis* may also cause CBP. However, gram-negative enteric organisms, particularly *E. coli*, are the most common cause.[67]

Clinical signs associated with CBP include recurrent urinary tract infection, hematuria, purulent or sanguineous urethral discharge, tenesmus, and constipation. Recurrent urinary tract infection caused by the same pathogen is a hallmark of CBP, because the pathogen persists in the prostate during antimicrobial therapy for the bacteriuria. Although the urine can be sterilized and the signs controlled during therapy, discontinuation of treatment leads to reinfection of the urine and recurrence of clinical signs.[68] Constant or intermittent dripping of sanguineous or purulent exudate from the penis independent of urination, another common finding with CBP, is attributed to an increase in the secretory rate of prostatic fluid induced by infection.[1] Constipation may occur secondary to CBP, because the dog may attempt to avoid pain induced by defecation.[1]

The diagnosis is based on the history, clinical signs, prostatic imaging, and prostatic fluid cytology and culture. The ultrasonographic appearance of a prostate from a dog with CBP (i.e., coarsely hyperechoic throughout the parenchyma) may be indistinguishable from that of BPH.[51] Regions of heterogenous echotexture and dystrophic mineralization, caused by fibrosis and chronic inflammation, may be indistinguishable from neoplasia.[52] Cytologic evaluation of prostatic fluid reveals degenerative neutrophils. Quantitative bacterial culture results show more than 10,000 bacteria of a single species per milliliter of seminal plasma.[15] In contrast to humans, the prostatic fluid pH, specific gravity, and cholesterol zinc concentrations are not reliable indicators for CBP.[69]

Chronic bacterial prostatitis is difficult to treat because most antimicrobial agents useful against the pathogens diffuse poorly into prostatic fluids (blood-prostate barrier). If left untreated, CBP can extend through the capsule into the abdomen, resulting in peritonitis.[33] In the absence of a specific secretory or active transport mechanism, an antimicrobial's ability to cross an epithelial membrane depends on its pKa and its lipid solubility (Figure 263-13). The pKa is the pH at which a drug exists equally in both ionized and nonionized forms. Only nonionized forms can cross epithelial membranes. Basic drugs (e.g., trimethoprim-sulfamethoxazole, erythromycin, clindamycin) diffuse easily from blood (pH 7.4) to prostatic fluid (pH less than 7.0).[42,68,70] Both chloramphenicol and enrofloxacin readily cross epithelial membranes; however, ciprofloxacin does not penetrate the prostate well.[71] Drugs with low lipid solubility do not cross epithelial membranes (e.g., ampicillin, penicillin, cephalothin). Antibiotics should be continued for 4 to 6 weeks, regardless of earlier disappearance of clinical signs. Prostatic fluid should be recultured 3 to 7 days after discontinuation of the antibiotics. Adjunctive treatment for CBP includes elimination of BPH. In one study in which CBP was experimentally induced with *E. coli,* castrated dogs cleared the infection within 4.2 weeks, compared with 9.5 weeks for intact dogs.[72] Because 5-alpha-reductase inhibitors also reduce prostate size and secretory function, medical treatment with finasteride should be included if owners decline surgery.

Figure 263-13 Factors determining the diffusion and concentration of antimicrobial drugs across the prostatic acinar epithelium. (From Stamey TA: Pathogenesis and Treatment of Urinary Tract Infections. Baltimore, Williams & Wilkins, 1980.)



263.7 PROSTATIC CARCINOMA

Prostatic carcinoma arising from the glandular or ductal epithelial cells occurs in intact and castrated dogs and is the most common prostate disorder in castrated dogs.[6] Castration at any age has not shown a sparing effect on the development of prostatic carcinoma[73]; however, the influence of early age castration (less than 8 weeks of age) has not been evaluated. Prostatic carcinoma is seen primarily after 6 years of age. Benign prostatic neoplasia has not been reported, and metastasis is common, usually developing in the sublumbar lymph nodes, lumbar vertebral bodies (see Figure 263-5), and lungs.

The diagnosis of prostatic carcinoma is made based on the history, clinical signs, and results of prostatic imaging, fluid analysis, and histopathology. Clinical signs of prostatic carcinoma were reported from 76 dogs and included hematuria, stranguria, and incontinence (62%); tenesmus associated with prostatomegaly (30%); musculoskeletal system involvement (36%); and weight loss and anorexia (42%).[74] In intact dogs, prostatic carcinoma is not always associated with prostatomegaly. However, in castrated dogs, prostatomegaly is highly associated with prostatic carcinoma (Figure 263-14). On palpation, the prostate may be normal in size but may feel firm and asymmetric and adhered to the pelvic canal. Ultrasonographically, a prostate from a dog with prostatic neoplasia typically appears large and irregularly shaped with hyperechoic and heterogenous foci (Figure 263-15).[51,52] Additional ultrasonographic findings from prostatic neoplasia may include areas of mineralization, parenchymal cysts (Figure 263-16), involvement of the bladder neck, capsular disruption with extension into adjacent fat and the peritoneal cavity, irregular contour of caudal lumbar vertebral bodies, and large, heterogenous sublumbar

lymph nodes (Figure 263-17). The appearance of neoplastic cells on prostatic fluid cytologic examination is diagnostically significant, but not finding neoplastic cells does not eliminate the possibility of neoplasia.

Figure 263-14 Necropsy specimen of a prostate *(P)* and bladder *(B)* with adenocarcinoma. Note the irregular contour and cyst formation *(arrow)*.

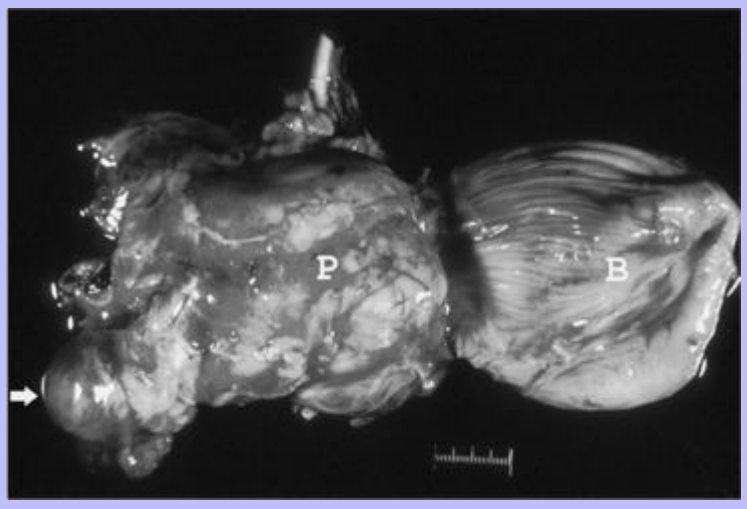


Figure 263-15 Sagittal ultrasonographic image of a prostate with adenocarcinoma. Note the hyperechoic and hypoechoic areas and irregular capsule typical of this lesion. (From Root Kustritz MV, Klausner JS: Prostatic diseases. *In* Ettinger SJ, Feldman EC [eds]: Textbook of Veterinary Internal Medicine, 5th ed. Philadelphia, WB Saunders, 2000, p 1696.)

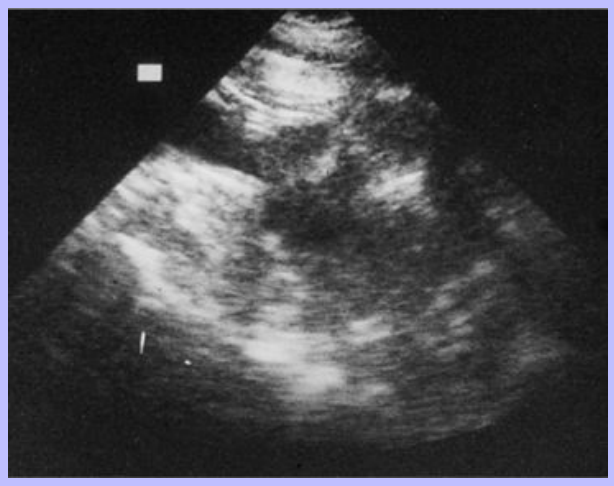

Figure 263-16 Sagittal **(A)** and transverse **(B)** ultrasonographic images of a prostate with adenocarcinoma. Note the enlarged size of the prostate for a castrated male dog, and the increased echogenicity and presence of large, coalescing cysts with hypoechoic luminal contents. The ultrasonographic appearance of a prostatic cyst or abscess may be similar to that of a prostatic carcinoma, and the diagnosis should be confirmed by prostatic fluid analysis and/or prostatic biopsy.

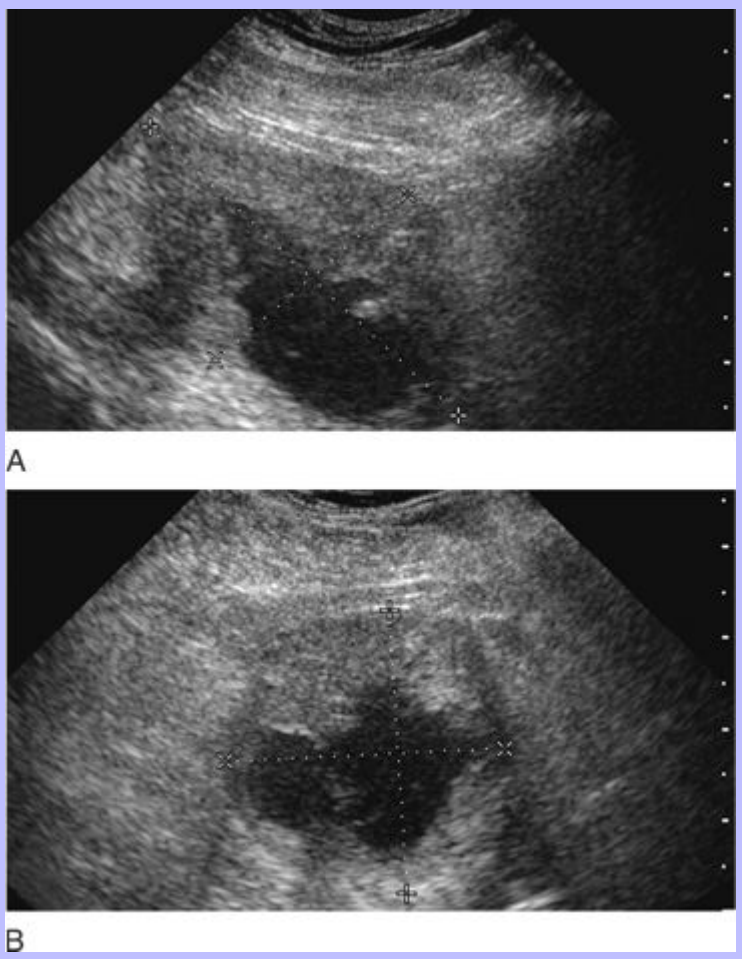


1817

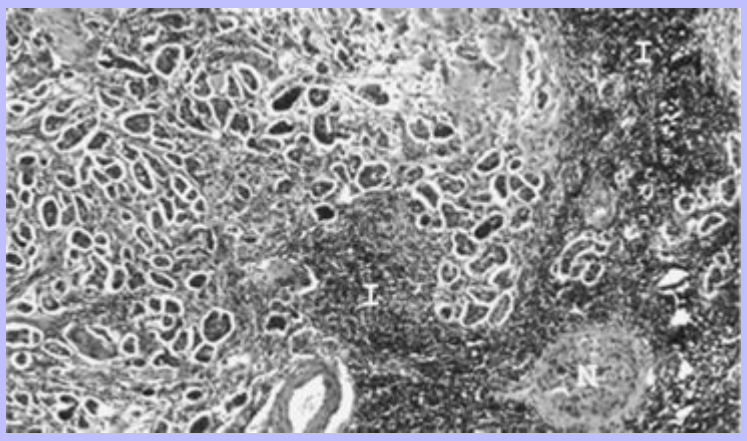
Figure 263-17 Sagittal ultrasonographic image of a mildly enlarged and abnormally hypoechoic medial iliac lymph node *(LN)* from the dog in Figure 263-13 with prostatic adenocarcinoma.

Adenocarcinoma is the most frequent histologic type of prostatic neoplasia, although more than half show intratumoral heterogeneity.[74] Histologic features of prostatic carcinoma include variation in glandular acinar size, shape, and spacing, with acinar cells containing enlarged nuclei and prominent nucleoli (see Figure 263-18).[74] Prostatic intraepithelial neoplasia (PIN), a common precursor prostatic neoplasia in humans, has been reported in the prostates of older dogs with and without neoplasia.[75] In dogs with prostatic neoplasia, the occurrence of PIN (7% to 66% of dogs with prostatic neoplasia) is too variable to be clinically useful.[74–76] Tumor markers frequently used in human medicine, such as PSA and prostatic acid phosphatase, are not useful in the diagnosis of prostatic neoplasia in the dog.[77]

The prognosis for dogs with prostatic neoplasia is poor. Treatment is primarily palliative and includes complete or partial resection of the prostate. There is no evidence that canine prostatic neoplasia is androgen dependent. Castration is recommended, however, because BPH can occur concurrently and may contribute to clinical signs associated with prostatomegaly.

Intraoperative orthovoltage radiotherapy (radiation therapy to surgically exposed prostate tumors) is currently the best adjunctive treatment for dogs without evidence of metastases, because it has the longest survival times (longer than 9 months).[78] Daily treatments (Monday through Friday) with external beam radiation therapy (43 to 54 Gy in 2.7 to 3.3 Gy fractions for 19 to 28 days) are reported to have limited success, with the complication of colitis developing in 56% of cases.[79] The use of radiation potentiators, such as cisplatin (OPLA-Pt), in conjunction with external beam radiation therapy reportedly increases survival times.[79]

Figure 263-18 Histopathology from the prostate in Figure 263-14. Note that, compared with the normal prostatic epithelial cells *(N),* the neoplastic epithelial cells are irregularly arranged and are not bordered by a basement membrane. Inflammatory infiltrate *(I)* is also evident.



Piroxicam, a specific cyclo-oxygenase-1 (COX-1) inhibitor, administered at a dosage of 0.3 mg/kg given orally once a day, has been used successfully to reduce the size of several canine carcinomas.[80–82] In one study, combining cisplatin treatment (60 mg/m^2 given intravenously every 21 days) with piroxicam therapy resulted in complete or partial tumor remission in 71% dogs, compared with no tumor remission with cisplatin therapy alone.[83] *In vitro* experiments suggest that piroxicam treatment will be effective in the treatment of prostatic adenocarcinoma.[84]

Treatment options currently under investigation include endothelin receptor antagonists and tyrosine kinase inhibitors. Atrasentan, a selective endothelin A receptor antagonist, significantly delayed the progression of metastatic, androgen-refractory prostatic neoplasia in humans at a dosage of 10 mg given orally once a day.[85] Tyrosine kinase inhibitors (CEP-751, CEP-701) inhibit the growth of prostatic neoplasia in rats regardless of androgen sensitivity and metastatic ability.[86] Another potential treatment option for prostatic carcinoma is photodynamic therapy (PDT). Researchers have investigated the biologic responses of the prostate and adjacent vital structures to two photosensitizers, meso-tetra-(m-hydroxyphenyl) chlorin and aluminum disulfonated phthalocyanine, but the completeness of treatment and long-term therapeutic effectiveness in prostate cancer have yet to be determined.[87]

263.8 ACUTE BACTERIAL PROSTATITIS AND PROSTATIC ABSCESS

Acute bacterial prostatitis and prostatic abscesses are uncommon in dogs. The occurrence of prostatic abscesses has been associated with BPH[88] and administration of estrogen.[1] Clinical signs associated with acute bacterial prostatitis and prostatic abscesses include anorexia, fever, depression, vomiting, gait abnormalities, and caudal abdominal pain. Neutrophilia with a left shift is also seen. The ultrasonographic appearance of acute bacterial

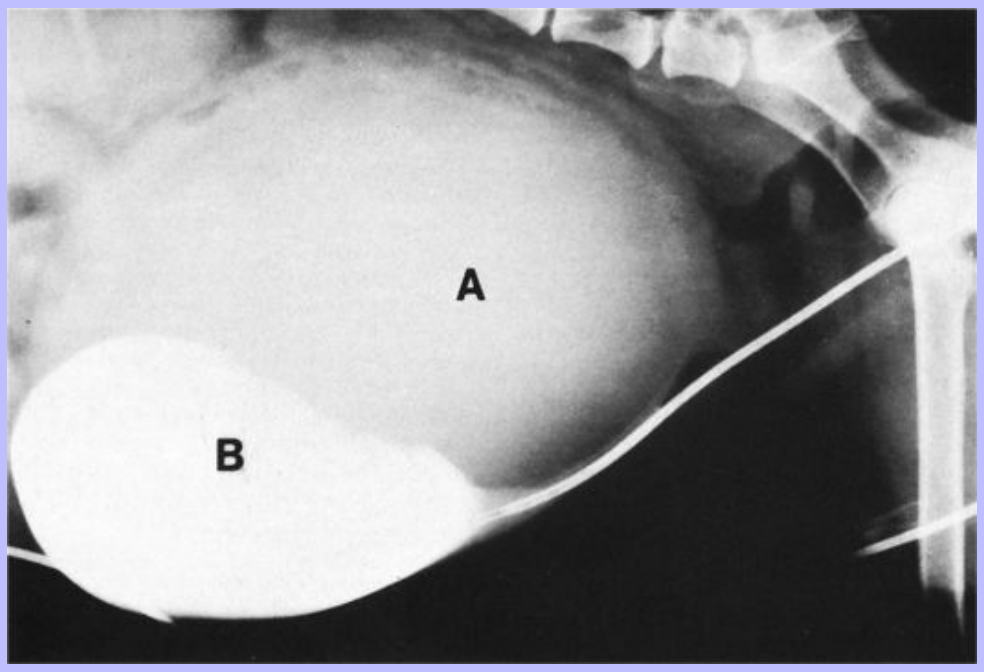
prostatitis is that of a normal-sized prostate with a hypoechoic parenchyma containing small cysts, whereas the ultrasonographic appearance of a prostatic abscess is that of prostatomegaly and one or more large anechoic cysts.[52]

Although the clinical signs may be similar, therapeutic differences between these two diseases make the treatment of acute bacterial prostatitis and prostatic abscess distinctly different. Acute bacterial prostatitis can be treated with an appropriate antimicrobial, as determined by culture and sensitivity, because the prostatic-blood barrier has been breached by infection.[89] Prostatic abscesses, on the other hand, do not resolve with antimicrobial treatment alone. Traditionally, prostatic abscesses have been treated by drainage through a capsulectomy incision via celiotomy. Marsupialization through the abdominal wall has been described but is associated with many complications, including prolonged recovery time, recurrent abscessation, dysuria, urinary incontinence, and septic peritonitis. Alternatives to marsupialization, reportedly associated with a lower risk of complications, include a modified Penrose drain technique[90] or omentalization (inserting omentum through the capsulectomy).[91,92] Surgery texts should be consulted for a more complete description of the techniques. Nonsurgical methods for treating prostatic abscesses have also been reported, with results showing varying efficacy. Antimicrobial therapy in conjunction with castration has been ineffective at resolving prostatic abscesses.[91] However, percutaneous, ultrasonographically guided drainage followed by alcoholization of the cavity was effective at resolving a prostatic abscess in one dog.[88]

1818

1819

Figure 263-19 Large paraprostatic cyst *(A)* demonstrated with use of contrast material to outline the bladder *(B)*. (From Greiner TP, Johnson RG: Diseases of the prostate gland. *In* Ettinger SJ [ed]: Textbook of Veterinary Internal Medicine, 2nd ed. Philadelphia, WB Saunders, 1983, p 1477.)



263.9 PARAPROSTATIC CYST

The etiology of paraprostatic cysts is unknown. These large cysts, located outside the prostatic parenchyma, have a stalk that connects to the prostate. They may result from dilated paramesonephric duct remnants or from retention cysts.[26] Paraprostatic cysts are uncommon and are often not clinically discernible until their size is sufficient to impinge on the colon or urethra, or unless secondary infection occurs and an abscess develops.[93] Paraprostatic cysts vary in size, shape, and location. Most cysts are located cranial or dorsal to the prostate and urinary bladder.[93] The ultrasonographic appearance of a paraprostatic cyst is that of a well-circumscribed, ovoid structure with anechoic or hypoechoic contents.[93] However, a pyometra of the uterine masculinus can occur secondary to infection without hormonal influence and appears as multiple, convoluted, tubular cavitations.[52] Radiographically, a paraprostatic cyst appears as a "second" bladderlike structure (Figure 263-19). Occasionally, paraprostatic cysts have calcified walls. Fine needle aspiration of a paraprostatic cyst yields fluid varying from clear and yellow to turbid and brown.[1] The recommended treatment for paraprostatic cysts that cause symptoms of prostatic disease is surgical removal.[94]

264 CHAPTER • 264 Familial Renal Disease in Dogs and Cats

Stephen P. DiBartola

Most familial renal diseases result in chronic renal failure at a young age (less than 5 years), but some are characterized by renal tubular defects (e.g., Fanconi syndrome in the basenji) or morphologic abnormalities that result in hematuria (e.g., renal telangiectasia in Pembroke Welsh corgis). A *familial* disease is one that occurs in related animals with a higher frequency than would be expected by chance. *Congenital* diseases are present at birth and may be genetically determined or may result from exposure to adverse environmental factors during development. In many familial renal diseases of dogs, the kidneys are thought to be normal at birth but undergo structural and functional deterioration early in life. Some familial renal diseases of dogs probably are examples of renal dysplasia. The term *renal dysplasia* refers to disorganized development of renal parenchyma as a result of abnormal differentiation; the condition is characterized by the presence of structures in the kidney inappropriate for the stage of development of the animal. Lesions suggestive of renal dysplasia include asynchronous differentiation of nephrons (indicated by persistence of immature or "fetal" glomeruli) and persistent mesenchyme (usually in the medullary interstitium).[1] Persistent metanephric ducts, atypical tubular epithelium, and dysontogenic metaplasia are observed less frequently.

Many familial renal diseases are variable in severity and rate of progression among individual animals. Most of these diseases are progressive and ultimately fatal, and therapy usually is limited to conservative medical management of chronic renal failure. The mode of inheritance and specific pathogenesis for many of these diseases are unknown. The primary nature of the renal disease and its mode of inheritance, when known or suspected, are listed in Table 264-1.

264.1 SIGNALMENT

Familial renal disease has been reported in many dog breeds (see Table 264-1) and may occur sporadically in mixed-breed animals. The clinician should consider the possibility of familial renal disease whenever chronic renal failure occurs in immature or young adult animals. In cats, familial amyloidosis has been characterized in Abyssinian, Siamese, and Oriental shorthair cats, and polycystic kidney disease (PKD) is common in the Persian breed.

In most of these diseases there is no clear sex predilection. In Samoyeds, however, hereditary glomerulopathy arises from an X-linked dominant trait. The age of onset of familial renal disease usually is 6 months to 5 years, with many animals developing signs before 2 years of age. Renal amyloidosis in beagles and English foxhounds, suspected glomerular basement membrane disease in beagles,[2] and telangiectasia of the Welsh corgi occur in older dogs (≥5 years), whereas PKD in cairn and West Highland white terriers is detected at a young age (5 to 6 weeks).

264.2 HISTORY AND PHYSICAL FINDINGS

The most common historical findings in dogs and cats with chronic renal failure due to familial renal disease are anorexia, lethargy, stunted growth or weight loss, polyuria and polydipsia, and vomiting. Other less common client complaints are poor haircoat, diarrhea, foul breath, and nocturia. In the Pembroke Welsh corgi with renal telangiectasia, the most common client complaints are hematuria, dysuria, and apparent abdominal pain. Hematuria also has been reported in German shepherds with multifocal renal cystadenocarcinomas.[3]

Dogs and cats with chronic renal failure due to familial renal disease may be thin and dehydrated. On oral examination, pallor of the mucous membranes, foul odor, and uremic ulceration may be noted. The kidneys usually are small and irregular, with the exception of cairn and West Highland white terriers and Persian cats with PKD, in which the kidneys often are markedly enlarged. Signs of fibrous osteodystrophy, such as “rubber jaw” or pathologic fractures, usually are detected in young growing dogs with renal failure. Signs of renal osteodystrophy rarely are apparent in older dogs with renal failure. The blood pressure should be measured and a fundic examination performed to evaluate for complications of hypertension (e.g., retinal hemorrhage, retinal detachment).

264.3 LABORATORY FINDINGS

The most common laboratory findings in dogs with familial renal disease resulting in chronic renal failure are azotemia, hyperphosphatemia, isosthenuria, and nonregenerative anemia. The serum calcium concentration in dogs may be normal, decreased, or increased. Hypercalcemia may be more common in young versus older dogs with renal failure. Compensated metabolic acidosis also may be observed. The presence of hypercholesterolemia and proteinuria should lead to suspicion of primary glomerular disease. Beagles with glomerular amyloidosis and Bernese mountain dogs with membranoproliferative glomerulonephritis develop nephrotic syndrome and proteinuria; however, proteinuria is variable and depends on the extent of glomerular involvement in Shar Peis and Abyssinian cats with familial amyloidosis. Glucosuria is found in Norwegian elkhounds and basenjis with primary renal tubular disorders.

Juvenile renal disease in the basenji is an animal model of Fanconi syndrome and is characterized by glucosuria, proteinuria, isosthenuria, and amino aciduria. Affected basenjis may also have decreased fractional resorption of phosphate, sodium, potassium, and urate. They may develop hypokalemia and metabolic acidosis with a normal anion gap (hyperchloremic metabolic acidosis). In Welsh corgis with renal telangiectasia, the major laboratory finding is hematuria, but urinary tract infection may also be present. Blood loss anemia is more common than nonregenerative anemia because of the large amounts of blood that may be lost in the urine. Affected Welsh corgis may develop nephrocalcinosis and calculi, and hydronephrosis may occur if a blood clot or calculus obstructs the ureter.

264.4 PATHOLOGIC FINDINGS

Familial renal disease is characterized by the presence of primary dysplastic lesions, compensatory lesions, and degenerative lesions.[1] In many cases the secondary degenerative lesions overshadow the underlying primary dysplastic lesions, making correct diagnosis difficult. Primary dysplastic lesions that have been observed in some familial renal disease of dogs include immature or “fetal” glomeruli, hyperplasia or adenomatoid proliferation of the medullary collecting ducts, and persistent mesenchyme in the renal medulla. Such changes are most prominent in the Lhasa apso, Shih Tzu, soft-coated wheaten terrier, standard poodle, chow chow, and miniature schnauzer. Juvenile renal diseases in the Samoyed, English cocker spaniel, and bull terrier result from abnormalities of type IV collagen in glomerular basement membranes and represent animal models of X-linked dominant, autosomal recessive, and autosomal dominant hereditary nephritis in humans, respectively.

Secondary degenerative lesions commonly observed in familial renal disease include interstitial fibrosis, interstitial infiltration by mononuclear inflammatory cells, dystrophic mineralization, and cystic glomerular atrophy.

The pathologic features of several individual familial renal diseases are presented below.

264.4.1 Abyssinian Cat

Abyssinian cats with familial amyloidosis usually develop clinical signs between 1 and 5 years of age. Male and female cats are affected. Amyloid deposits first appear in the kidneys between 9 and 24 months of age, and in many cats amyloid deposition leads to chronic renal failure within the first 3 years of life. Amyloid deposition in the kidney may be mild, and some affected cats may live to an advanced age without detection of the amyloid deposits. Proteinuria is a variable clinical finding and reflects the severity of glomerular involvement. Difficulty determining the mode of inheritance arises from the variability in severity and progression of amyloidosis among affected Abyssinian cats, but the disease appears to be inherited as an autosomal dominant trait with variable penetrance. Amyloid deposits in the kidneys of affected Abyssinian cats contain amyloid protein AA.[4]

Table • 264-1 Familial Renal Diseases of Dogs and Cats

BREED	DISEASE	AGE AT PRESENTATION	INHERITANCE	PROGRESSIVE RENAL FAILURE?
Beagle	Amyloidosis	5 to 11 yr	Unknown	Yes
English foxhound	Amyloidosis	5 to 8 yr	Unknown	Yes
Shar Pei	Amyloidosis	1 to 6 yr	Unknown	Yes
Abyssinian cat	Amyloidosis	1 to 5 yr	Autosomal dominant (incomplete penetrance)*	Yes
Oriental shorthair cat	Amyloidosis	<5 yr	Unknown	Variable; also, severe liver involvement
Siamese cat	Amyloidosis	<5 yr	Unknown	Variable; also, severe liver involvement
Basenji	Tubular dysfunction (Fanconi syndrome)	1 to 5 yr	Unknown	Variable
Norwegian elkhound	Tubular dysfunction (renal glucosuria)	Not reported	Unknown	No
Beagle	Unilateral renal agenesis	Incidental finding	Unknown	No
Bull terrier	Basement membrane disorder	<1 to 10 yr	Autosomal dominant	Yes
Doberman pinscher	Basement membrane disorder	<1 to 6 yr	Unknown	Yes
English cocker spaniel	Basement membrane disorder	<2 yr	Autosomal recessive	Yes
Samoyed	Basement membrane disorder	<1 yr	X-linked dominant (males)	Males
NAV dogs†	Basement membrane disorder	<1 yr (males) 1 to 3 yr (females)	X-linked dominant	Males and females
Bernese mountain dog	Membranoproliferative glomerulonephritis	2 to 5 yr	Autosomal recessive*	Yes
Brittany spaniel	Membranoproliferative glomerulonephritis (C3 deficiency)	4 to 9 yr	Autosomal recessive	Variable
Rottweiler	Glomerular disease	≤1 yr	Unknown	Yes
Norwegian elkhound	Periglomerular fibrosis (primary lesion unknown)	<1 to 5 yr	Unknown	Yes
Soft-coated wheaten terrier	Glomerular disease (membranoproliferative glomerulonephritis)	2 to 11 yr	Unknown	Yes
Beagle	Glomerular disease (basement membrane disorder?)	2 to 8 yr	Unknown	Yes
Cairn terrier	Polycystic kidneys	6 wk	Autosomal recessive*	Not reported
West Highland white terrier	Polycystic kidneys	5 wk	Autosomal recessive*	Not reported
Bull terrier	Polycystic kidneys	<1 to 2 yr	Autosomal dominant	Yes; also, valvular heart disease
Persian cat	Polycystic kidneys	3 to 10 yr	Autosomal dominant	Yes

* Suspected.

† Dogs from Navasota, Texas.

The principal pathologic lesions in the kidneys of Abyssinian cats with familial amyloidosis are medullary amyloid deposits, papillary necrosis, chronic tubulointerstitial nephritis characterized by lymphoplasmacytic infiltration and fibrosis, and variable glomerular amyloid deposits. Glomerular amyloidosis is mild and often difficult to detect in many affected cats but occasionally can be severe. Medullary amyloid deposition was found in all affected Abyssinians, whereas glomerular deposits were found in 75%.[5] Medullary interstitial amyloid deposits interfere with blood flow to the renal papilla, resulting in papillary necrosis and secondary interstitial medullary fibrosis and mononuclear inflammation.[6] Amyloid deposition is not restricted to the kidneys in Abyssinian cats with amyloidosis; deposits frequently are found in other organs (e.g., adrenal glands, thyroid glands, spleen, stomach, small intestine, heart, liver, pancreas, and colon).[5] However, amyloid deposits in these other organs do not appear to make an important contribution to the clinical syndrome, which is that of chronic renal failure. In Siamese and Oriental shorthair cats, however, severe deposition of amyloid in the liver can result in hepatic rupture and hemoabdomen. The amino acid sequence of the amyloid AA protein in affected Siamese cats differs slightly from that found in affected Abyssinian cats, and this difference may explain the predilection for hepatic deposition in affected Siamese cats.[7,8]

1821 1822

264.4.2 Alaskan Malamute

Chronic renal failure in three sibling malamute pups (4 to 11 months of age) was associated with histologic evidence of renal dysplasia.[9] The lesions observed included immature ("fetal") glomeruli, cystic glomerular atrophy, glomerular sclerosis, periglomerular fibrosis, adenomatoid hyperplasia of tubules, and persistent mesenchymal tissue.

264.4.3 Basenji

Histologic findings in the kidneys of basenjis with Fanconi syndrome are not consistent. Nonspecific findings include tubular atrophy and interstitial fibrosis. One morphologic marker for this disease may be enlarged, hyperchromatic nuclei in renal tubular cells (renal tubular cell karyomegaly). Affected animals may deteriorate rapidly and die of acute renal failure with papillary necrosis or pyelonephritis.

264.4.4 Beagle

A family of adult beagles developed glomerular amyloidosis and nephrotic syndrome characterized by proteinuria, hypercholesterolemia, and renal failure.[10] Some dogs had mild medullary deposition of amyloid. The amyloid deposits were sensitive to permanganate oxidation, suggesting the presence of amyloid protein AA. In another study, a family of beagles with proteinuria, late-onset renal failure, and multilaminar splitting of the glomerular basement membranes was described.[2]

264.4.5 Bernese Mountain Dog

Membranoproliferative glomerulonephritis resembling membranoproliferative glomerulonephritis type I in humans was described in young (2-to 5-year-old) male and female Bernese mountain dogs.[11,12] Affected dogs had typical laboratory abnormalities of renal failure, as well as marked proteinuria, hypercholesterolemia, and hypoalbuminemia. Pedigree analysis suggested an autosomal recessive mode of inheritance. Ultrastructural lesions included a double-layered glomerular basement membrane and electron-dense deposits, primarily in a subendothelial location. Immunoglobulin M and the third component of complement were identified by

immunofluorescence in glomeruli of affected dogs. Most of the dogs had high serologic titers against *Borrelia burgdorferi,* but the organism could not be detected immunohistochemically in the tissues of affected dogs. Membranoproliferative glomerulonephritis also has been reported in Brittany spaniels with deficiency of the third component of complement.[13]

264.4.6 Bull Terrier

Familial renal disease leading to chronic renal failure has been reported in bull terriers 1 to 8 years of age.[14,15] Both male and female dogs are affected, and the disease is inherited as an autosomal dominant trait.[16] It may represent an animal model of the dominant form of Alport syndrome in human beings.[17] Proteinuria, an early manifestation, correlated with underlying glomerular lesions in affected bull terriers.[18] Repeated urine protein to creatinine (UPC) ratios greater than 0.3 are considered supportive evidence of the disease in suspect bull terriers over 2 years of age that do not have overt evidence of renal failure.[15,18]

Light and electron microscopy of affected bull terriers shows thickening and splitting of glomerular basement membranes and involvement of tubular basement membranes.[14,16,18,19] Familial PKD that occurs in association with nodular thickening of the mitral and aortic valves and mitral dysplasia also has been reported in bull terriers.[20] Affected dogs did not have hepatic cysts.

264.4.7 Cairn and West Highland White Terriers

Autosomal recessive polycystic disease in the cairn terrier is characterized by the presence of multiple cysts throughout the liver and kidneys. Autosomal recessive PKD also has been reported in young (5-week-old) West Highland white terriers.[21]

264.4.8 Chow Chow

Chronic renal failure in six young, related chows chows (five male and one female) was suggestive of renal dysplasia.[22] Renal failure developed in four dogs by 6 months of age and in two dogs after 1 year of age. Renal dysplasia was suspected based on the presence of immature (“fetal”) glomeruli and pseudostratified columnar epithelium in the renal tubules of some dogs.

264.4.9 Doberman Pinscher

Diffuse thickening or multifocal irregular thickening with lamellation of the lamina densa has been observed in the glomerular basement membranes of Doberman pinschers with glomerulopathy.[26] Occasionally, deposits of immunoglobulins have been detected in the glomerular capillary wall, but these are thought to result from nonspecific trapping of immune complexes in basement membranes with some underlying structural defect. Unilateral renal aplasia has been observed in some affected female Doberman pinschers. Additional glomerular lesions include lobular accentuation of glomerular capillary loops, increased mesangial matrix, hypercellularity, intraglomerular adhesions, fibroepithelial crescent formation, and periglomerular fibrosis.[26]

264.4.10 English Cocker Spaniel

Juvenile renal disease in the English cocker spaniel is an animal model of autosomal recessive hereditary nephritis in humans.[23–25] Mutations have been identified in genes for the alpha-3 (COL4A3) and alpha-4 (COL4A4) chains of type IV collagen on chromosome 2 in affected human patients, and these loci are candidate genes for the disease in the English cocker spaniel.

The disease affects both male and female English cocker spaniels and manifests itself between 6 and 24 months of age. The earliest detectable abnormality (5 to 8 months of age) is proteinuria followed by reduced growth rate, impaired urinary concentrating ability, and azotemia (7 to 17 months of age).[24] The primary lesion is thickening and multilaminar splitting of the glomerular basement membrane. This lesion is identical to that observed in Samoyeds with X-linked hereditary nephritis and is similar to lesions observed in bull terriers with hereditary nephritis. The disease ultimately leads to diffuse glomerular sclerosis and periglomerular fibrosis with secondary tubulointerstitial disease; it is invariably fatal.

264.4.11 English Foxhound

Renal amyloidosis was reported in related adult English foxhounds.[27] The disease was associated with acute illness, renomegaly, and papillary necrosis in some affected dogs. Amyloid deposits were sensitive to permanganate oxidation, suggesting the presence of amyloid protein AA.

1822

1823

264.4.12 German Shepherd

German shepherds with bilateral, multifocal renal cystadenocarcinomas are usually 5 to 11 years of age when they develop nonspecific signs such as anorexia, weight loss, polydipsia, and gastrointestinal disturbances.[3,28,29] The renal lesions are accompanied by cutaneous and subcutaneous nodules (dermatofibrosis) and multiple uterine leiomyomas in affected female dogs. The disorder is thought to be inherited as an autosomal dominant trait.

264.4.13 Golden Retriever

Chronic renal failure has been reported in young golden retrievers (less than 3 years of age).[30,31] Hypercholesterolemia was a common finding despite lack of other evidence of primary glomerular disease in most affected dogs. Hypercalcemia also was common and was attributed to an increased serum complexed calcium concentration. Cystic glomerular atrophy and periglomerular fibrosis were common histologic lesions, whereas immature (“fetal”) glomeruli were uncommon. Adenomatoid proliferation of the collecting ducts suggestive of primitive metanephric ducts, observed in several dogs, supports a diagnosis of renal dysplasia. Pyelonephritis occasionally complicates the disease in affected dogs.

264.4.14 Lhasa Apso and Shih Tzu

In the Lhasa apso and Shih Tzu, microscopic findings include a reduced number of glomeruli, glomerular atrophy, and small, immature (“fetal”) glomeruli that are hypercellular and that have inconspicuous capillary lumens. Tubular changes include atrophy, dilatation, and epithelial hyperplasia. Interstitial fibrosis is particularly severe in the renal medulla, but interstitial inflammation is minimal. To a certain extent, increased

interstitial medullary tissue may be persistent mesenchyme and, along with the immature glomeruli, is evidence of a primary renal dysplasia.

264.4.15 Miniature Schnauzer

Chronic renal failure suggestive of renal dysplasia was reported in eight related miniature schnauzers ranging in age from 4 months to 3 years.[32] Immature ("fetal") glomeruli, glomerular sclerosis, and severe interstitial fibrosis were observed.

264.4.16 Norwegian Elkhound

In the Norwegian elkhound, periglomerular fibrosis is an early histologic lesion that may be detected in some dogs before the onset of azotemia. Pathologic findings in dogs with more advanced disease consist of generalized interstitial fibrosis with glomerular sclerosis and atrophy. Hyperplasia of the collecting ducts also has been observed and may represent a primary dysplastic change, but immature ("fetal") glomeruli have not been observed. Norwegian elkhounds may also develop primary renal glucosuria that is not associated with chronic renal failure.

264.4.17 Persian Cat

PKD is inherited as an autosomal dominant trait in Persian cats.[33,34] The prevalence of PKD has been observed to be 35% to 57% in Persian cats surveyed by ultrasonography.[35–37] Cysts originate from both the proximal and distal tubules, they occur in both the renal cortex and the medulla, and they increase in number and size over time.[38] They can be detected by ultrasonographic examination of affected kittens as early as 6 to 8 weeks of age, but the absence of cysts at this early age does not preclude their development at a later age. In one study, ultrasound examination had a sensitivity of 75% and a specificity of 100% when performed at 16 weeks of age and a sensitivity of 91% and specificity of 100% when performed at 36 weeks of age.[34] Although common in human patients with PKD, hypertension has been absent or mild in cats with PKD that have been evaluated.[39,40] Affected Persian cats usually do not develop renal failure until later in adult life (average, 7 years), and renomegaly may be an incidental finding on physical examination. Occasionally, cysts may be found in the liver.[41,42]

264.4.18 Rottweiler

Chronic renal failure was reported in four related rottweilers (three females and one male) ranging in age from 6 to 12 months.[43] Hypercholesterolemia and an abnormally increased UPC ratio were consistent with a diagnosis of primary glomerular disease. Histologically, cystic glomerular atrophy and irregular thickening of glomerular basement membranes were observed.

264.4.19 Samoyed

Male Samoyeds with hereditary nephritis develop proteinuria, glucosuria, and isosthenuria by 2 to 3 months of age and azotemia by 6 to 9 months of age; death from renal failure usually occurs by 12 to 16 months of age.[44] Mesangial thickening, glomerular sclerosis, and periglomerular fibrosis are observed by light microscopy in affected males by 8 to 10 months of age.[45] Affected females develop proteinuria at 2 to 3 months of age but

remain clinically normal, other than failing to achieve normal adult body weight. This difference in the clinical course is a consequence of the X-linked dominant inheritance pattern and results from normal random inactivation of one X chromosome in each cell of the female embryo during development.[46]

Juvenile renal disease in the Samoyed is a hereditary glomerulopathy arising from a single nucleotide substitution in the gene (COL4A5) for the alpha-5 chain of type IV collagen on the X chromosome.[47] At birth, the glomerular basement membranes of affected male Samoyeds are morphologically normal, but reduplication and bilaminar splitting of the lamina densa are detected by electron microscopy at 1 month of age and progress to multilaminar splitting, thickening, and glomerular sclerosis by 8 to 10 months of age.[48] Affected females have only focal splitting of glomerular basement membranes and do not develop progressive disease.

Proteinuria and progressive renal disease presumably result from damaged glomerular basement membranes weakened by abnormal cross-linking of type IV collagen.[49] Deterioration of basement membranes and the onset of renal failure in affected males can be delayed but not prevented by feeding a diet low in protein and phosphorus beginning at 1 month of age.[50] Treatment of affected dogs with angiotensin-converting enzyme (ACE) inhibitors[51] or cyclosporine[52] has slowed progression of the disease. An X-linked dominant form of hereditary nephritis also has been described in dogs from Navasota, Texas (NAV dogs).[53] This disorder was characterized by earlier onset of renal failure in affected females, and alpha-3, alpha-4, and alpha-5 chains of type IV collagen were absent from the glomerular basement membranes in affected dogs. However, no mutation was found in exon 35 of the COL4A5 gene in affected dogs; consequently, this disease appears to result from a different mutation in the COLA5 gene.

264.4.20 Shar Pei

Familial amyloidosis resulting in chronic renal failure at a young age (mean, 4 years) occurs in male and female Shar Peis.[54] Proteinuria and laboratory evidence of nephrotic syndrome (e.g., hypoalbuminemia, hypercholesterolemia) may be present, depending on the severity of glomerular involvement. Some affected Shar Peis had a previous history of episodic joint swelling (usually the tibiotarsal joints) and high fever that resolves within a few days, regardless of treatment.[55,56] Recurrent fever and joint swelling that culminate in renal failure due to reactive systemic amyloidosis in young Shar Peis may represent an animal model of familial Mediterranean fever in humans. Some evidence indicates that amyloidosis in the Shar Pei is inherited as an autosomal recessive trait.[57]

1823

1824

Affected Shar Peis have moderate to severe renal medullary deposition of amyloid, but only two thirds have glomerular involvement. These findings are similar to those seen in Abyssinian cats with familial amyloidosis. The remaining renal lesions are those of end-stage renal disease. Amino acid sequence analysis has demonstrated that the amyloid deposits in affected Shar Peis contain amyloid A protein.[58] In addition to the kidney, amyloid deposits may be observed in many other organs (e.g., liver, spleen, gastrointestinal tract, thyroid gland). Icterus, hepatomegaly, and occasionally hepatic rupture with hemoabdomen may occur in Shar Peis with severe deposition of amyloid in the liver.[59]

264.4.21 Soft-Coated Wheaten Terrier

Pathologic findings in some soft-coated wheaten terriers (SCWTs) with juvenile renal disease are suggestive of renal dysplasia.[60,61] Histologic lesions include interstitial fibrosis, periglomerular fibrosis, cystic glomerular atrophy, decreased numbers of glomeruli, and the presence of immature ("fetal") glomeruli. Adenomatous proliferation of the collecting duct epithelium also is a prominent feature.

SCWTs also are predisposed to protein-losing enteropathy (PLE), protein-losing nephropathy (PLN), or both.[62] Food hypersensitivity and increased gut permeability presumably lead to immune complex glomerulonephritis that progresses to end-stage renal disease. The results of gastroscopic food sensitivity testing and dietary challenge support the hypothesis of food hypersensitivity,[63] but gluten hypersensitivity does not seem to be involved.[64] The disease is thought to be present in 10% to 15% of SCWTs and affects middle-aged to older dogs, with a slight predilection for females. The mode of inheritance is uncertain. Clinical findings include polyuria, polydipsia, vomiting, and weight loss in dogs with PLN; proteinuria, hypoalbuminemia, hypercholesterolemia, azotemia, hyperphosphatemia, and nonregenerative anemia are common laboratory findings. Hypertension occasionally develops, and thromboembolism complicates the disease in 12% of SCWTs with PLN.[62] Renal lesions consist of membranous to membranoproliferative glomerulonephritis that progresses to glomerular sclerosis, periglomerular fibrosis, and chronic interstitial nephritis. Mesangial deposition of immunoglobulin A (IgA), IgM, and complement has been detected by immunofluorescence, which suggests that renal disease in the SCWT may be an animal model of IgA nephropathy or IgM mesangial nephropathy.[65] The disease is progressive, treatment is palliative, and the prognosis is poor. Thus familial renal disease in the SCWT may take the form of renal dysplasia or membranoproliferative glomerulonephritis.

264.4.22 Standard Poodle

In affected standard poodles, cystic glomerular atrophy and large numbers of immature ("fetal") glomeruli are observed, especially in dogs presented at 3 to 4 months of age. The cortical interstitium contains segmental areas of fibrosis, whereas more diffuse lesions occur in the medulla.

264.4.23 Welsh Corgi

Welsh corgi dogs with renal telangiectasia have red to black nodules in the kidneys, especially in the renal medulla adjacent to the corticomedullary junction. Clotted blood often is identified in these lesions and in the renal pelvis. Hydronephrosis (presumably caused by ureteral obstruction) occurs in almost half of affected dogs. Similar nodular lesions may be identified in other tissues, including the subcutis, spleen, duodenum, anterior mediastinum, thoracic wall, retroperitoneal space, and central nervous system. Histologically these lesions are cavernous, blood-filled spaces lined with endothelium, and thrombosis is a frequent finding in the sinuses. These sinuses, with their simple endothelial linings, may represent vascular malformations rather than benign tumors of vascular origin.

265 CHAPTER • 265 Renal Tubular Diseases

Marie E. Kerl

The renal tubules are responsible for absorption of various components of the blood that has been filtered through the glomerulus. Among the filtered components that are reabsorbed into the blood are glucose, amino acids, and electrolytes. The tubules are also responsible for secretion of drugs and electrolytes, regulation of acid-base balance, and maintenance of fluid balance. Tubular defects occur regionally or globally and are either congenital or acquired. The glomerular filtration rate (GFR) is the main determinant of renal function, but the tubules are responsible for the final composition of the urine. Indicators from biochemical profiles, blood gas analysis, and urinalysis can be monitored to assess tubular function.

The renal tubules can be described according to function and anatomic location. The proximal convoluted tubule, loop of Henle, distal convoluted tubule, collecting tubule, and collecting duct are each responsible for various functions. The proximal tubule receives ultrafiltrate from Bowman's space and reabsorbs 60% to 65% of the filtrate. Absorption is accomplished by active transport of sodium (Na^+), which in turn promotes passive resorption of other solutes. The proximal tubule also actively secretes some solutes (e.g., organic anions, cations, and hydrogen ions [H^+]).[1] Solutes are not reabsorbed uniformly; virtually all filtered glucose and amino acids are reabsorbed, whereas lesser amounts of bicarbonate (HCO_3^-), Na^+, and chloride are reabsorbed. The loop of Henle, with the characteristic hairpin configuration central to the kidney's ability to excrete concentrated urine, is divided into four segments, having different absorption characteristics. The main function of the loop of Henle is to reabsorb approximately 30% of filtered sodium chloride (NaCl) against a concentration gradient to create an ultrafiltrate that is hyposmolar to plasma.[2] The distal tubule and the collecting tubule and duct are responsible for fine control of electrolytes including Na^+, potassium, and calcium; final regulation of acid-base balance; and water resorption to produce a concentrated urine.[3] Clinical manifestations of renal tubular disorders include formation of cystic calculi, metabolic acidosis, glucosuria, aminoaciduria, electrolyte disorders, and failure of urine concentration.[4,5]

265.1 CYSTINURIA

Cystinuria is caused by an inherited proximal tubular defect in which resorption of particular amino acids fails. Of these amino acids, cystine is relatively insoluble in urine, resulting in the formation of cystic calculi in acidic urine.[6–8] Plasma concentrations of cystine are normal in affected animals. The exact nature of the defect remains unknown; some breeds have cystine loss only, whereas other breeds fail to reabsorb a variety of amino acids.[7]

Many dog breeds have been reported with cystinuria, and occasional reports have been made for cats.[9,10] Commonly affected dog breeds include English bulldogs, Australian cattle dogs, dachshunds, mastiffs, basset hounds, Newfoundlands, Staffordshire bull terriers, and French bulldogs. Mixed-breed dogs are also affected.[8,11,12] The mode of inheritance in various breeds is sex linked or autosomal recessive, but cystinuric dogs do not always develop calculi.[8] The mean age of calculus formation is 4.5 years. The degree of cystinuria can vary among individuals and may decrease with age.[6] Males are over-represented for clinical cystine calculi, but cystinuria without calculi formation has been reported in females. Newfoundlands appear to have a more severe form of cystinuria, with calculi formation occurring in both males and females and at a younger age than for other breeds.[8]

Clinical signs associated with cystine calculi formation include stranguria, pollakiuria, and hematuria. Male dogs may develop secondary urethral obstruction. Evaluation of urine sediment reveals cystine crystalluria in some affected dogs, but a complete blood count and serum biochemical analysis do not aid diagnosis. Imaging studies may identify calculi, but the size, shape, and radiographic density of calculi vary. The radiographic density of larger calculi is similar to that of soft tissue, which allows them to be visualized on plain film radiographs; small calculi may not be visualized by this technique. Ultrasonography and contrast cystourethrography may be diagnostic if plain film radiography is unrewarding.[8]

Treatment involves mechanical removal or medical dissolution of calculi and long-term medical management to prevent recurrence. Surgical management is indicated in animals with urethral obstruction. Quantitative calculi analysis provides a definitive diagnosis. Bacterial urinary tract infection should be resolved with appropriate antibiotic therapy. Dissolution and prevention strategies include exclusive feeding of protein-restricted diets. Cystine is twice as soluble at a pH of 7.8 as at 6.5, therefore urinary alkalization is desired.[5] Some protein-restricted diets (Prescription Diet Canine u/d, Hill's Pet Nutrition, Topeka, Kansas) result in the formation of an alkaline urine, but if dietary therapy does not maintain the urine pH at the desired level, oral potassium citrate is recommended.[8] Induction of diuresis (e.g., by feeding canned, low-protein food or adding water to dry food) is likely to be beneficial.[6,8]

Drug therapies to reduce the formation of cystine calculi include the thiol drugs D-penicillamine and 2-mercaptopropionylglycine (2-MPG). Cystine is formed by a disulfide bond between two cysteine molecules. Thiol drugs form a disulfide bond with cysteine to form a more soluble cystine-thiol drug complex. Although both drugs are effective, metal chelation and gastrointestinal side effects of D-penicillamine make it a less desirable choice.[7] 2-MPG, administered at a dosage of 30 to 40 mg/kg of body weight, divided and given orally twice daily, is the treatment of choice, in combination with dietary modifications for dissolution and prevention of cystine calculi.[6–8,13]

265.2 CARNITINURIA

Carnitine is a sulfur-containing nonessential amino acid that functions as an enzyme cofactor necessary to transport energy-generating fatty acids from the cytosol to the mitochondrial matrix. Continued deficiency, which has been reported in dogs with dilated cardiomyopathy, may result from defective biosynthesis, defective tissue uptake or retention, or excessive renal excretion.[14,15] Carnitinuria has been reported in dogs with cystinuria.[16] Although high-fat, low-protein diets are recommended for the management of cystinuria, high-fat diets increase renal carnitine excretion in humans. Healthy dogs that consume low-and high-fat diets excrete similar amounts of carnitine; however, cystinuric dogs with altered amino acid resorption might excrete an excessive amount of carnitine if they consume a high-fat diet.[15] Chronic carnitine excretion in these animals eventually may result in carnitine deficiency, leading to cardiomyopathy.

265.3 HYPERURICOSURIA

Abnormal purine metabolism or excretion accounts for hyperuricosuria in dogs of certain breeds or those with underlying hepatic disease. The purine portions of nucleic acids undergo metabolism to form hypoxanthine and xanthine, which are oxidized to uric acid by xanthine oxidase (XO). Uric acid is hepatically metabolized by the enzyme uricase. Most mammals excrete allantoin almost exclusively, but humans and higher apes excrete mostly uric acid.[17]

Two subsets of dogs commonly develop purine urolithiasis: Dalmatians and dogs with primary hepatic disease. Dalmatians are intermediate between dogs of other breeds and humans with regard to purine metabolism, excreting approximately one half to two thirds as much allantoin as urate. Differences exist between Dalmatians and non-Dalmatian dogs in both hepatic and renal management of urates. The enzyme uricase, which converts uric acid to allantoin, is stored in hepatic peroxisomes.[18] Uric acid must be transported into hepatocytes before conversion to allantoin can occur. Dalmatians have normal amounts of uricase compared with non-Dalmatian dogs, but Dalmatians have abnormal uric acid transport across the hepatic membrane.[19] Also, both Dalmatians and non-Dalmatian dogs secrete and reabsorb urates in the proximal tubules, but Dalmatians appear to have less proximal tubular resorption. In addition, they have active distal tubular secretion of urates as a result of a membrane transport defect.[17,20,21] Although all Dalmatians have high urine uric acid levels, only a small percentage develop calculi. Certain breeds, such as English bulldogs, have been reported to have an increased frequency of urate calculi without obvious hepatic disease. These dogs might have a metabolic defect that predisposes to urate calculi formation, but the mechanism is unknown.[20,22]

Dogs with primary hepatic disease have reduced conversion of uric acid to allantoin and of ammonia to urea. These metabolic defects cause hyperuricuria and hyperammonuria.[23] Portal vascular anomalies and hepatic microvascular dysplasia have been most commonly associated with urate calculi formation, although any severe hepatic dysfunction could predispose to calculi formation.[24] Cats have been reported with urate urolithiasis.[10]

1825

1826

The clinical signs of urate urolithiasis are consistent with lower urinary tract disease. Male dogs can develop urethral obstruction. Young to middle-aged dogs are more commonly affected than older dogs.[25] For Dalmatians, males are more frequently affected with urinary calculi than females. Dogs with primary hepatic disease have no gender predisposition for calculi formation. Definitive diagnosis of cystic calculi depends on calculi retrieval and quantitative analysis. Urate calculi are radiolucent on plain film radiography. Abdominal ultrasonography or double-contrast cystography is helpful for identifying calculi. Hepatic function studies are appropriate for non-Dalmatian dogs and for cats. Urate calculi are typically small and smooth and vary in color from yellow to green to black.[20]

Treatment consists of calculi removal or dissolution, followed by long-term medical management to prevent recurrence. Dissolution therapy includes a calculolytic diet, medication with XO inhibitors, alkalization of the urine, elimination of secondary infections, and induction of isosthenuria.[20] A purine-restricted diet that is low in claculogenic minerals (e.g., Prescription Diet Canine u/d; Hill's Pet Nutrition, Topeka, Kansas) is recommended.[20,21,26,27] The synthetic XO inhibitor allopurinol is used to treat and prevent urate urolithiasis because it can reduce the serum and urine uric acid concentrations.[28] Allopurinol should be administered only to dogs consuming a purine-restricted diet to avoid the formation of xanthine calculi.

Urine alkalization reduces renal tubular production of ammonia, thereby diminishing the production of urinary ammonium ions that complex with urate to form calculi. Alkalizing agents (e.g., oral sodium bicarbonate [$NaHCO_3$] and potassium citrate) should be administered at a dosage that maintains the urine pH near 7.0 to 7.5.[20,27] Dilute urine production is accomplished by feeding protein-restricted diets that reduce renal medullary concentrating ability.

Mechanical calculi removal should be considered in animals with urethral obstruction or in those that do not respond to dissolution therapy. The average time to dissolution of urate calculi is approximately 3.5 months (range, 1 to 18 months).[20,27] Dissolution sometimes occurs with definitive repair of a portovascular anomaly, but

calculi do not resolve without resolution of underlying hepatic defects.[23] Because the causes of urate stones differ, allopurinol therapy is not recommended for dogs with hepatic defects.[20,23]

The prognosis is fair to guarded for calculi recurrence in Dalmatians and depends on the owner's commitment to ongoing management and expense. In dogs with underlying liver disease, the prognosis is good if definitive therapy for the liver disease exists but guarded in dogs with irreparable liver disease.

265.4 HYPERXANTHINURIA

Xanthine calculi are rare. Xanthine is derived from dietary purines and is metabolized to uric acid by activity of XO. Reduced enzymatic conversion increases urinary excretion of xanthine, which has a solubility similar to that of uric acid in urine.[29] Most dogs that form xanthine-containing calculi are receiving allopurinol, an XO inhibitor, for urate calculi.[22,25,29] Congenital xanthinuria has been reported in a family of Cavalier King Charles spaniels and in a wirehaired dachshund.[30,31] Prevention consists of monitoring for xanthine crystalluria in dogs receiving allopurinol to prevent urate calculi.

265.5 RENAL GLUCOSURIA

Under normal conditions, glucose is freely filtered at the glomerulus and reabsorbed in the proximal tubules by facilitated diffusion in a cotransport mechanism with Na^{+}.[1] The transport mechanism has a maximum capacity, which is exceeded at a blood glucose concentration of 180 to 220 mg/dL in dogs and 260 to 310 mg/dL in cats.[4] When hyperglycemia (e.g., stress hyperglycemia, diabetes mellitus) exceeds the transport maximum, glucosuria occurs. Proximal tubular defects caused by tubular damage or inherited disorders can result in glucosuria in the absence of hyperglycemia.[32,33]

Primary renal glucosuria is rare but has been reported in Scottish terriers, basenjis, Norwegian elkhounds, and mixed-breed dogs.[4,34] Persistent glucosuria typically causes polyuria and polydipsia from osmotic diuresis, although some dogs are asymptomatic. Evaluation of serial blood glucose measurements or the serum fructosamine concentration should be considered to diagnose renal glucosuria definitively by ruling out hyperglycemia as a cause for glucosuria.[35] Because bacterial or fungal urinary tract infections occur frequently with persistent glucosuria, regular monitoring and appropriate antibiotic therapy are important. There is no cure for primary renal glucosuria, but the long-term prognosis is good with appropriate fluid intake and control of urinary infections. In some dogs, renal glucosuria is the initial sign of Fanconi syndrome.

265.6 FANCONI SYNDROME

In humans, Fanconi syndrome is an inherited proximal tubular defect that results in glucosuria, aminoaciduria, proteinuria, phosphaturia, and hypophosphatemia. Fanconi syndrome has also been reported in dogs, and basenjis are most commonly affected. Fanconi syndrome is thought to be inherited in 10% to 30% of all basenjis, but the mode of inheritance is uncertain. Idiopathic and inherited Fanconi syndrome has been reported rarely in other dog breeds.[4,32] Acquired Fanconi syndrome has been reported in association with gentamicin administration, ethylene glycol toxicity, and primary hypoparathyroidism.[4,33]

Fanconi syndrome causes abnormal fractional excretion of many solutes.[36] Abnormal glucose absorption, resulting in glucosuria and osmotic diuresis, is the most obvious sign. Amino acid resorptive abnormalities vary

from one individual to another but generally include abnormal absorption of cystine. Abnormal absorption of bicarbonate, sodium, potassium, and urate also occur. Isosthenuria sometimes occurs prior to glucosuria and osmotic diuresis as a result of nephrogenic diabetes insipidus.[4,36]

The onset of clinical signs in affected basenjis typically occurs by 4 to 8 years of age, with females outnumbering males 3:1.[32] Clinical signs typically include polyuria, polydipsia, weight loss, poor haircoat, weakness, and dehydration. Diagnostic testing reveals glucosuria, euglycemia, and isosthenuria. As the disease progresses, hyperchloremic metabolic acidosis and renal failure occur. Clinically significant hypokalemia might contribute to muscle weakness. Progression is variable; some affected dogs develop renal failure within a few months of the onset of clinical signs, whereas others remain stable for years.[4]

Treatment is supportive, because there is no cure for the tubular defects. Monitoring for metabolic acidosis, urinary tract infections, and azotemia should be performed regularly. Veterinarians are frequently asked to participate in a management protocol developed by basenji breed enthusiasts. This protocol involves oral administration of sodium bicarbonate to manage chronic metabolic acidosis, which exacerbates bicarbonaturia. Urinary alkalization with potassium citrate does not cause bicarbonaturia and provides potassium supplementation. The goals of alkalization should be to maintain the serum HCO_3^- concentration above 12 mEq/L and the potassium concentration at 4 to 6 mEq/L.[4] Renal failure should be managed with dietary protein restriction, fluid therapy, histamine-2 receptor antagonists, and treatment of hypertension. Treatment for acquired Fanconi syndrome should be directed at resolving the underlying cause of the disorder and providing supportive care. The prognosis for short-term management is guarded to good, depending on the severity of azotemia at the time of diagnosis. The long-term prognosis is guarded to poor.

1827

265.7 RENAL TUBULAR ACIDOSIS

The renal tubules regulate acid-base homeostasis through two processes: (1) resorption of 80% to 90% of filtered HCO_3^- in the proximal renal tubule, and (2) excretion of acids by means of titration of urinary buffers and excretion of ammonium in the distal renal tubule.[37] The term *renal tubular acidosis (RTA)* describes rare tubular disorders that lead to hyperchloremic metabolic acidosis. Various types of RTA have been described based on the area of the affected renal tubules. Proximal RTA (type II) occurs as a result of inability of the proximal tubules to prevent loss of HCO_3^-, and distal RTA (classic, or type I) occurs as the result of inability of the distal tubule to excrete H^+. Type IV RTA is distal RTA and hyperkalemia secondary to hypoaldosteronism or aldosterone deficiency. Unique diagnostic criteria exist for each type of RTA.[38]

A defect in the basolateral membrane Na^+-HCO_3^- cotransporter, with leakage of HCO_3^- into the tubular lumen, results in proximal RTA.[39] This disorder can occur alone or as part of another clinical tubular defect (e.g., Fanconi syndrome).[38] Ongoing loss causes a reduced plasma bicarbonate concentration, but the associated metabolic acidosis is self-limiting because of the distal tubule's ability to excrete acid. If oral sodium bicarbonate ($NaHCO_3$) is prescribed to normalize the plasma bicarbonate concentration, the amount of HCO_3^- presented to the distal tubule increases and overwhelms the distal buffering system, resulting in marked bicarbonaturia.[38]

Table • 265-1 Clinical Features of Proximal and Distal Renal Tubular Acidosis (RTA)

FEATURE	PROXIMAL RTA	DISTAL RTA
Hypercalciuria	Yes	Yes
Hyperphosphaturia	Yes	Yes
Urinary citrate	Normal	Decreased
Bone disease	Less severe	More severe
Nephrocalcinosis	No	Possible
Nephrolithiasis	Not usually	Yes
Hypokalemia	Mild	Mild to severe
Potassium wasting	Worsened by alkali therapy	Improved by alkali therapy
Alkali required for treatment	>11 mEq/kg/day	<4 mEq/kg/day
Other defects of proximal tubular function*	Yes	No
Reductions in plasma bicarbonate (HCO_3^-)	Moderate	Variable
Fractional excretion of HCO_3^- with normal HCO_3^- concentration	>15%	<15%
Urine pH during acidemia	<6.0	>6.0
Urine pH after ammonium chloride administration	<6.0	>6.0

From Bartges JW: Disorders of renal tubules. *In* Ettinger SJ, Feldman EC (eds): Textbook of Veterinary Internal Medicine, 5th ed. Philadelphia, WB Saunders, 2000, p 1704.

* Decreased resorption of sodium, potassium, phosphate, uric acid, glucose, and amino acids.

The diagnosis of proximal RTA is based on an acid urine pH and hyperchloremic metabolic acidosis, with a normal GFR but increased urine pH and fractional excretion of HCO_3^- (greater than 15%) after normalization of the plasma HCO_3^- concentration with alkali administration. Identification of concurrent proximal tubular defects (e.g., euglycemic glucosuria, aminoaciduria) also helps localize proximal RTA.[38] Bicarbonate wasting makes metabolic acidosis from proximal RTA difficult to correct, and alkali therapy exacerbates potassium wasting. Potassium citrate is better suited for chronic use than sodium bicarbonate.[38] One 540 mg tablet of potassium citrate provides 5 mEq of potassium and 1.7 mEq of citrate, and its metabolism yields 5 mEq of HCO_3^{-5}.

Distal RTA causes impairment of urinary acidification as a result of impaired H^+ secretion in the distal tubule.[37,38] Consequently, the kidneys are unable to maximally acidify urine in response to systemic metabolic acidosis. Under normal conditions, the distal tubule is able to excrete H^+ ions against a steep concentration gradient because of a hydrogen ion–adenosine triphosphatase (H^+-ATPase) pump. These tubular segments have tight junctions that resist backleak of acid, and they are able to generate ammonia to capture H^+ ions by forming ammonium ions, which are subsequently excreted.[39]

Type IV distal RTA is associated with hypoaldosteronism or aldosterone antagonism. Acidosis most likely results from loss of aldosterone stimulation of H^+-ATPase and decreased distal Na^+ absorption. This syndrome has not been characterized in veterinary medicine but should be considered in animals with hyperchloremic metabolic acidosis and hypokalemia.[37,38]

Characteristics useful in the diagnosis of distal RTA include hyperchloremic metabolic acidosis with an increased urine pH (greater than 6.0). In contrast to proximal RTA, with relatively mild systemic metabolic acidosis, distal RTA can have a more severe metabolic acidosis, because the distal tubule does not provide

buffering ability. Clinical characteristics seen in humans with distal RTA include nephrolithiasis, nephrocalcinosis, bone demineralization, growth retardation, and hypokalemia.[37,39] Distal RTA has been reported in cats with pyelonephritis and in one cat with hepatic lipidosis.[4,38] The diagnosis may be made by failure to acidify urine with an ammonium chloride challenge test. This test is performed by measuring the urine pH before and at hourly intervals for 6 hours after oral administration of 110 mg/kg of ammonium chloride. Normal dogs should acidify to a urine pH of 5.0, and cats to a pH of 5.5.

1827

1828

Treatment for distal RTA consists of administration of an alkali source. A combination of potassium and sodium citrate, at a dosage range of 1 to 5 mEq/kg/day, orally, divided into 2 doses, may be preferred over HCO_3^- as the alkali source. Characteristics of proximal and distal RTA are presented in Table 265-1.[5,38]

265.8 NEPHROGENIC DIABETES INSIPIDUS

The term *nephrogenic diabetes insipidus (NDI)* describes any disorder in which the urinary concentrating mechanism is unable to respond to antidiuretic hormone (ADH) to produce concentrated urine. ADH is produced in the hypothalamus in response to hyperosmolarity or hypovolemia. Upon release, it attaches to receptors at the basolateral membrane of the collecting tubules and collecting ducts, causing the tubular luminal surface to become permeable to free water and resulting in the formation of urine that is more concentrated than plasma. Acquired NDI is a common cause of polyuria, because it can result from receptor interference caused by toxins (e.g., *Escherichia coli* endotoxin), drugs (e.g., glucocorticoids, chemotherapeutics), metabolic conditions (e.g., hypokalemia, hypercalcemia), tubular injury or loss (e.g., renal cystic disease, bacterial pyelonephritis), or alterations in the medullary concentration gradient (e.g., medullary washout).[40]

Congenital NDI is a rare disease caused by a deficiency of ADH receptors. Clinical signs, apparent soon after birth, include severe polydipsia and polyuria and a hyposthenuric urine (specific gravity of 1.001 to 1.005; osmolarity less than 200 mOsm/kg). The diagnosis is based on failure to concentrate urine after modified water deprivation testing, failure to respond to exogenous ADH, and exclusion of more common causes of NDI.[4]

Treatment for acquired NDI should be directed at resolving the underlying cause. Congenital NDI therapy consists of free-choice water consumption, dietary sodium and protein restriction, and/or thiazide diuretics (chlorothiazide, 20 to 40 mg/lb given orally every 12 hours; or hydrochlorothiazide, 2.5 to 5 mg/lb given orally every 12 hours). Dietary sodium and protein restriction reduces the amount of solute presented to the kidney that must be excreted in the urine each day, further reducing obligatory water loss.[41] The addition of diuretic therapy to dietary restrictions results in mild dehydration, increased fluid and sodium uptake in the proximal tubule, and 20% to 50% reduction of urine output.[41] If medical management is not an option for the client and polyuria can be tolerated, the animal can be maintained on free-choice water consumption alone.

266 CHAPTER • 266 Feline Lower Urinary Tract Diseases

Jodi L. Westropp

C.A. Tony Buffington

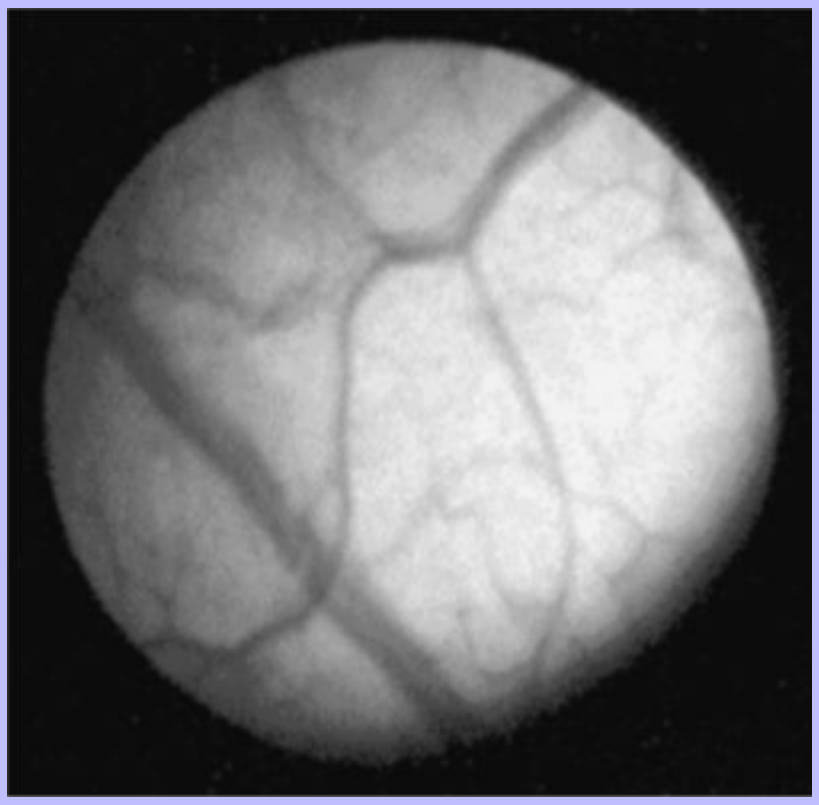
Dennis Chew

The terms *feline urologic syndrome* (FUS) and *feline lower urinary tract disease* (FLUTD) have served as shorthand descriptions for the well-known signs of straining, hematuria, pollakiuria (frequent passage of small amounts of urine), and periuria (urinations in inappropriate locations) in cats.[1] In 1925 an accurate clinical description of cats with lower urinary tract (LUT) signs described the disorder as common.[2] The roles of confinement and highly nutritious food were discussed, and the common occurrence of the problem in Persian cats was identified. In 1970, the term *FUS* was coined by Osbaldiston and Taussig[3] to describe a problem, "characterized by dysuria, urethral obstruction, urolithiasis (although no stones were reported), and hematuria." During the 1980s, Osborne and colleagues[4] suggested that FUS should be considered synonymous with FLUTD.

No diagnosis for the clinical signs of irritative voiding can be determined in approximately two-thirds of cats with LUT signs, and they are classified as having feline idiopathic cystitis (FIC). If a cystoscopy is performed and characteristic submucosal petechial hemorrhages are seen,[5] a diagnosis of feline interstitial cystitis can be made (Figures 266-1 and 266-2). This term was chosen because of the similarities between cats and humans with interstitial cystitis, an idiopathic pelvic pain syndrome that is characterized by difficult, painful, and frequent urinations without a diagnosable cause. Two forms of interstitial cystitis exist in humans: (1) nonulcerative and (2) ulcerative.[5] Cats with FIC generally have the nonulcerative form, however, the "classic Hunner's ulcers" have been described rarely in cats.[6] The name *FIC* will be used in this chapter for cats with idiopathic lower urinary tract disease. The term *LUT signs* will be used when referring to all possible causes of LUT disorders.

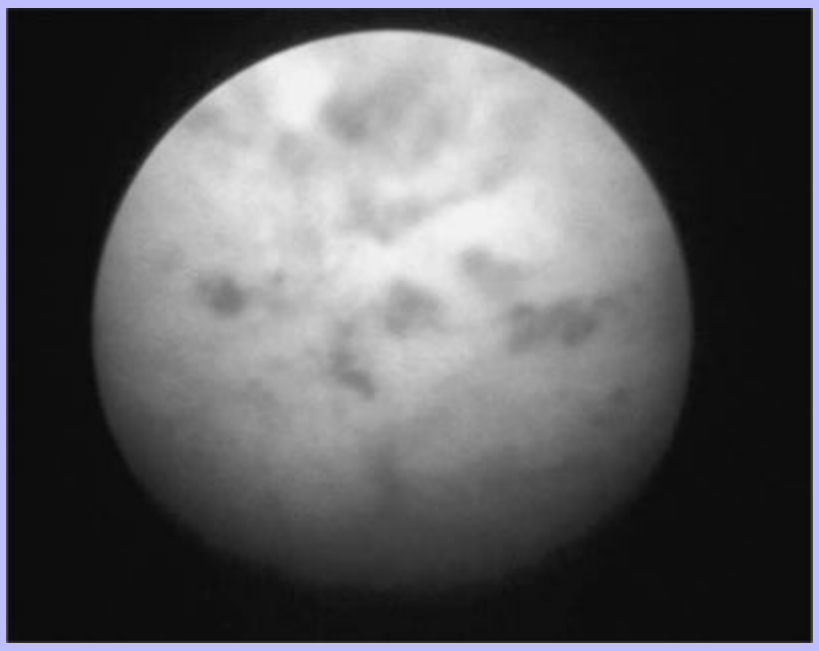
Approximately 4 million cats are destroyed annually in the United States for "elimination problems," the majority of which are related to the urinary tract.[7] Estimates of the prevalence of LUT signs were approximately 1.5% when private practices were evaluated.[8] Results of university-based studies during the past 40 years suggest that most (55% to 69%) cats presented for evaluation of nonobstructive LUT disorders have FIC; some 13% to 28% have uroliths.[9,10] Other less common problems such as urinary tract infections (UTIs), anatomic defects, behavioral problems, neoplasia, and obstructive uropathy (reflex dyssynergia) account for most other definable disorders referable to the LUT.

Figure 266-1 Cystoscopic appearance of blood vessels in a normal bladder from a healthy cat using liquid distention to 80 cm water pressure.



When cats present for periuria (but not spraying) as the only reported clinical sign, it can be difficult to decide if they should be classified as FIC or a behavioral problem. On cystoscopy in cats with only periuria, more than half had abnormalities in their bladder such as increased vascularity, edema, or glomerulations (submucosal petechial hemorrhages).[10] Cats with FIC may have a behavioral component simultaneously, and as many as 40% of cats with periuria have had a previous diagnosis of cystitis.[11] Regardless of the presence or absence of cystoscopic lesions, we treat cats with periuria similarly to cats with FIC.

Figure 266-2 Cystoscopic appearance of a bladder from a cat with feline idiopathic cystitis (FIC). Multiple small submucosal petechial hemorrhages (glomerulations) are present, as well as edema.



266.1 EPIDEMIOLOGY

The ratio of LUT cases to all cases seen in a clinic or hospital is called the *proportional morbidity rate*. Proportional morbidity differs from incidence because its denominator is biased toward sick animals owned by clients who are willing and able to bring their pets to a veterinarian, as well as the clinical interests of veterinarians involved in the study. Proportional morbidity estimates of LUT signs in cats have ranged from 1% to 6%,[12] and a recent study reported a rate of approximately 1.5%.[8] Recurrence rates for LUT signs are high. In one study, 45% of male cats experienced recurrence within 6 months of an initial episode of LUT obstruction.[13] In another study, the recurrence rate for affected cats without obstruction was 39% within 1 year.[14] A slightly higher recurrence rate (approximately 55%) was reported in another study.[15]

1829 1830

A case-control study of cats with LUT signs was conducted recently in New Zealand (1991 to 1993).[16] One hundred ninety-three affected cats were compared with 189 case-matched (sex and age) and 189 random control cats from 13 private veterinary practices. No difference in age, gender or neuter status was identified between cases and controls. Increased risk of LUT signs was found for use of a litter tray only for elimination (cat unable to leave the house to eliminate), confinement indoor greater than or equal to 21 hours per day, sleeping inside, a move to a new house during the past 3 months, *ad libitum* feeding of dry cat food, and dry cat food feeding with low fluid intake. An increased incidence occurred during winter months, and further analysis identified a highly significant association with rainy days during the previous month. Access to outdoor prey was found to be protective.

Other studies have also reported an increased risk for LUT signs in cats fed exclusively dry food. A recent analysis of these data suggested increased risk with increased dry food consumption.[12] We found a 1-year recurrence rate of 39% in nonobstructed cats with FIC fed the dry formulation of a commercial food, whereas the recurrence rate in cats fed the canned formulation was 11%.[17] In another study, risk increased with the number of meals fed per day and was greater with periodic feeding than with *ad libitum* feeding.[12]

These studies support previous studies that found the risk for LUT signs to be highest in indoor-restricted cats that predominantly eat dry food.[12] Risk factors, however, must be kept in perspective. The proportional morbidity of LUT signs in the cat population is approximately 1.0%, although many cats are kept indoors and fed dry food exclusively.[18] The reformulation of many commercial cat foods (based on earlier epidemiologic studies) apparently has not reduced the role of dry food as a risk factor for LUT signs in cats. This circumstance suggests that environmental factors may unmask an underlying predisposition to LUT signs in some cats. The exact nature of this predisposition remains to be determined. The identification of differences in breed susceptibilities suggests that internal and environmental factors can influence disease risk in cats. Willeberg,[12] in a 1984 review, concluded that Siamese cats had a reduced risk of LUT signs, whereas Persians were at an increased risk. Jones and colleagues[16] reported an increased risk of LUT signs among long-haired but not purebred cats.

LUT signs can occur at any age but are unusual in cats less than 1 year of age and most frequent in cats 2 to 6 years of age. When clinical signs are considered without regard to obstruction, no difference in risk between males and females is observed. Adjustment for age is important because both neutering and LUT signs are age related. When adjusted for age, risk is greater for castrated males and spayed females than for intact cats,[12] but the age at neutering does not seem to be important.[19]

Excessive body weight and decreased activity have been associated with increased risk for LUT signs in some studies. When evaluating husbandry, the data concerning risk for LUT signs are mixed, indicating variously no effect[12,16] or increased risk.[20] If an increased risk exists in multiple-cat households, it could be associated with feeding and husbandry practices, territorial conflict, or horizontally transmitted infectious agents that could play a role in the development of LUT signs. Lack of a difference between affected and control cats in upper respiratory disease and the increase in risk associated with increasing amounts of time spent *indoors* seem to argue against infection as a causative factor in LUT signs of cats.[16]

266.2 FELINE IDIOPATHIC CYSTITIS

266.2.1 Pathophysiology

A variety of abnormalities have been found in the bladders, nervous system, hypothalamic-pituitary-adrenal axis, and other body systems in cats with FIC. FIC in cats is similar to interstitial cystitis in human beings. Humans serve as a useful model for cats with FIC, and vice versa.[5] Cats are classified as having *feline interstitial cystitis* if cystoscopy is performed and characteristic glomerulations are seen. Cats with feline interstitial cystitis meet all of the inclusion criteria, and exclusion criteria for diagnosis of interstitial cystitis that can be applied to animals.[21] Thus (allowing for species differences), cats with feline interstitial cystitis meet the National Institutes of Health (NIH) criteria for humans. Feline interstitial cystitis primarily resembles nonulcer interstitial cystitis in humans, although ulceration and inflammatory infiltrates occasionally have

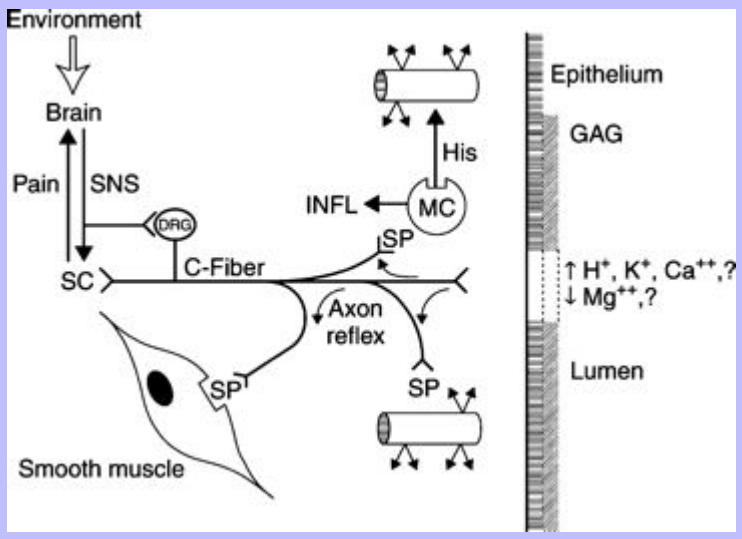
been observed in cats. Abnormalities of local bladder factors, sensory (afferent) neurons, central nervous system (CNS), and sympathetic (efferent) neurons occur in cats as they do in humans.[22]

Gender distribution seems to be different between affected males and females of cats and humans. In cats, both genders are affected roughly equally, whereas 90% of humans are women.[23] One reason for the gender discrepancy may be related to differences in diagnoses rather than diseases. For further details, the reader is referred to a recent review on similarities between cats and humans and to other models of interstitial cystitis.[21]

Both humans with interstitial cystitis and cats with FIC seem to excrete smaller amounts of both total urinary glycosaminoglycan[25] (GAG) and a specific GAG (GP-51)[26,27] than do normal individuals. GAG and GP-51 contribute to the surface mucus covering the urothelium that is believed to inhibit bacterial adherence and urothelial injury from the constituents of the urine. A defective GAG layer or damaged urothelium could permit hydrogen, calcium, potassium ions, or other constituents of urine to come into contact with sensory neurons innervating the urothelium. These ions can stimulate local release of neurotransmitters and result in neurogenic bladder inflammation[28] (Figure 266-3). Sensory neurons reach the bladder via the pelvic and hypogastric nerves, and the central processes of these nerves synapse in the dorsal horn of the sacral and lumbar spinal cord, respectively.[29] These neurons include unmyelinated nociceptive fibers, commonly referred to as *C fibers*. In one study of normal cats, only ~2.5% of C fibers responded to bladder distention. However, more than 10% of these fibers responded after infusion of an irritant into the bladder lumen. This increase was attributed to activation of normally "silent" C fibers, which respond only to noxious stimuli.[30]

Histologic changes associated with FIC are generally nonspecific and may include an intact or damaged urothelium with submucosal edema, dilation of submucosal blood vessels with marginated neutrophils, submucosal hemorrhage, and sometimes increased mast cell density[5] (Figure 266-4). Bladder mastocytosis appears to be involved in the pathogenesis of interstitial cystitis in some human patients and also in some cats with FIC[31–33] (Figure 266-5). Scanning electron microscopy of bladders in cats with FIC revealed patches devoid of superficial epithelial cells (so-called umbrella cells of the urothelium)[34] and disruption of tight junctions that worsened after hydrodistention (Figure 266-6). No correlation between histology, cystoscopic lesions, and clinical signs appears to exist in cats. In fact, owners have reported complete remission of LUT signs in cats with FIC, but visualization of their bladder revealed glomerulations and other abnormalities.[35] Similar studies have been documented in humans with interstitial cystitis.[36] Because of these findings, the authors do not routinely use cystoscopy or histopathology to monitor response to therapy.

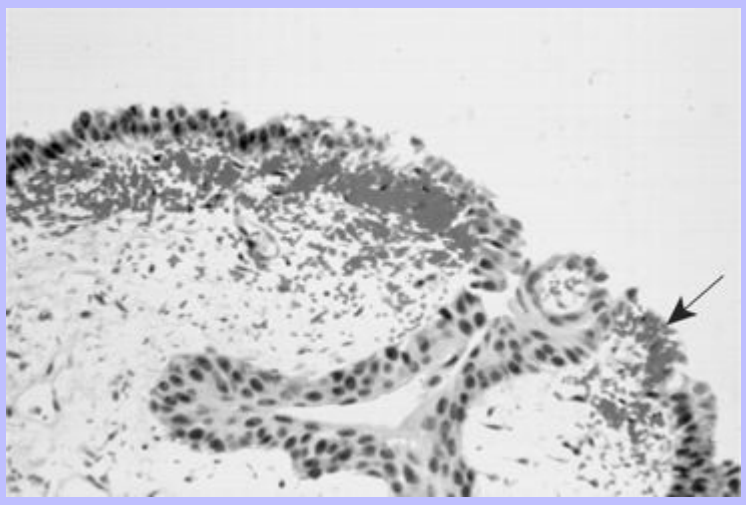
Figure 266-3 Conceptual model of bladder response to noxious stimuli. Damage of malfunction of glycosaminoglycan *(GAG)* layer or urothelium may permit urine constituents to activate sensory neurons *(C fiber)* in submucosa, which transmit action potentials to the spinal cord *(SC)* that are perceived as painful by the brain. Sensory fibers can also generate local axon reflex without propagating action potential. Axon reflex results in release of peptide neurotransmitters, such as substance P *(SP),* by nerve endings. Interaction of SP with receptors on vessel walls results in vascular leakage, which can be augmented by SP-induced release of histamine *(HIS)* by mast cells *(MC)*. These actions may give rise to submucosal petechial hemorrhages observed at cystoscopy. SP receptors also occur on smooth muscle, which when activated stimulate muscle contraction. In addition to luminal insults, increased vascular permeability and desquamation of superficial cells of urothelium can also results from systemic and environmental stimuli, and activate C fibers and mast cells. *SNS*, Sympathetic nervous system; *INFL*, inflammation; *DRG*, dorsal root ganglia.



Studies in cats with FIC have shown increased leakage of ions across the urothelium and urea leakage in nonhydrodistended bladders. Marked increases in permeability after hydrodistention were also present.[34] Bladder permeability is reported to be increased in cats with FIC. Bladder permeability to sodium salicylate was increased in an *in vivo* study of cats with FIC.[37] Additionally, *in vitro* bladder epithelial urea permeability

was significantly increased from normal in both undistended and distended bladders, water permeability was significantly increased in distended bladders, and transitional cell desquamation was identified in cats with FIC.[34] Cyclophosphamide-induced cystitis in rats and other animal models of cystitis have increased bladder permeability.[38] Therefore it is likely this finding is not specific to FIC but an underlying problem that might affect the nerves in the urothelium causing a perpetuation of clinical signs.

Figure 266-4 Histopathologic section of a bladder biopsy from a cat with feline idiopathic cystitis (FIC). Usually, cats with this disease have a very mild cellular infiltrate. Blood and edema can "pool" under the urothelium, and breaks in the urothelium can be seen. Submucosal hemorrhages would appear as a glomerulations when viewed cystoscopically. (H&E; × 40.)



Substance P (SP), an 11 amino acid peptide neurotransmitter, has been identified in the bladder C fibers of cats with FIC. The authors have observed a modest increase in SP immunoreactivity (IR) in the bladder of cats with FIC.[39] Significant increases in the SP receptor density (NK-1 receptors) in the bladder of humans with interstitial cystitis and cats with FIC also have been reported.[41,42] Unfortunately, clinical trials of the analgesic properties of SP antagonists in humans have been disappointing.[43,44] SP antagonists have not been investigated in cats with FIC.

1831

1833

Figure 266-5 Histopathologic section of a bladder from a cat with feline idiopathic cystitis (FIC) stained with toluidine blue to visualize mast cells. Bladder mastocytosis may contribute to the pathophysiology of FIC in some cats, but mast cell stabilizing drugs do not appear to be beneficial in most cases.

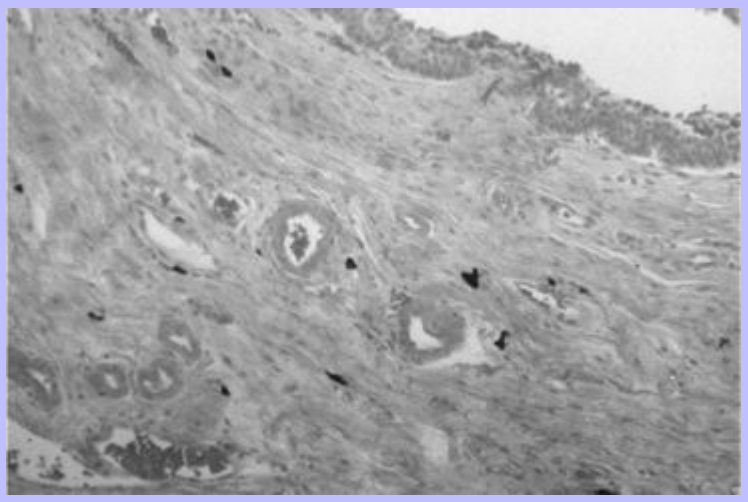


Figure 266-6 Scanning electron microscopy analysis of hydrodistended bladders from normal and feline idiopathic cystitis (FIC) cats. **A,** Low-magnification view of control bladder. **B,** High-magnification view of control bladder showing individual umbrella cells. **C,** Low-magnification view of FIC bladder demonstrating region where umbrella cell layer is disrupted. **D,** Close-up of area enclosed by box in **C. E,** Low-magnification view of FIC bladder showing regions where the urothelium is denuded from the underlying connective tissue. **F,** Close-up of area enclosed by box in **E**. (From Lavelle JP et al: Urothelial pathophysiological changes in feline interstitial cystitis: a human model. Am J Physiol Renal Physiol 278(4):540–553, 2000. Used by permission.)

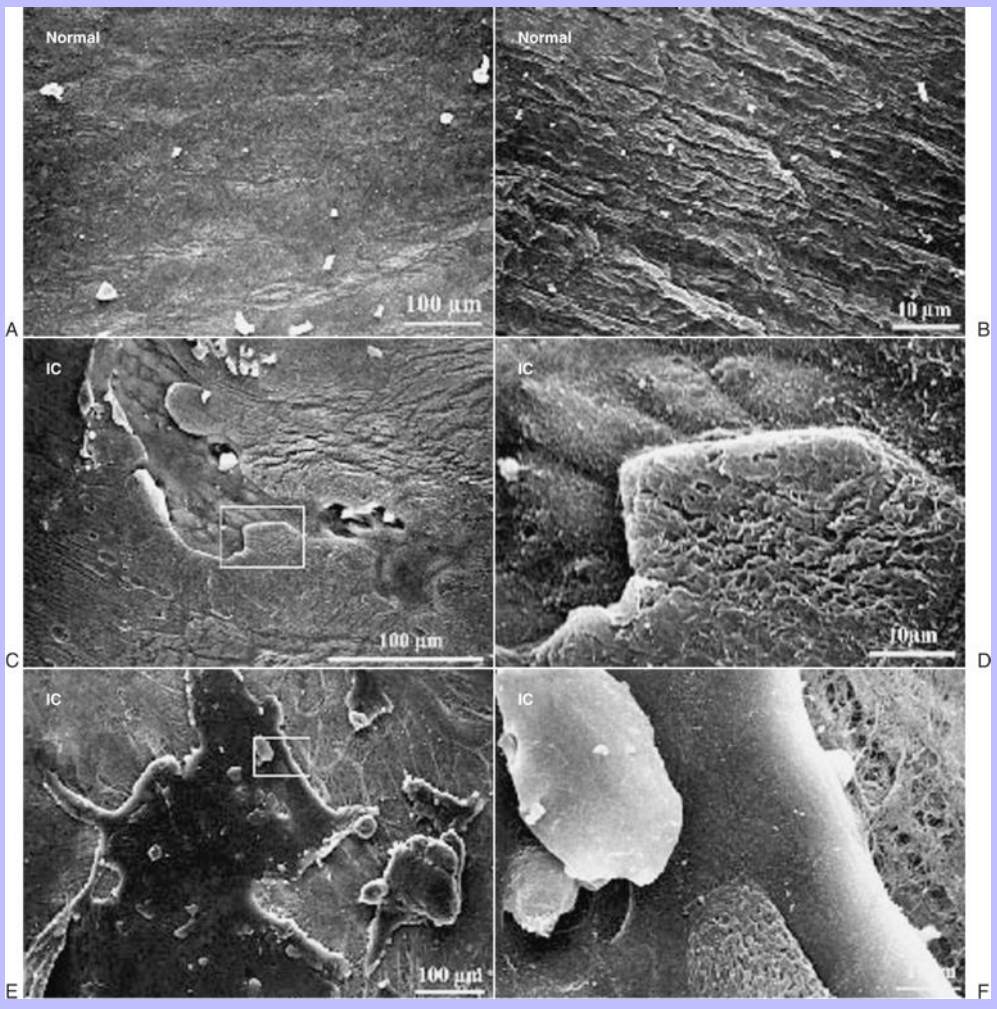

Figure 266-7 Photomicrographs of coronal sections of locus coeruleus *(LC)* of normal cat **(A)** and a cat with FIC **(B)**, immunostained for tyrosine hydroxylase *(TH)*. Reader should note increased staining density in LC complex *(LCc)*, parabrachial lateral *(PBL)*, and Kolliker-Fuse *(KF)* nuclei of cat with FIC compared with normal cat. Scale bar: 20 µm.

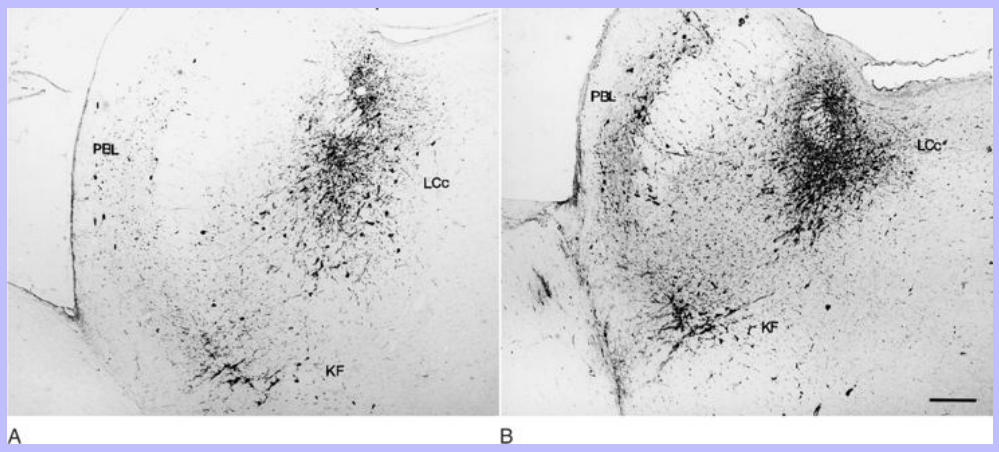


A significant increase in tyrosine hydroxylase (THIR) has been identified in the locus coeruleus (LC)[45] and in the paraventricular nucleus of the hypothalamus in cats with FIC[46] (Figure 266-7). TH is the rate-limiting enzyme of catecholamine synthesis. Bladder distention stimulates neuronal activity in the LC, and the LC (Barrington's nucleus) is the origin of the descending excitatory pathway to the bladder.[47] Moreover, chronic stress can increase TH activity in the LC,[48] with accompanying increases in autonomic outflow.[49] The LC contains the largest number of noradrenergic neurons and is the most important source of norepinephrine (NE) in the feline and human CNS. It is involved in such global brain functions as vigilance, arousal, and analgesia and appears to mediate visceral responses to stress.[50] The increased THIR observed in the LC of cats with FIC may provide a clue to the observation that clinical signs of FIC follow a waxing and waning course, and that they can be aggravated by environmental stressors.[28,51]

In addition to increased LC activity, cats with FIC also have increased plasma NE concentrations.[52] Increased plasma and CSF catecholamine concentrations and their metabolites compared with healthy cats have been measured during stressful situations. The stress studies included removing food 12 hours prior to testing, moving the cats to different cages, and abruptly changing their diets. As the healthy cats acclimated to the stress, their plasma catecholamine concentrations decreased, whereas cats with FIC demonstrated even higher concentrations of plasma NE, epinephrine, and their metabolites.[53] Enhanced stimulus-induced local NE release from the bladder,[61] and functional desensitization of central alpha-2 adrenoceptors (α-2 AR) have been reported in cats with FIC.[55] In the LC, α-2 agonists inhibit NE release, whereas in the spinal cord they inhibit transmission of nociceptive input to the brain.[56,57] Although spinal α-2 AR activation can inhibit nociceptive

input acutely, the receptors can become desensitized or down-regulated after chronic stimulation (i.e., by continuously elevated NE).[58,59]

In the bladder, α2-ARs are found primarily in the urethral submucosa and bladder mucosa (not the muscle), suggesting a role in the regulation of blood flow and urethral lubrication.[60] In this study, no α2-ARs were found in the bladder muscle, implying these receptors are not involved in bladder contraction. However, the α2-ARs can modulate NE outflow and may alter bladder contractility. Decreased sedation after clonidine administration intramuscularly and decreased mydriasis after medetomidine, a more selective α2 agonist, was found in cats with FIC, suggesting decreased α2-AR responsiveness *in vivo*. The reason for this is unclear, but it could be caused by receptor down-regulation due to persistent elevation in NE. In the presence of elevated NE, presynaptic α2-ARs could become down-regulated and unable to inhibit NE release. Electrical field stimulation studies of bladder strips from FIC cats revealed that atipamezole, an α2 antagonist, did not alter the relaxing effect of NE, further suggesting that α2-ARs are down-regulated in this disease.[61]

Based on history, physical examination and clinical signs, pelvic pain is a feature in cats with FIC. Abnormalities in the α2-ARs could be detrimental to patients because postsynaptic spinal α2-ARs possess antinociceptive properties and the α2a-AR subtype has been documented to play the major role in the control of spinal nociceptive responses.[62]

In addition to the sympathetic nervous system (SNS), abnormalities in the hypothalamic-pituitary-adrenal axis (HPA) have also been observed in cats with FIC. After a high dose (125μg) of synthetic adrenocorticotropic hormone (ACTH) was administered, cats with FIC had significantly decreased serum cortisol responses compared with healthy cats.[64] Using computed tomography (CT) and gross histopatholgic evaluation, the adrenal volume (both absolute and per kilogram body weight) were significantly lower in FIC cats, but no correlations could be found between adrenal size and cortisol production.[65] Although no obvious histologic abnormalities were identified, the areas consisting of the zonae fasciculata and reticularis were significantly smaller in sections of glands from cats with FIC than from healthy cats. Therefore it appears that although the sympathoneural system is fully activated in this disorder, the HPA axis is not. The significance of this finding is not known.

1833

1834

Based on the identified sensory abnormalities in cats with FIC, the authors have begun to measure response to acoustic startle. These studies are designed to evaluate the observed anxiety-related behaviors. The acoustic startle response (ASR) is a brain stem reflex that responds to unexpected, loud stimuli. The magnitude of the response can be altered by a variety of experimental manipulations and is affected by many pathologic conditions. These attributes have led to use of the ASR to study neurologic dysfunctions of sensorimotor information processing. Given the role of neural abnormalities in cats with FIC,[52] it was speculated that their ASR responses might be abnormal, and initial results revealed the magnitude of ASR to 105 dB averaged more than double that of healthy cats.

The pathophysiology of FIC is not fully understood and may involve complex interactions between a number of body systems. Abnormalities are not localized just to the bladder, but are present in the nervous,[52] endocrine,[65] and cardiovascular systems.[67] How these systems communicate and manifest as FIC in some cats but not in others remains to be determined. To better treat their patients, it is important for clinicians to understand that this syndrome is not just a “bladder disease” amenable to simple diet or drug therapies.

266.2.2 Approach to the Patient

In humans with interstitial cystitis, various assays for urine markers have been evaluated to attempt to properly identify a marker unique to this disease.[68] Of all the factors evaluated, the recently identified *antiproliferative factor* had the least crossover with healthy controls and could be used to aid in the diagnosis of this disease. This and other assays have not been studied and are not readily available for human or feline patients. Therefore the diagnosis of FIC still remains a *diagnosis of exclusion.* An algorithm to aid clinicians in the diagnostics and treatment of FIC is presented in Figure 266-8. Because some two thirds of cats with LUT signs have FIC, and it appears that approximately 85%[69] of cats with FIC resolve their clinical signs in 2 to 3 days without treatment, it is debatable whether any diagnostics should be performed for a young cat in its first presentation of LUT signs. The basic tests are listed, and the clinician must decide based on the cat's signalment and clinical signs which tests will yield the most benefit for each individual patient.

266.2.2.1 Radiography

A plain abdominal radiograph that includes the entire urinary tract (including urethra) can be a useful diagnostic tool in cats with LUT signs. Approximately 15% of cats with stranguria, hematuria, pollakiuria, or a combination of these conditions will have radiographic evidence of cystic calculi. If only one diagnostic test can be performed, survey abdominal radiography is likely to provide information that is most clinically relevant. Contrast studies of the bladder and urethra in cats with FIC are usually unremarkable, though 15% have diffuse or asymmetrical thickening of the bladder wall.[70] A contrast cystogram and urethrogram can be helpful to evaluate for nonradiopaque calculi and other lesions such as mass lesions, blood clots, and strictures in cats with recurrent episodes. Contrast studies are especially indicated in elderly cats (> 10 years of age) where FIC is not as likely.

266.2.2.2 Urinalysis and culture

Less than 2% of young (<10 years of age) cats have true bacterial cystitis, so urine culture is a low-yield test.[1,10] Quantitative urine culture should be performed in all cats with recurrent (>2 episodes) LUT signs. The possibility of a UTI increases with age, perineal surgery, cystic calculi, or dilute urine.[71] A quantitative urine culture should be performed in cats with LUT signs older than 10 years of age, with a urine specific gravity (USG) less than 1.030, which has undergone perineal urethrostomy, or after a urinary catheter has been placed.

Urinalysis findings such as hematuria, proteinuria, and crystalluria are not specific for any particular type of bladder disease or even a specific stone type. For example, one can see pyuria if a true UTI is present, but mild pyuria can also be present in sterile cystitis upon occasion. Crystalluria can be found in many cats with no signs referable to their LUT. A baseline urinalysis is valuable to exclude polyuria. If submaximal urine concentration is present (<1.035 for cats eating solely dry food; <1.025 for cats eating primarily canned foods), it is possible that increased urine volume contributed to the condition. Therefore a serum biochemical profile and thyroid evaluation should be obtained.

When radiographic findings are negative and a urine culture reveals no growth in cats with no other identifiable abnormalities, the diagnosis of FIC is likely. However, if clinical signs persist after proper environmental and drug therapy have failed, the veterinarian should consider a referral to a specialty clinic for cystoscopy.

266.2.2.3 Cystoscopy

Cystoscopy is performed at referral practices when LUT signs fail to resolve after standard therapy in those cats with negative findings from radiography and urine cultures. This tool allows one to visualize the urethra and bladder at low and high pressures. Small cystic calculi, urachal diverticula, ectopic ureters, and small polyps all can be visualized (Figures 266-9 and 266-10). The authors do not use cystoscopy to "rule in" FIC, but rather to exclude less common diseases. Occasionally, increased vascularity and glomerulations have been noted in stressed, otherwise healthy cats; such lesions may remain in affected cats without clinical signs following treatment.[35]

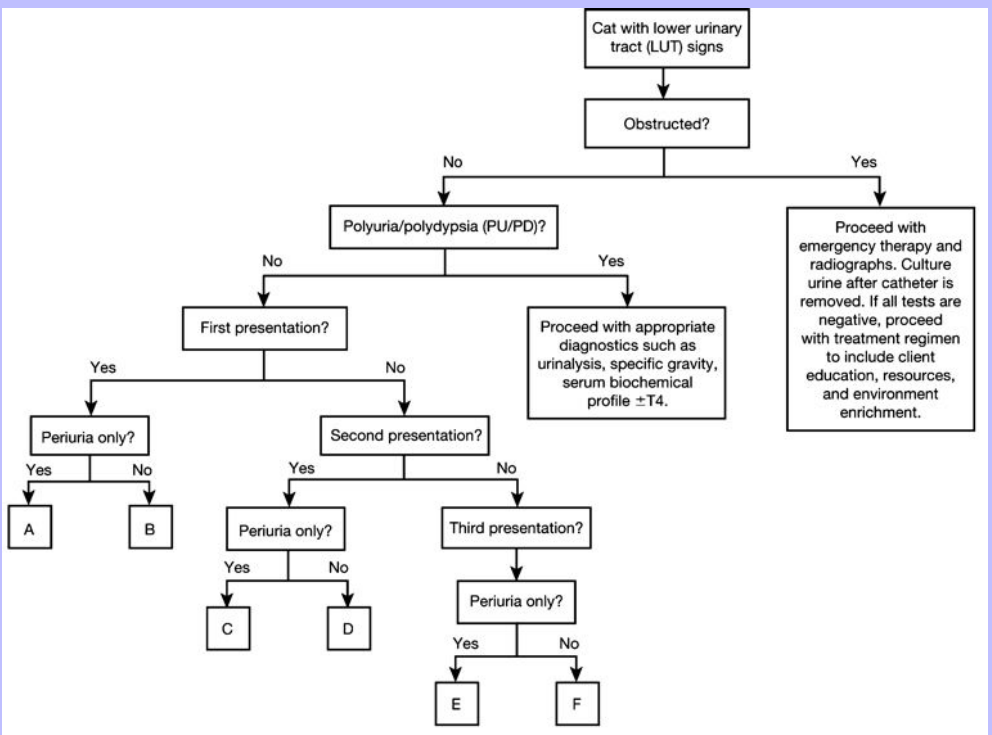
266.2.3 Treatment of Feline Idiopathic Cystitis

Having the proper tools to help owners understand FIC is important in maintaining client satisfaction when beginning any treatment regimen. It is not yet possible to predict which cats with FIC will relapse, so clients should be told what they can do to help decrease the risk of another episode. Clinical signs resolve spontaneously in as many as 85% of cats within 2 to 3 days, regardless of treatment. About 40% to 50% of these cats will have another episode within 12 months.[15,73] Some cats will have multiple recurrences, whereas a smaller population will never have complete resolution of clinical signs.

The underlying cause of this disorder is unknown, so current treatment recommendations must be tentative. The current goals of therapy for cats with FIC are not to "cure" them, but to decrease the severity of signs and to increase *interepisode* intervals, especially for severely affected cats.

Enhanced stress response system activity seems to be central to maintaining the chronic inflammatory process. Any treatment strategy to decrease SNS outflow may be important in reducing inflammation. Reduction of the noxiousness of urine or normalizing bladder permeability may also prove useful. An overarching premise is that FIC is not just a bladder disorder but involves complex interactions of the nervous and endocrine systems.[65] The development of chronic FIC requires the presence of a susceptible cat in a provocative environment. The challenge is to identify what is provoking the susceptible cat in hopes of preventing future bouts. Analgesia, changes in diet and water intake, discussion of feeding practices, litter box management, cleaning of soiled areas, restoration of normal cat behaviors and activities, and drug therapy all are considered as part of the authors' current approach to therapy.

Figure 266-8 Algorithm for lower urinary tract signs in the cat.



A **Diagnostic:** None are usually necessary.
Treatment: Litter box management and cleaning of soiled areas should be addressed.
Medications: No medications are recommended.

B **Diagnostic:** A radiograph should be considered, especially if hematuria is present.
Treatment: If the radiograph is negative, therapy should include analgesia for 2 to 3 days during the acute episode. Litter box management and cleaning of soiled areas should be addressed.
Medications: No medications are recommended.

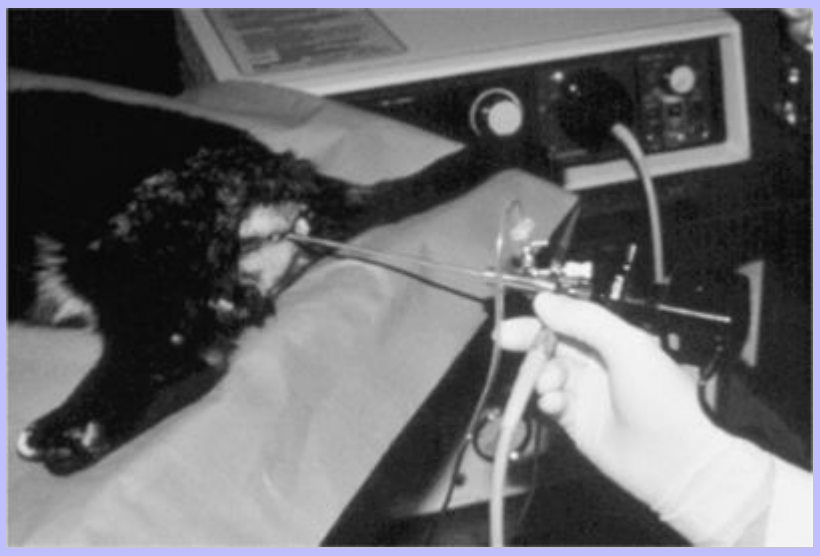
C **Diagnostic:** A urinalysis is recommended. If submaximal urine-specific gravity is present, then appropriate diagnostics are needed.
Treatment: If diagnostic tests are negative, then the resource checklist should be reviewed and additional areas that were not previously addressed should be incorporated.
Medications: Phermonotherapy is recommended.

D **Diagnostic:** A radiograph, urinalysis, and urine culture are recommended.
Treatment: If all tests are negative, analgesia should be provided for 2 to 3 days during acute episode. Canned food is encouraged for the cat in addition to litter box management and cleaning of soiled areas. The cat's urine-specity gravity is monitored for 3 to 4 weeks to assess the cat's water intake.
Medications: Phermonotherapy is recommended.

E **Diagnostic:** A urinalysis should be performed if it has not already been done. Radiographs, urine culture, and biochemical profile are also recommended.
Treatment: If all tests are negative, then the resource checklist is formally reviewed and those areas that have not already been addressed should be incorporated. Further information for cleaning soiled areas should be provided. Additional resources (web sites, books) on how to provide an enhanced indoor environment for cats should be provided to clients. Intercat conflict issues should also be addressed.
Medications: Phermonotherapy should be used in conjunction with behavior-altering medications such as tricyclic antidepressants (TCAs) or buspirone. The medication should be taken for 4 weeks; if no improvement is seen, a referral for further diagnostics and consultation should be considered.

F **Diagnostic:** A radiograph, an urinalysis, and a urine culture should be performed. A complete blood count (CBC) and biochemical profile should also be submited. If all tests are negative, a contrast study or abdominal ultrasound of the bladder and urethra should be condered to rule out nonradiopaque calculi and other mass lesions.
Treatment: If all diagnostics are negative, analgesia should be provided for 2 to 3 days during acute episode. In addition to canned food, the sheet on "Increasing your cat's water intake" should be reviewed. Water should be viewed as a "drug," and the cat's urine-specific gravity should be monitored to evaluate water intake. The resource checklist should be formally reviewed, and those areas that have not already been addressed should be incorporated. Additional resources (web sites, books) on how to provide an enhanced indoor environment for cats should be provided to clients. Intercat conflict issues should also be addressed. Follow up and support for clients are essential.
Medications: Phermonotherapy should be used in conjunction with behavior-altering medications such as TCAs or anxiolytics. Medication should be taken for 4 weeks; if no improvement is seen, a referral for further diagnostics such as a cystoscopy should be considered.

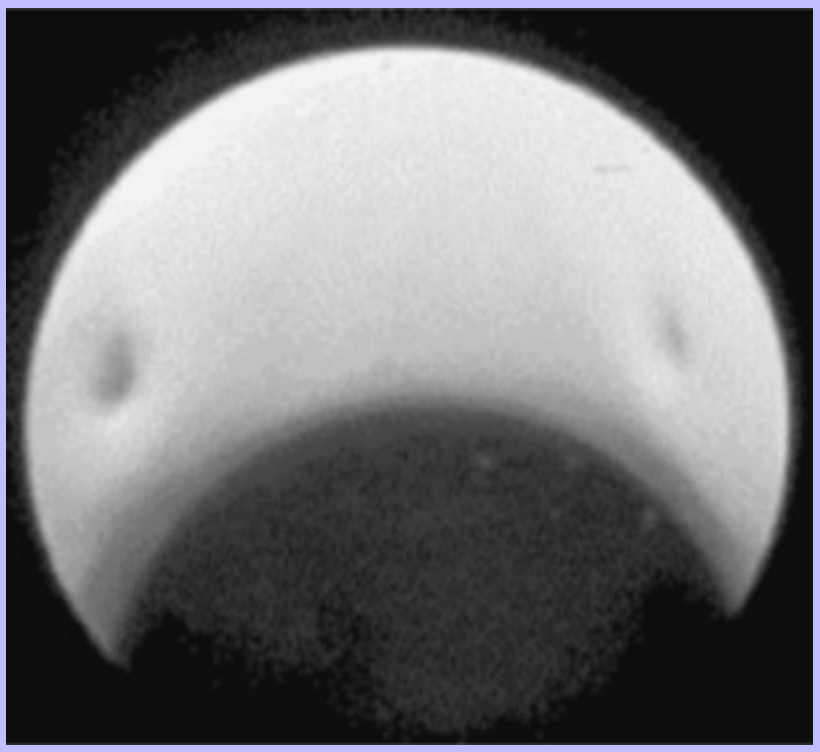
Figure 266-9 Cystoscopy of an anesthetized female cat using a 9F rigid cystoscope.



Using strategies from the literature,[74] the authors have found that clients will report a positive outcome (regardless of how well their cat responds to recommended therapies) if the client feels:

1. Listened to.
2. They receive an explanation for the problem that makes sense to them.
3. They feel care and concern being expressed by the caregivers and others in the clinic.
4. They gain an enhanced sense of mastery or control over the cat's illness or its symptoms.

Figure 266-10 Cystoscopic view of the right and left ureteral openings in a cat. They often appear to be in the proximal urethra when the bladder is not fully distended.



Because FIC can be a chronic, frustrating disease, the authors have found that keeping these four points in mind when communicating with clients benefits the client, pet, and clinician. The authors have also established a technician program whereby staff members follow a cat's progress as often as necessary to be sure that problems are explained thoroughly and that client gains enough understanding of the disease process to feel comfortable with managing the cat's disease.

266.2.3.1 Provisional Recommendations (Environmental Changes and Resources Available for Cats with FIC)

A list of necessary resources for indoor-housed pet cats has not yet been validated, but some recommendations are available.[75–78] Cats appear to benefit from appropriate access to resources, control of interactions with owners, and a tolerable level of conflict with other animals. The authors have assembled a provisional list for use by owners to guide consideration of some of these parameters (Box 266-1).

1836

1837

The following tentative recommendations are organized to follow Box 266-1; more comprehensive suggestions are available in the many available publications about pet cats. Owners should try to institute environmental modifications slowly, one at a time, and in such a way that the cat can express its like or

dislike for the change.[79] The clinician should follow a staged approach to therapy that begins with client education and environmental enrichment. If a cat relapses, these topics are thoroughly reviewed and pheromonotherapy or drug therapy may then be instituted in conjunction with environmental strategies.

There should be enough litter boxes in different locations throughout the house. A rule that many find helpful is 1+1: *one* for each cat of a household plus *one*—and placing litter boxes in quiet, convenient locations. If different litters are provided, it may be preferable to offer them in separate boxes, because individual preferences for litter type have been documented.[80] Cats with a history of LUT problems reportedly prefer, unscented clumping litter.[11] Litter boxes should be cleaned regularly and replaced; some cats seem quite sensitive to dirty litter boxes. Litter box size and whether or not it is open or covered also may be important to some cats.[81]

Research has demonstrated that blowing an innocuous puff of air into a cat's face while it eats can lead to behavioral abnormalities.[82] This suggests that cats should be fed individually in a quiet location where they will not be startled by other animals, sudden movement, or activity of an air duct or appliance that may begin operation unexpectedly. Although canned food may be preferable for cats with FIC due to the increased water content, some cats may prefer dry foods;[83] offering choices in separate, adjacent containers rather than replacing the usual food with a new food permits cats to express their preferences. Feeding behavior also includes predatory activities. These may be simulated by hiding small amounts of food around the house, or by putting dry food in a container from which the cat has to extract individual pieces[84] or move to release the food pieces (if such interventions appeal to the cat).[77] Cats also seem to have preferences for water that can be investigated. Consideration may be given to freshness, taste, movement (water fountains, dripping faucets, or aquarium pump–bubbled air into a bowl), and shape of container (some cats seem to resent having their vibrissae touch the sides of the container when drinking). Food and water bowls should be cleaned regularly unless individual preference suggests otherwise.

The physical environment should include opportunities for climbing, scratching, hiding, and resting. Cats seem to prefer to monitor their surroundings from elevated vantage points; provision of climbing frames, hammocks, platforms, raised walkways, shelves, or window seats have been recommended.[77,78] Playing a radio to habituate cats to sudden changes in sound and human voices also has been recommended,[85] and videotapes to provide visual stimulation are available.[77]

Some cats may prefer to be petted and groomed, whereas others may prefer play interactions.[86] Play interactions with cats may include lures or laser pointers.[76,77] Cats also may enjoy playing with toys, particularly those that are small, move, and that have characteristics of natural prey.[87,88] For cats that prefer novelty, a variety of toys should be provided and rotated or replaced regularly.[87]

In multicat houses, cats also interact with each other. Because cats housed in groups do not appear to develop distinct dominance hierarchies or conflict-resolution strategies, they may attempt to circumvent agonistic encounters by avoiding others or decreasing their activity.[89] Unrelated cats housed together in groups appear to spend less time interacting with one another than related ones.[83] These cats may prefer to have their own separate food and water sources, litter boxes, and resting areas to avoid competition for resources and to avoid unwanted interactions.[89] Published guidelines for introducing new cats into a home are available and may be recommended to clients adding cats to their households.[76] Because of the dearth

of controlled trials, it is not currently possible to prioritize the importance of these suggestions or to predict which would be most appropriate in any particular situation.

266.2.3.2 Dietary Treatment

Dietary modifications may reduce the risk of recurrence of LUT signs in affected cats. Struvite crystals do not appear to damage normal urothelium, and efforts to acidify the urine to reduce struvite crystalluria by dietary modification are often *not* necessary. Efforts to acidify the urine using dry foods have no demonstrated value in treatment of FIC. Clinical experience suggests that diet change can result in recurrence of FIC signs in some cats. Moreover, with the advent of many similarly formulated prescription and commercial foods marketed for use in cats with urolithiasis or to "promote urinary tract health," changing diets can still result in recurrence of signs associated with FIC. It is not recommended to frequently change diets. It is encouraged to increase water intake, and consumption of a canned food is one way to accomplish this. To avoid the potential stress of being confronted with an unfamiliar diet, it is recommended to begin feeding new canned food alongside the original diet.

In studies from the United States and New Zealand, cats with idiopathic cystitis were significantly more likely to be fed dry food exclusively.[10–16] LUT signs recurred in only 11% of affected cats during 1 year of feeding canned formulation of a dietary product. Recurrence occurred in 39% of cats fed the dry formulation of the same food, suggesting that both constancy and consistency (i.e., increased water intake) may be important. Both diets contained similar potential renal solute load and resulted in a similar urine pH. The average USG of cats fed the dry formulation was 1.050, whereas that of the cats fed the canned formulation was 1.030. It appears that the canned form protected nearly 90% of cats against recurrence of LUT signs for up to 1 year, constancy of diet protected about 60%, and 10% were offered no protection from recurrence by diet. In addition to water contained in food, the suggestions the authors provide owners to encourage increased water intake by their cats are presented in Box 266-2 and 266-3.

266.2.3.3 Pheromonotherapy

Pheromones are fatty acids that seem to transmit highly specific information between animals of the same species. Although the exact mechanisms of action are unknown, pheromones reportedly induce changes in both the limbic system and the hypothalamus that alter the emotional state of the animal.[90] Five facial pheromones have been isolated from the cat (Table 266-1). A cat deposits the F3 fraction of facial pheromones on prominent objects (including humans) by rubbing their head against the object when the cat feels safe and at ease.[90] Feliway® (Ceva Sante Animale, Libourne, France), a synthetic analogue of this naturally occurring feline facial pheromone, was developed in an effort to decrease anxiety-related behaviors of cats. Although not specifically tested in cats with FIC, treatment with this pheromone has been reported to reduce the amount of anxiety experienced by cats in unfamiliar circumstances, a response that may be helpful to both cat and owner. Increased grooming and food intake in hospitalized cats[91] also has been reported with the use of Feliway®. Others have reported decreased spraying in multicat households,[92] decreased marking,[93] and a significant decrease in scratching behavior.[90] Although, Feliway® is not a panacea for unwanted cat behaviors or FIC, it has been used successfully in combination with environmental enrichment, drug therapies, or both.

1837

1839

266.2.3.3.1

Box • 266-1 A Resource Checklist for Cat Owners

Enhanced stress response system activity seems to be central in exacerbating clinical signs in cats with feline idiopathic cystitis (FIC). Any treatment strategy to decrease sympathetic nervous system (SNS) outflow may be important in reducing these signs. By altering the environment of a cat that has had previous episodes of FIC, it is the authors' experience this can decrease clinical signs and increase the interepisode intervals. The authors provide this list to clients and tailor these resources on a case-by-case basis. Although most cats do not require all suggestions from this list, a detailed history obtained from the owner will dictate which areas seem to be most relevant for each patient. If drug therapy is necessary in the patient, it should be used in conjunction with the environmental strategies listed following.

Litter Box Management	Yes	No
Boxes are located on more than one level in multilevel houses.	_	_
Boxes are located so that another animal cannot sneak up on the cat while it uses it.	_	_
Boxes are located away from appliances or air ducts that could come on unexpectedly while the cat uses them.	_	_
The litter is kept clean, scooped as soon after use as possible (at least daily).	_	_
Boxes are washed regularly (at least weekly) with a mild detergent (e.g., dishwashing liquid), rather than strongly scented cleaners.	_	_
Unscented clumping litter is used.	_	_
The brand or type of litter purchased is changed infrequently (less than monthly).	_	_
If a type of litter is offered, it is put in a separate box so that the cat can choose to use it if it wants to.	_	_
Each cat has its own litter box in a convenient, well-ventilated location that still gives the cat some privacy while using it.	_	_
Food and Water		
Each cat has its own food and water bowl in a convenient location that provides some privacy while eating or drinking.	_	_
Bowls are located such that another animal cannot sneak up on the cat while it eats.	_	_
Bowls are located away from appliances or air ducts that could come on unexpectedly while the cat eats or drinks.	_	_
Food and water is kept fresh (daily).	_	_
Bowls are washed regularly (at least weekly) with a mild detergent.	_	_
The brand or type of food purchased is changed infrequently (less than monthly).	_	_
If a new food is offered, it is put in a separate dish next to the familiar food so that the cat can choose to eat it if it wants to do so.	_	_
Environmental Considerations		
Scratching posts are provided.	_	_
Toys are provided, rotated, or replaced regularly.	_	_
Each cat has the opportunity to move to a warmer or cooler area if it chooses to do so.	_	_
Each cat has a hiding area where it can get away from threats if it chooses to do so.	_	_
Each cat has its own space that it can use if it chooses to do so.	_	_
Rest		
Each cat has its own resting area in a convenient location that still provides some privacy.	_	_
Resting areas are located such that another animal cannot sneak up on the cat while it rests.	_	_
Resting areas are located away from appliances or air ducts that could come on unexpectedly while the cat rests.	_	_
If a new bed is provided, it is placed next to the familiar bed so that the cat can choose to use it if it wants to do so.	_	_
Movement—each cat has the opportunity to move about freely, explore, climb, stretch, and play if it chooses to do so.	_	_
Social contact—each cat has the opportunity to engage in play with other animals or the owner if it chooses to do so.	_	_

266.2.3.3.2

Box • 266-2 Increasing a Cat's Water Intake

Another important aspect to treat cats with feline idiopathic cystitis (FIC) and urolithiasis is to increase the cat's water intake. The authors have compiled a list of ways for clients to increase water intake. These “tricks” can be used by themselves or in combinations.

1. Switch from a dry diet to a canned formulation. See Box 266-4 for recommendations on how best to acclimate a cat to its new diet.

2. Add water to the food, whether it is dry or canned. Start slowly, and proceed as the pet's appetite permits. If food is available all the time, feeding the pet two meals a day before beginning to add water could help it accept the water more readily.
3. Place water next to the food. Some animals prefer a full, shallow dish; others seem to like reaching down into a container.
4. Add “wet” foods to the cat's food, like water-packed tuna, clam juice, and (low salt) gravy mixes.
5. Offer distilled or bottled water.
6. Try a pet “fountain” that can be purchased from pet stores and magazines.
7. Leave some water in the bottom of a sink, bathtub, or shower. Putting a shallow bowl under a slow drip ensures a drink of fresh water whenever the cat might want one.
8. Make ice cubes out of meat or fish broth. Bring the contents of a 6 oz can of tuna or salmon, or a cup of ground meat, to boil in 2 cups water, simmer for 10 minutes, and strain through cheesecloth into an ice tray. A broth cube in the pet's water bowl will flavor it and increases water intake in some cats.

A urine specific gravity (USG) should be obtained after 4 weeks of “water therapy” and should be approximately 1.030 if clients are successful.

Feliway® is sold as both a spray and room diffuser, and there has been success in the management of some FIC cats using Feliway®. The spray can be used to treat areas of the house where the cat is urinating by use of a single spray to the affected spot for 30 days. The authors also have found Feliway® to be beneficial to decrease anxiety associated with traveling. Clients can spray the cat carrier 15 minutes prior to the trip and then place the cat in the carrier to help decrease the stress and anxiety most cats associate with travel. The treated areas should be sprayed at least 15 minutes prior to the cat encountering the area, because the vehicle (ethanol) for this pheromone is offensive to most cats. The room diffuser can be placed in a room where the cat inappropriately urinates. One room diffuser is reported to cover approximately 650 square feet and to last for 30 days. This method of administration of the pheromone is new, and controlled trials are needed to make recommendations.

Table • 266-1 Chemical Components of the Facial Scent Gland Secretions in Cats

SECRETION	COMPONENTS	FUNCTION
F1	Oleic acid, caproic acid, trimethylamine 5-aminovaleric acid, *n*-butyric acid, α-methylbutryic acid	Unknown
F2	Oleic acid, palmitic acid, propionic acid, *p*-hydroxyphenylacetic acid	Sexual facial marking in tomcats
F3	Oleic acid, azelaic acid, pimelic acid, palmitic acid	Facial marking on items, antagonist of urine marking and scratching
F4	5β-choestan acid 3β-ol, oleic acid, pimelic acid, *n*-butyric acid	Allomarking, antagonist of territorial or irritative aggression
F5	Palmitic acid, isobutyric acid, 5-aminovaleric acid, *n*-butyric acid, α-methylbutyric acid, trimethylamine, azelaic acid, *p*-hydroxyphenlacetic acid	Unknown

266.2.3.4 Drug Therapy

266.2.3.4.1 Analgesics

A lack of objective information exists to guide analgesic treatment of animals with chronic visceral pain. Amitriptyline (please see following discussion for further details) appears to provide analgesia for some cats, but use of this drug is usually reserved for cats with severe, recurrent FIC. Providing analgesia with nonsteroidal anti-inflammatory agents such as carprofen and ketoprofen, butorphanol, or more potent opioids such as fentanyl (patches) has been suggested; however, no studies have been reported to date, and many drugs are not approved for these uses. Breaking the chronic pain-inflammation cycle may be important in the management of at least some cats with severe disease. During acute flare-ups, some form of analgesia, such as butorphanol (Table 266-2), should be combined with a short-term tranquilizer such as acepromazine. Alternatively, buprenorphine can be used subcutaneously and, anecdotally, per os (a syringe can be used to squirt the injectable form into the cat's mouth). The effects of buprenorphine can last longer than butorphanol because of its high affinity toward mu receptors in the CNS.[94] It is generally easier for clients to give injections to their cats as compared with oral formulations. Because stress has been documented to perpetuate clinical signs, the least invasive approach for the cat should be attempted first, so routes of medication should be tailored for individual cats.

1839

1843

Table • 266-2 Drugs Commonly Used to Treat and Manage Cats with Lower Urinary Tract Disease

DRUGS COMMONLY USED FOR ANALGESIA	CLASS	MECHANISM OF ACTION	INDICATION FOR USE	DOSE	POTENTIAL SIDE EFFECTS
Butorphanol (Torbugesic® or Torbutrol®)	Synthetic partial opiate agonist	Kappa and Sigma receptor agonist; analgesic effects in the limbic system	Analgesia for acute episode of FIC	0.2–0.4 mg/kg PO, SQ BID-TID	Sedation
Buprenoprhine (Buprenex®)	Synthetic partial opiate agonist	Partial mu receptor agonist	Analgesia for acute episode of FIC	0.01–0.02 mg/kg BID-TID; 0.015 mg/kg PO BID to TID (anecdotal)	Sedation
Fentanyl (Duragesic®)	Opiate agonist	Mu and opiate agonist	Analgesia for acute episode of FIC	25 g/hr	Respiratory depression; bradycardia
Drugs Commonly Used To Alter Bladder/Urethral Contractility					
Acepromazine (PromAce®)	Phenothiazine neuroleptic agent	Block postsynaptic central dopamine receptors; varying degrees of anticholinergic, antihistaminic, antispasmodic and alpha-adrenergic blocking capabilities	For sedation and antispasmodic for urethral obstruction	0.05 mg/kg SQ BID-TID	Hypotension; sedation
Prazosin (Minipress®)	Alpha-adrenergic antagonist	Inhibits α-1 adrenergic receptors	For sedation and antispasmodic for urethral obstruction	0.5 mg/kg PO BID	Hypotension; sedation
Phenoxybenzamine (Dibenzyline®)	Alpha-adrenergic antagonist	Inhibits α-adrenoceptors	For sedation and antispasmodic for urethral obstruction	2.5 mg PO BID	Hypotension; sedation
Bethanechol (Urecholine®)	Synthetic parasympathomimetic	Stimulates primarily muscarinic receptors	Detrusor atony	2.5–5.0 mg PO BID	Vomiting, diarrhea, and salivation
Drugs Commonly Used for the Treatment of FIC					

Amitriptyline (Elavil®)	Tricyclic antidepressant (TCA)	NE reuptake inhibition; central and peripheral anticholinergic activity; antagonism of the H1 receptor; 5-HT reuptake inhibition; glutamate and Na channel receptor antagonist	Chronic FIC	5.0–12.5 mg PO SID-BID	Sedation; weight gain; urine retention; urolith formation
Clomipramine (Anafranil® [human], Clomicalm® [veterinary])	TCA	NE and serotonin reuptake inhibition	Chronic FIC; urine spraying	0.5 mg/kg PO SID	Sedation; anticholinergic effects
Buspirone (BuSpar®)	A nonbenzodiazepine anxiolytic agent	Mixed dopaminergic agonist/antagonist; other mechanisms not well understood	Chronic FIC; urine spraying; anxiety	2.5–5.0 mg PO BID	Rare, but sedation or other neurologic effects
Fluoxetine (Prozac®)	Antidepressant	Selective serotonin reuptake inhibitor	Chronic FIC; urine spraying	1 mg/kg PO SID	Decrease food intake; vomiting and lethargy rare
Pentosan polysulfate sodium (Elmiron®)	GAG replacer	Unknown	Chronic FIC	50 mg PO BID	Diarrhea and vomiting rare
F3 fraction of feline facial pheromone (Feliway®)	Synthetic pheromone	Alter the emotional state of the animal via the limbic system and hypothalamus	Anxiety related behaviors; chronic FIC	1 spray in affected area SID or room diffuser	None reported
Drugs Commonly Used to Manage Urolithiasis					
DL-methionine	Sulfur-containing amino acid	Methionine metabolized and sulfate excreted in urine as sulfuric acid, thereby acidifying urine	For urine acidification when dietary management fails	0.5–1.0 g PO on food once daily	Gastrointestinal (GI) distress; metabolic acidosis
Ammonium chloride	Acid forming salt	Administration results in a decrease in serum bicarbonate and decrease in blood and urine pH	For urine acidification when dietary management fails	20 mg/kg PO BID	Metabolic acidosis; GI distress
Potassium citrate (Uracit-K®)	Alkalinizing salt	Citrate oxidized to bicarbonate; citrate chelates calcium, forming a more soluble salt	To reduce risk of calcium oxalate formation	100–150 mg/kg/day	GI

Allopurinol	Xanthine oxidase inhibitor	Inhibits the enzyme xanthine oxidase, which is responsible for the conversion of oxypurines to uric acid	For prevention/dissolution of ammonium urate stones	9 mg/kg/day	Xanthine stones; rarely used incats so side effects and safety unknown
2-MPG	Sulfhydryl compound related to penicillamine	Undergoes thiol-disulfide exchange with cystine to form a more water-soluble compound	For prevention and treatment of cystine urolithiasis	No studies performed in cats	No information available in cats; anemia in dogs is reported
FIC, feline ideopathic cystitis; SQ, subcutaneously; BID, twice a day; TID, three times a day; PO, oral administration					

We have used amitriptyline, (a tricyclic antidepressant [TCA]) in uncontrolled trials to successfully decrease clinical signs of severe, recurrent FIC.[35] Amitriptyline (Elavil®), may provide analgesia by inhibition of NE reuptake at noradrenergic nerve terminals[95] and possibly due to inhibition of a wide range of nociceptive neurons in the spinal trigeminal nucleus.[96] The beneficial effects of amitriptyline treatment on pain appear to be independent of its effect on depression in human beings.[97] This point is important when considering this drug for cats, because analgesia can occur at lower doses, which potentially could decrease the unwanted side effects such as weight gain and lethargy. Other actions of amitriptyline include the ability to stabilize mast cell membranes (by antagonism of the H1 receptor), serotonin (5-HT) reuptake inhibition, and antagonism of both glutamate receptors and sodium channels.[98] Urine retention through anticholinergic effects of the TCAs may result. Findings in a series of cats with severe FIC showed that the clinical signs of some cats were reduced during amitriptyline treatment during a 12-month period. Improvement in clinical signs was not always accompanied by improvement in the cystoscopic appearance of the bladder. Controlled studies of the safety and efficacy of amitriptyline in cats with FIC are not available, but it has been used with apparent safety by animal behaviorists for more than 10 years.

The drug should be given orally once daily before the owner retires for the night. The dose should then be adjusted to produce a barely perceptible calming effect on the cat (usually 2.5 to 12.5 mg). The reduction in severity of clinical signs can be dramatic in some cats; but in others little or no beneficial effect is observed. If no improvement is seen within 2 to 4 months, the medication should be gradually tapered and then stopped.

Clomipramine hydrochloride (Clomicalm®, veterinary label; and Anafranil®, human label) is also a tertiary amine like amitriptyline, but has more selectivity for blocking the reuptake of 5-HT. It has been reported to provide a beneficial effect (in combination with environmental strategies) for psychogenic alopecia in cats.[99] The authors have prescribed this in recurrent cases of FIC with anecdotal improvement in some cats. Complete blood count (CBC) and serum biochemical profile are recommended before treatment and at 1 and 3 months to ensure no untoward effects of therapy during the use of any TCA.

The selective serotonin reuptake inhibitor, fluoxetine (Prozac®),[100] has been reported to help cats with inappropriate urinations with variable success rates. Fluoxetine was used to help decrease the rate of urine marking after environmental alterations such as litter box hygiene and appropriate cleaning strategies. The nonbenzodiazepine anxiolytic, buspirone (BuSpar®) has been used to decrease high

arousal and reduce anxiety in intercat aggression.[101] Because cats with FIC have exacerbation of clinical signs associated with stressful situations, we have also prescribed buspirone for this disease with some success. Diazepam (Valium®) is a benzodiazepine that is used for behavioral disorders and has sedative, anticonvulsant, and anxiolytic effects. The most serious side effect encountered with the use of oral diazepam in cats is that of idiosyncratic hepatic necrosis,[102] which removes this drug from consideration for long-term therapy. Other benzodiazepines such as alprazolam and temazepam have not been reported to be associated with hepatic toxicity,[103] but experience with the use of these drugs in cats with FIC have not been reported.

We do not recommend amitriptyline for acute treatment of FIC because it has been shown to have minimal to no benefit in the short-term resolution of signs.[15] The authors reserve all the TCAs and the selective serotonin reuptake inhibitors for recurrent, severe cases. These drugs need to be used only after environmental strategies, diet changes (if necessary), and behavior modifications have failed. Furthermore, it is the authors' opinion that these drugs should then only be used in conjunction with the previously mentioned therapeutic strategies for optimal effects.

Amitriptyline (and TCAs) should not be discontinued abruptly, but tapered slowly over 2 to 3 weeks to avoid any possible withdrawal responses that cause exacerbation of clinical signs. The TCAs are extensively metabolized by the cytochrome P450 enzyme system and, although specific drug interactions and safety trials have not been evaluated in animals, caution is recommended when prescribing TCAs with other drugs known to affect drug metabolism.[103]

The act of medicating a cat can be stressful for some cats and owners. Transdermal delivery systems for drugs are available that make the administration of the drug much easier, but no clinical trials compare the plasma concentration, safety, and efficacy of the transdermal preparations to their oral counterparts. The authors are reluctant to recommend transdermal preparations until the pharmacokinetics and pharmacodynamics of compounds administered by this route have been investigated in affected cats.

266.2.3.4.2

Glycosaminoglycans

GAG replacement treatment has been used with some success in humans with interstitial cystitis[104] but usually does not provide long-term relief. The untested assumption is that exogenous GAG will attach to the defective urothelium, thereby decreasing bladder permeability. In addition, GAG can exert analgesic and anti-inflammatory effects that might prove useful. A study in humans reported that pentosanpolysulfate, a synthetic, branched polysaccharide that resembles the natural proteoglycan chondroitin sulfate, appeared to inhibit allergic and nonimmune mast cell stimulation and decrease intracellular calcium ion concentrations, which suggests another alternative for the benefit of this drug in some human patients.[105] However, there may be differences in the relative efficacy of the various available GAG. GAG replacers, such as Elmiron® can be tried. Side effects in humans can include gastrointestinal (GI) side effects (diarrhea) and hematologic abnormalities. Other veterinary marketed GAG replacers such as Cosequin® and Adequan® can be tried, but no evidence exists as to their efficacy in FIC.

266.3 UROLITHIASIS, URETHROLITHS, AND URETHRAL PLUGS

266.3.1 Urethral Obstruction

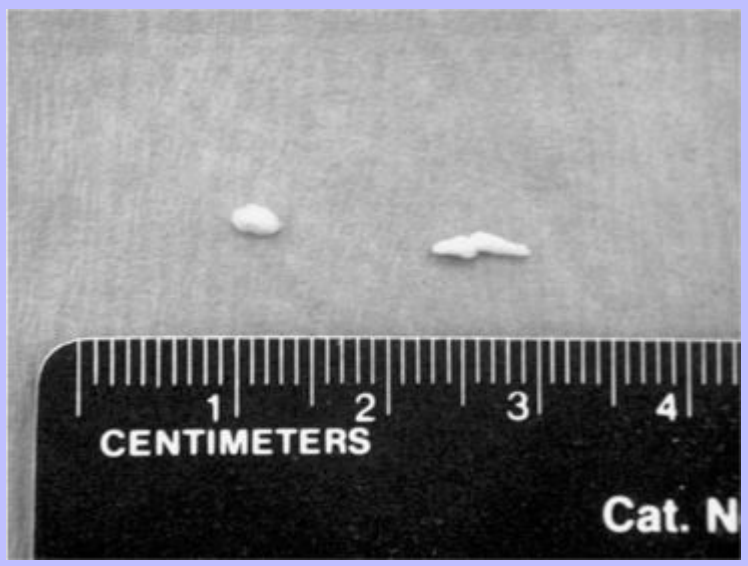
Urethral plugs are the most common cause of obstruction in male cats. In one series from the 1980s,[9] urethral plugs occurred in 60% of cats, no cause was found in 30%, uroliths alone were documented in only 10%, and uroliths with bacterial UTI were observed in 2%. Occasionally stricture and rarely neoplasia cause the obstruction. Urethral obstruction due to calcium oxalate urethroliths appears to be more common currently as compared with the early to mid-1980s.

It is unlikely for the urethra of female cats to become obstructed, but male cats have a narrow penile urethral lumen and are predisposed to obstruction with a urolith or urethral plug. Currently, it is unknown what causes the matrix of urethral plugs to form and is probably the outcome of several mechanisms. Many urethral plugs are composed of struvite with a proteinaceous matrix[9] (Figure 266-11). Struvite urethroliths were the sole type reported in cats from the 1980s, but calcium oxalate urethroliths occur more commonly now.

1843

1844

Figure 266-11 Fragments of urethral plugs obtained in a male cat after digital manipulation of the distal urethra and manual compression of the bladder.



It has been hypothesized that the concomitant occurrence of UTIs and crystalluria may lead to formation of matrix-crystalline plugs that obstruct various portions of the urethra, especially in male cats.[106] It was hypothesized that Tamm-Horsfal mucoprotein (THP) is contained within urethral plugs. Once this coalesces together with the crystals, white blood cells (WBCs), and red blood cells (RBCs), it can be surrounded by amorphous material and then obstruct the urethra. No evidence of THP in urethral plugs obtained from obstructed cats was identified in one group of cats we evaluated. However, the eletrophoretic pattern of some plugs resembled that of albumin and its degradation products, suggesting that the plug resulted from

precipitated serum proteins. The authors hypothesize that vasodilatation and leakage of plasma proteins from the suburothelial capillary plexus (*bladder weeping*) and secondary urethritis, which can be seen cystoscopically in cats with FIC, may trap crystals within the lumen of the male cat urethra and may result in obstruction. It is likely that oozing of plasma proteins into urine during active inflammation increases the urinary pH that contributes to the precipitation of struvite crystals that participate in urethral plug formation. Though conventional wisdom indicates that urethral plugs form in the urethra, the authors have observed with cystoscopy what appear to be plugs in the bladder. It is interesting that the mineral components of urethral plugs continue to be predominantly composed of struvite despite the apparent increase in frequency of calcium oxalate urolithiais. This may be due to the narrow range of *metabolic supersaturation* of struvite in urine. These and other hypotheses are not mutually exclusive, and plugs may form by different mechanisms, depending on a variety of factors present at any particular instance.

Regardless of the underlying cause or causes, relief of obstructions, re-establishment of urine flow, and correction of fluid, electrolyte, and acid-base imbalances associated with obstruction and postrenal azotemia are the first steps in proper management. Decompressive cystocentesis is a recommended first step, prior to attempts to pass a urinary catheter. A small (22-or 23-gauge) butterfly needle inserted into the lateral bladder wall midway between the apex and urethral outflow works well for this procedure and aids in the removal of urine without reinsertion of the needle. Alternatively, if a longer needle is necessary, it can be attached to an extension set and urine removed with a syringe in a similar manner. The bladder should be continuously palpated during the drainage and further pressure exerted on the bladder to allow nearly complete evacuation of urine. Complications are rare but include extravasation of urine into the peritoneal cavity and damage to the bladder wall.

Cats with urethral obstruction should be managed aggressively with medical treatment unless recurrent obstructions occur. A perineal urethrostomy surgery may be needed to prevent future episodes of urethral obstruction. This surgery carries some risks or complications such as bacterial UTIs and postoperative strictures.[107] Furthermore, clients need to be made aware that this surgery does not correct the underlying problem. Recurrent uroliths and FIC episodes can still occur. It is reported that the frequencies of feline urethrostomies performed at the University of Minnesota Veterinary Teaching Hospital has declined over the past 20 years, which is due, in part to a decrease in urethral plugs that are diagnosed.[108] The 50% decrease in occurrence of urethral obstruction could be due to the widespread use of urinary acidifying diets because struvite is the most common component to the urethral plug. Other factors that could have contributed to the decrease in perineal urethrostomy surgery could include more such surgeries done by private practitioners in primary or referral practices. Although the decline in urethral obstructions was halved, the frequency of urethrostomies decreased by 90%, suggesting that clinicians at this institution are now managing urethral obstruction successfully by nonsurgical methods.

For most obstructed cats (other than neurogenic obstruction), medical management with analgesics, antispasmodics (α1 adrenoceptor antagonists), and appropriate fluid therapy can be rewarding. Serum biochemistry, CBC, and urinalysis should be obtained, though is not necessary to evaluate such results prior to obstruction relief. Cats that are moribund should be resuscitated with intravenous fluids and correction of serious electrolyte and acid-base disturbances before anesthesia for placement of a urinary catheter. Specific rescue from the cardiotoxic effects of severe hyperkalemia (calcium salts, glucose, or insulin + glucose) may be necessary even before specific values for serum potassium return from the laboratory. An electrocardiagraphic assessment of all systemically ill cats with urethral obstruction should be performed. Only 12% of cats with urethral obstruction had severe hyperkalemia (> 8.0 mmol/L) in one recent report.[109]

Anesthesia is needed to allow proper manipulation of the cat's penis and passage of the urinary catheter. Isoflurane gas anesthesia can be administered by facemask to provide sedation and urethral relaxation. Alternatively, propofol infusion can be given for anesthesia. The combination of ketamine and Valium given intravenously to effect has been used for many years but does not provide adequate relaxation for some cats. After decompressive cystocentesis, the clinician should relieve the obstruction by catheterization and retropulsion with hydraulic forces using a sterile physiologic solution. Any urethral plug or urolith that is retrieved should be submitted for quantitative analysis. An indwelling catheter is not always needed once the obstruction is removed but is advised for cats with pronounced azotemia, those with a poor urine stream after advancing a catheter, and for those with an extremely large bladder volume at the time of obstruction relief because they are more likely to develop detrusor atony.

Urine output should be monitored frequently in severely ill cats. Cats recovering from severe postrenal uremia often have substantial postobstructive diuresis. Urine output is expected to be greater than 2.0 mL/kg/hr shortly after relief of obstruction and intravenous infusion of rehydration fluid volumes. Urine output can be marked, making it essential to ensure the amount of intravenous fluid volume infused is adequate to replace urine volume lost. Diuresis usually subsides as the waste products are excreted, which typically lasts 2 to 5 days. In some instances, the amount of intravenous fluids administered continues to drive the diuresis. The intravenous fluid infusion rate may be decreased by 25% to see if urine volume declines in concert. If so, continued tapering of intravenous fluids is recommended. Tapering of intravenous fluids can also be initiated after there has been resolution of azotemia. The magnitude of postobstructive diuresis is usually parallel to the magnitude of azotemia. Cats with minimal azotemia are not expected to have much, if any, diuresis.

1844
1845

Nearly all cats treated for urethral obstruction at a university referral hospital survived initial treatment and stabilization.[109] Death can occur due to consequences of severe dehydration, hyperkalemia, metabolic acidosis, and hypocalcemia. Rarely, cats have a ruptured bladder secondary to long-standing urethral obstruction. Prognosis for survival in these cats is much worse.

Analgesics such as butorphanol, hydromorphone, and fentanyl (patches) can be used to alleviate pain. α-adrenoceptor antagonists (e.g., phenoxybenzamine, prazosin) and the phenothiazine derivative, acepromazine, can be used to help prevent smooth muscle urethral spasms that can occur after obstruction relief. Urethral spasms are a primary reason for cats to reobstruct once a plug or urethrolith has been removed. Preemptive therapy with antispasmodic medications may help prevent the recurrence of obstruction and help avoid need for perineal urethrostomy surgery. If detrusor atony is suspected, bethanechol can be added to the regimen provided the urethra is patent. After the cat has been successfully managed in the short term, care similar to that given to cats with FIC should be given.

266.3.2 Uroliths

Uroliths are organized concretions found in the urinary tract that contain primarily organic or inorganic crystalloid (ionic component of crystals) and a much smaller amount of organic matrix. When 70% or more of the urolith is composed of one type of crystal it is named for that crystal. Secondary crystalloids can comprise up to 30% of the total weight. Urine is commonly supersaturated with crystalloids, and observation of individual crystals in the urine does *not* mean the cat is at risk for urolithiasis. Crystalluria is not a disease, and no particular treatment is necessary unless a urolith is present, or a urolith or urethral plug has formed in the past. Supersaturation of urine with crystalloids depends on the interaction of dozens of crystalloid species formed by common mineral elements in the urine derived from the amount of each solute ingested and excreted in the volume of urine produced.[110] Moreover, these complex calculations do not take into account

potential organic molecule contributions, such as protein inhibitors or promoters of crystallization.[111] Urine pH also affects crystal formation. Struvite, calcium carbonate, and calcium phosphate are less soluble in alkaline urine; cystine and uric acid are less soluble in acid urine, but urate is less soluble in alkaline urine. Urine pH *per se* does not appear to have a major effect on the solubility of calcium oxalate; however, most calcium oxalate stones occur in cats with acid urine. Factors that predispose to urinary stasis play an important role in urolithiasis, because crystals must reside in the urinary tract for a sufficient time for a urolith to form.

266.3.3 Struvite Urolithiasis

The chemical composition of struvite is $MgNH_4PO_4$-$6H_2O$. Calcium phosphate (apatite) sometimes is present in small amounts (2% to 10%). The presence of three cations (Ca^{2+}, Mg^{2+}, and NH_4^+) detected by earlier qualitative methods led to the name *triple phosphate* previously used for these stones. Struvite uroliths are spherical, ellipsoidal, or tetrahedral in shape and may be present singly or in large numbers of varying sizes. The bladder is the most common site of struvite uroliths, although they may occur at any site in the urinary tract. In cats, struvite stones usually form in sterile urine. More than 90% of dogs, in contrast, have struvite stones associated with a urease-producing bacterial infection. Struvite solubility is reduced in urine of pH greater than 6.7. Struvite urolithiasis and urethral obstruction have been induced experimentally in healthy cats by feeding diets containing three to ten times the amount of magnesium found in commercial cat foods.[112] These studies led to the conclusion that magnesium was a primary cause of naturally occurring struvite urolithiasis in cats. It subsequently was learned that struvite stones in the bladder of healthy cats fed large quantities of magnesium dissolved when the urine pH was reduced to approximately 6.0.[112] These results suggested that magnesium's effect on struvite formation depended on the urine pH—an idea supported by the finding that the form of magnesium used in previous studies had increased the urine pH.[113] Therefore factors that may be associated with alkaline urine (e.g., family history of struvite stones, diet based on vegetable proteins [rare in cats], distal renal tubular acidosis) should be considered.

Lekcharoensuk and colleagues,[114] evaluated the association between dietary factors and struvite formation (Table 266-3). They reported that diets low in sodium or potassium or formulated to maximize urine acidity had a decreased risk for struvite urolith formation. Diets with the highest magnesium, phosphorus, calcium, chloride, or fiber contents, moderate protein content, and low fat content were associated with increased risk of magnesium ammonium phosphate urolith formation. However, these differences may also have been confounded by the many correlations between the dietary components and is compatible with the nutrient profile of relatively low-quality cat foods. In addition to nutrients, ingredients, and their combinations, breed, age, sex, body condition, and living environment were also significantly different between case and control cats (which were adjusted for in the multivariate logistic regression). The many interacting variables demonstrate the complexity of the process of stone formation.

It has been reported that spayed female cats have a higher risk of developing struvite uroliths,[115] but a more recent study[116] found a slightly higher risk only for *male* cats. When reproductive status was evaluated in this same study, neutered animals were three and a half times as likely to develop struvite uroliths compared with sexually intact cats. Cats with struvite uroliths were significantly younger than cats with calcium oxalate uroliths in the same study; however, when evaluating age, cats 4 years of age or older and 7 years of age or less had the highest risk for developing struvite urolithiasis. Breeds at risk were reported to be the Foreign Shorthair, Ragdoll, Chartreux, Oriental shorthair, domestic shorthair (DSH), and Himalayan. The Rex, Burmese, Abyssinian, Russian blue, Birman, Siamese, and mixed breed cats had a significantly lower risk of developing struvite uroliths.

266.3.3.1 Management of Urolithiasis

Patients who have had cystic calculi initially should be monitored every 2 to 3 months for recurrence. Uroliths larger than 3 mm will usually be evident with a plain abdominal radiograph. A double-contrast study or abdominal ultrasound may also be necessary for stones that are not radiodense (e.g., urate). If "sand and debris" or even very small stones (3 to 5 mm) are seen in the urinary bladder, surgery may not be necessary and voiding urohydropropulsion may be used to remove the stones (Figure 266-12, *A* and *B*). For a complete review of this technique, the reader is referred to the literature.[117] Stones as large as 5 mm can sometimes be removed from female cats by this method, but one should be prepared for surgical removal of stones that are not successfully removed with voiding urohydropropulsion.

Data from table obtained from Lekcharoensuk C et al: Association between dietary factors and calcium oxalate and magnesium ammonium phosphate urolithiasis in cats. J Am Vet Med Assoc, 219:1228, 2001.

* Ranges over which significant differences in risk for affected cats were identified by multivariate analysis. Ranges with increased risk are denoted by "avoid." Reader should see reference for details and limitations of such interpretations.

† May be related to phosphorus salt used.

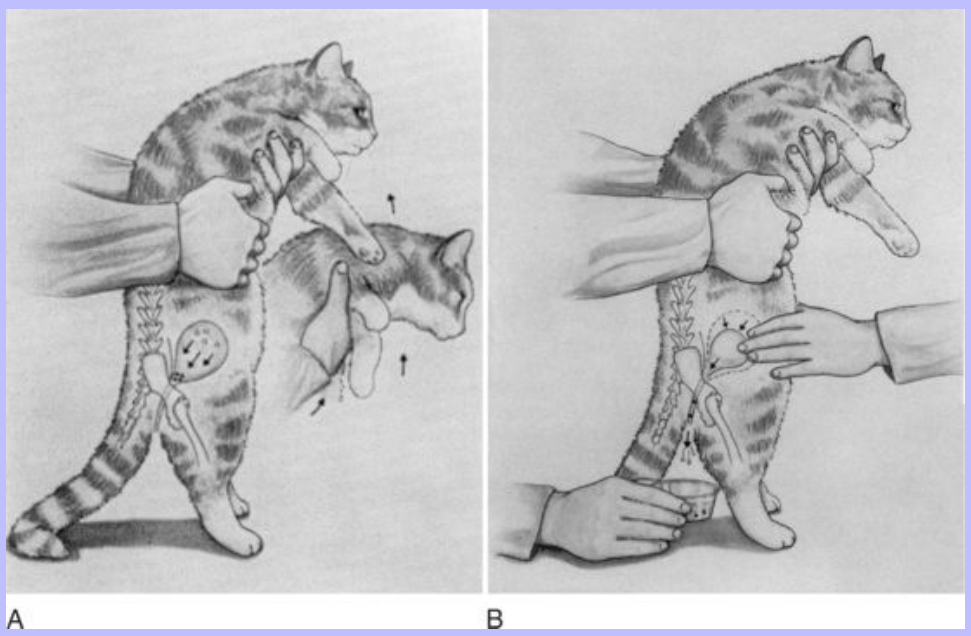
‡ Not considered biologically significant by authors.

§ Urine pH less than 6.3 could result in metabolic acidosis.

Once a urolith has been removed, the cat should be fed a canned diet, if possible, to decrease the urine concentration of stone mineral precursors. If a cat will not accept the new diet, water intake can be increased by the use of drinking fountains, flavored juices (e.g., ham, tuna), and the addition of ice cubes to

the cat's water (see Box 266-1 for further suggestions). Increasing water consumption is the cornerstone of therapy for urolithiasis in human[118] and veterinary medicine. When a urolith is diagnosed, the cat should be encouraged to consume enough water in canned or moistened foods to increase the urine volume until the USG is decreased to less than 1.030. Clients are advised that the urine should be clear, colorless, and odorless. USG should be monitored at periodic re-evaluations.

Figure 266-12 **A** and **B,** To remove urocystoliths by voiding urohydropropulsion, the patient is positioned so that the longitudinal axis of the vertebral column is approximately vertical. As a result, uroliths move from the ventral portion of the urinary bladder to the bladder neck. To expel urocystoliths, voiding is induced by applying steady digital pressure to the urinary bladder. (From Lulich JP, Osborne CA: Management of urocystoliths by voiding urohydropropulsion. Disorders of the feline lower urinary tract II. Diagnosis and therapy. Vet Clin North Am 26(3):631–632, 1996. Used with permission.)



1846

1847

266.3.3.2 Struvite Urolithiasis Management

In cats with struvite urolithiasis without a UTI, urinary acidifiers played a more important role until most commercial cat foods were reformulated to reduce urine pH. Urine acidifiers should only be given to cats with urine pH greater than 6.5 measured under *ad libitum* feeding conditions. Ideally, urine should be collected from the cats in their own environment, and the sample brought to the hospital for assessment of

pH and specific gravity. A urinary pH meter is reported to be more accurate than urine dip strips.[119] Although the addition of D, L-methionine and ammonium chloride decreases the struvite activity product and sediment in the urine of healthy cats, this supplementation failed to reduce the urinary concentration of the HCL-insoluble fraction that may be a candidate for the matrix of struvite uroliths.[120] Ingestion of large quantities of urinary acidifiers can cause anorexia and systemic acidosis. A number of veterinary diets to help prevent the recurrence of struvite stones are available (Table 266-4 and Box 266-3); although these diets may be of benefit, none have evidence-based outcomes documenting their effectiveness in prevention of recurring struvite urolithiasis. Feeding patterns also may influence the development of struvite uroliths due to an increase in pH (postprandial alkaline tide) that may occur after a meal in meal-fed cats, depending on diet composition.[121] Therefore *ad-libitum* feeding in cats with struvite uroliths seems prudent.

Box • 266-3 Suggestions to Help Clients Change their Cats' Diets

Changing a cat to a new food may not seem easy or convenient at first, but it may be necessary for some cats with feline idiopathic cystitis (FIC) and urolithiasis. To help clients and their cats through this process, the authors offer the following suggestions, collected from clients and cats that have successfully made the change.

1. Before starting to change diets, be sure that the cat is at home, feeling better, and eating its usual diet normally. Never begin the recommended diet while the animal is still hospitalized.
2. A simple way to start is to offer the new food in the cat's usual feeding bowl next to the old diet in a different bowl. Putting both foods in similar bowls can make the change somewhat easier. If the cat eats the new diet readily, then old food can be removed. If the cat does not eat the new diet after 1 hour, take it up until the next feeding. At the next feeding, repeat the process, always providing fresh new food. Once the new diet becomes familiar to the cat (usually in 1 or 2 days), it should start eating it readily. When this occurs, start to decrease the amount of the old diet offered by a small amount (about 25%) each day until the change is complete. Using this strategy, the change should be completed over a period of 1 to 2 weeks.
3. If necessary, small quantities (less than a tablespoon per cup or can of food) of the cat's favorite food, or meat or fish juices can be mixed with the new food initially to make it more appealing.
4. Cats should be fed in a quiet environment where it will not be distracted or startled by humans or other pets.
5. If a cat has food available all the time and refuses the new diet, it may be easier to start by changing its feeding schedule to meal feeding by only leaving food out for 1 hour at each feeding time. If the cat does not eat all its food every day, this may be normal. No more than a 10% loss of weight should occur during this transition. If the inappetence continues, offer the cat's regular favorite diet once again. After 3 to 4 weeks a different diet may be tried once again. Fortunately, several diets are available for certain diseases, and certain cats might prefer one over the other.

If a struvite urolith was diagnosed with a recurrence, feeding a canned form of a calculolytic diet has been reported to induce dissolution of struvite calculi in female cats.[122] Calculoylysis usually occurs within 1 month. Caution should be observed when considering use of calculolytic diets; the diets should not be fed to growing kittens or to pregnant or lactating queens.

266.3.4

Calcium Oxalate Urolithiasis

Calcium oxalate stones are the most common stone type in people, and their incidence has been increasing in cats during the past 15 years.[114] These stones are composed of calcium oxalate monohydrate (whewellite) or calcium oxalate dihydrate (weddelite). Oxalate frequently is not detected by qualitative analysis, and quantitative analysis is necessary for diagnosis. Calcium oxalate calculi usually are white and hard. They often have sharp, jagged edges and may be single or multiple in number (Figure 266-13). Although they are found

most often in the bladder and urethra, when stones appear in the kidneys they are most likely calcium oxalate. 1847
Calcium oxalate uroliths frequently recur. If a UTI is present, it is usually a complication rather than a 1848
predisposing factor to oxalate urolithiasis.

The research implicating magnesium as a potential cause of struvite urinary stone disease in cats seems to have led cat food manufactures to restrict the magnesium content of diets, and add ingredients to promote more acidic urine in an attempt to minimize the struvite-promoting potential oftheir products. Unfortunately, an increase in the frequency of calcium oxalate urolithiasis appears to have occurred since these modifications began. Between 1984 and 1995 the proportion of calcium oxalate stones submitted to the University of Minnesota Urolith center increased from 2% to 40%.[123] Studies assessing the diet risk factors in cats with urolithiasis have reported that diets formulated to decrease risk of struvite uroliths by reducing pH reciprocally increased risk of calcium oxalate uroliths.[114] Other dietary risk factors for cats with calcium oxalate urolithiasis were evaluated in this study, and the reader is referred to Table 266-3.

Figure 266-13 Calcium oxalate stones obtained from a cat after a cystotomy.

Results have shown that differences in breed, age, sex, and reproductive status did not contribute to the apparent reciprocal relationship between occurrences of calcium oxalate and struvite uroliths in cats.[116] Indoor housing has also been reported to be an independent risk factor for calcium oxalate urolithiasis.[121] It has been suggested that indoor cats could void less often and allow a longer period for urolith-forming products to aggregate in the bladder.

Although urinary acidifiers can enhance the solubility of struvite crystals in cats, if acidosis occurs, they also promote release of calcium carbonate from bone, resulting in hypercalciuria.[124] Acidosis may be associated with decreased urinary citrate excretion and thus may predispose to calcium oxalate stone formation in humans.[125] Citrate forms a soluble complex with calcium and may normally be an inhibitor of calcium oxalate formation in humans, but this has not been studied in cats. Oxalate is derived both from the diet and endogenously from the metabolism of ascorbic acid (vitamin C) and the amino acid glycine. In human beings, increased dietary oxalate, increased colonic absorption of oxalate secondary to fat malabsorption, vitamin B_6 deficiency, and inherited defects of oxalate metabolism may predispose to the formation of calcium oxalate

stones. What, if any, role these and other diet-related factors play in naturally occurring oxalate urolithiasis in cats is not known.

Breeds reported to be at risk for calcium oxalate uroliths include ragdoll, British shorthair, foreign shorthair, Himalayan, Havana brown, Scottish fold, Persian, and exotic shorthair cats. The Birman, mixed breed, Abyssinian, and Siamese cats had significantly lower risks for developing calcium oxalate uroliths.[116] As mentioned previously, cats with calcium oxalate urolithiasis are generally older than cats with struvite urolithiasis. Cats 7 to 10 years of age are reported to be 67 times as likely to develop calcium oxalate uroliths as cats between the ages of 1 and 2 years.[116] Male cats were reported to be one and a half times as likely to develop calcium oxalate uroliths and neutered cats were seven times as likely compared with sexually intact cats.

Cats with calcium oxalate uroliths should have their serum analyzed to evaluate for the presence of hypercalcemia, a risk factor for stone formation. Correction of hyper-calcemia is important to prevent recurrent stone formation. Early intervention could prevent subsequent complications, such as renal failure. Altered calcium metabolism may play a role in development of oxalate urolithiasis in some cats. Mild hypercalcemia was reported from the University of Minnesota Urolith Center in 35% of cats with calcium oxalate uroliths.[123] In a recent study of hypercalcemic cats,[126] calcium oxalate urolithiasis was noted in 11 of 16 (69%) with LUT signs. Of these, 73% had calcium oxalate urolithiasis. In a series of case reports, five cats with hypercalcemia and calcium oxalate urolithiasis presented for evaluation of LUT signs also had been fed an acidifying diet or received urinary acidifiers (D, L-methionine).[127] Seven of 20 cats (35%) had urolithiasis in a series of cats with idiopathic hypercalcemia.[128] In four cats that were evaluated, all had elevated urinary fractional excretions of calcium (Figure 266-14). Calcium oxalate urolithiasis has also been reported in a cat with a functional parathyroid adenocarcinoma.[129]

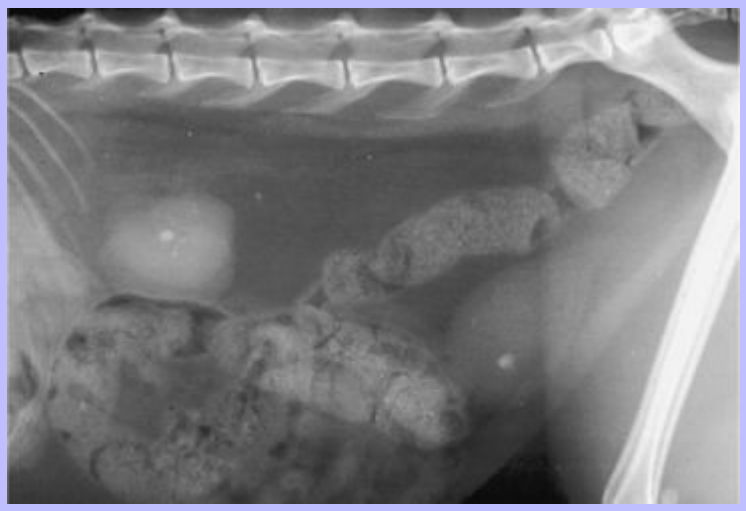
1849

266.3.5 Calcium Oxalate Management

Attempts to dissolve calcium oxalate stones have not been successful, and surgery or voiding urohydropropulsion is required to remove stones. Postoperatively, a diet restricted in calcium and oxalate seems logical, but no evidence-based studies in cats with naturally occurring disease are available to support this recommendation. Moreover, high intake of dietary calcium appears to decrease risk for symptomatic kidney stones in humans, whereas intake of supplemental calcium may increase risk. Thus the timing and association with intake of other nutrients may also influence the role of calcium and other nutrients on stone formation, and these effects may be different in animals with naturally occurring disease than in healthy cats. Reducing only one of these minerals could increase the availability of the other. Dietary phosphorus should not be excessively restricted because reduced phosphorus could result in increased activation of vitamin D_3 to calcitriol by 1-α-hydroxylase in the kidney and cause increased intestinal absorption of calcium. In addition, urinary pyrophosphate derived from the diet may function as an inhibitor of calcium oxalate formation. Magnesium intake should not be restricted because it may serve as an inhibitor of calcium oxalate formation. Although dietary salt supplementation has been controversial to manage LUT signs (by increasing water consumption), due to a potential for increased urinary calcium excretion, the overall diuretic effect appears beneficial. Studies in healthy dogs reported a decreased relative supersaturation for calcium oxalate urolithiasis with sodium chloride supplementation (Steveson AE et al: Effect of dietary moisture and sodium content on urine composition and calcium oxalate relative superasaturating in healthy miniature Schnauzers and Labrador retrievers, Res Vet Sci 74:145-151, 2003). No studies are available in cats. Salt supplementation should not be used in cats with impaired renal function, cardiovascular disease, or hypertension. Avoidance of

Vitamin C is recommended because ascorbic acid is a metabolic precursor of oxalate, but no stones have been reported to develop in cats due to use of vitamin C.

Figure 266-14 Radiograph of a cat with calcium oxalate stones in the renal pelvis and ureter. The cat was subsequently diagnosed with idiopathic hypercalcemia.



Administration of citrate as potassium citrate (Urocit-K®) could be helpful because urinary citrate may act as an inhibitor of calcium oxalate formation, although no data are available from clinical studies. Beyond this effect, therapeutic manipulation of urine pH is not known to be beneficial because oxalate solubility is relatively unaffected by a wide range of urine pH. The recommended dose of potassium citrate is 100 to 150 mg/kg/day but it is unclear if this dose will actually increase urinary citrate in cats. A number of commercial diets that have been used in attempts to prevent recurrence of oxalate stones are available and listed in Table 266-3, but no evidence-based outcomes of their use have been published.

266.3.6 Urate Urolithiasis

When evaluating mineral composition of 20,343 feline uroliths at the University of Minnesota Urolith Center, only 5.6% were composed of uric acid and urate.[132] The University of California-Davis Stone Analysis Laboratory reported that 6.4% of stones from cats over the past 10 years were uric acid. Urate stones in cats are composed of uric acid and the monobasic ammonium salt of uric acid (ammonium acid urate). Calcium oxalate may be a secondary component of some urate stones, and those found in cats with portosystemic shunts often contain struvite in addition to urate.[123] Often times, the cause or causes of urate urolith formation are unknown. Urate calculi are small, brittle, spherical stones with concentric laminations. They usually are multiple in number and light yellow, brown, or green in color. They are found most often in the bladder and urethra, and the recurrence rate may be as high as 30% to 50%. When it occurs, UTI is a complication of urate urolithiasis rather than a predisposing cause.

266.3.6.1 Urate Management

Attempts to dissolve urate stones have not been successful, and surgery or voiding urohydropropulsion is required to remove stones. The cat should be evaluated for liver abnormalities (e.g., portosystemic shunts) and if present, the underlying cause should be corrected. Dissolution and prevention protocols for *dogs* include some combination of urine dilution, low-purine diet, alkalinization of urine, and allopurinol. Dissolution of an ammonium urate stone in a cat was reported to occur using a combination of allopurinol and a diet relatively low in purine precursors.[132] Although allopurinol will reduce the formation of uric acid, xanthine uroliths can occur, and the efficacy and potential toxicity of allopurinol in cats are not known.

266.3.7 Cystine Urolithiasis

When evaluating mineral composition of 20,343 feline urolith at the University of Minnesota Urolith Center, only 0.2% were composed of cystine.[132] Approximately two thirds of the stones were located in the bladder, and slightly more than one fourth of them were voided. Cystine uroliths are usually identified in middle-aged to older cats.[133] Most cats with cystine uroliths are DSH, but Siamese cats appear slightly over-represented. Bacterial UTIs are usually a consequence of cystine uroliths and not a cause. Although the cause of cystine uroliths is unknown, cystinuria results from a hereditable defect in renal tubular transport of cystine and other dibasic amino acids (ornithine, lysine, and arginine). Not all animals with cystinuria develop cystine uroliths; therefore the crystals appear to be a predisposing factor rather than a cause.

266.3.7.1 Management of Cystine Urolithiasis

In addition to increasing urine volume in cats with cystine uroliths, cystine becomes more soluble as the pH increases. Therefore a nonacidifying canned food seems appropriate. (2-mercaptoproplonyl-glycine) glycine (2-MPG), which decreases the concentration of cystine by a thiol-disulfate exchange reaction resulting in a more soluble compound, has been reported to be of benefit in preventing recurrent cystine uroliths in a cat.[132] No adverse effects were documented in this one cat. Potassium citrate can be used to further alkalinize the urine if necessary. Sodium bicarbonate is not recommended because dietary sodium may enhance cystinuria.

1849 1850

266.3.7.2 Bacterial and Viral Cystitis

When interpreting the urinalysis, caution should be taken when reporting bacteria from the sediment. These “bacteria” are likely the result of cellular breakdown products in the urine that exhibit brownian motion and look similar to bacteria. Antimicrobials should be administered based on quantitative urine cultures and sensitivities. Bacterial UTIs are rare in cats but are more common in those with defenses that are compromised due to other diseases or treatments. Cats with previous urinary catheterizations, perineal urethrostomies, and tube cystostomies are more susceptible to infections.[71] Cats over 10 years of age with LUT signs have been diagnosed with bacterial UTIs in greater than half of the cases, often in association with renal failure.[134] The bacteria that cause UTIs in cats are similar to other species with *Escherichia coli* being the most common isolate. The gram-positive cocci such as staphylococci and streptococci account for the next most common isolates.[135]

Investigation of viruses as a causative agent of LUT signs began in the 1960s. Virus-like particles (suspected to be calicivirus) were identified in the matrix of urethral plugs from some male cats with urinary obstruction.[123] The isolation of feline calicivirus, bovine herpesvirus 4, and feline syncytia-forming virus from cats with naturally occurring LUT signs has also been reported.[136] Most recently, Rice and colleagues[137] documented feline caliciviruses (FCVs) from one female cat with FIC and one male cat with obstructive FIC in the 40 cats they evaluated. These viruses (FCV-U1 and FCV-U2, respectively) were genetically distinct from other known vaccine and field strains of FCV. What if any relationship viruses play in the etiopathogenesis in LUT sign in cats remains unknown.

267 CHAPTER • 267 Canine Lower Urinary Tract Diseases

Larry G. Adams

Harriet M. Syme

267.1 ANATOMY AND PHYSIOLOGY OF THE LOWER URINARY TRACT

The function of the urinary bladder and urethra is storage and voiding of urine. The urinary bladder acts as a low-pressure reservoir for storage of urine until voiding occurs. The urinary bladder consists of the detrusor muscle (smooth muscle), submucosa, mucosa (composed of transitional epithelium), and serosa. The ureters enter the urinary bladder on the serosal surface and tunnel though the bladder wall obliquely to the mucosal surface. The oblique path of the intramural ureter results in a valvelike effect termed the *vesicoureteral valve*. The vesicoureteral valve, along with ureteral peristalsis and a compliant bladder, promotes unidirectional flow of urine to aid in prevention of ascending infection or urine reflux to the kidneys. A protective glycosaminoglycan layer coats and protects the bladder urothelium, which if defective may increase bladder permeability.[1]

The detrusor muscle is continuous with the smooth muscle of the urethra and helps form the internal urethral sphincter. The internal urethral sphincter is not an anatomically distinct sphincter; rather, it is a functional sphincter involving the proximal urethral and bladder neck.

The innervation of the lower urinary tract (LUT) includes sympathetic, parasympathetic, and somatic innervation. The internal urethral sphincter is innervated by sympathetic (α-adrenergic) innervation from the lumbar spinal cord (L1-L4) via the hypogastric nerve. The external urethral sphincter is composed of skeletal muscle and receives somatic innervation from S1-S3 via the pudendal nerve. The detrusor muscle of the urinary bladder receives parasympathetic innervation from S1-S3 via the pelvic nerve (causing contraction) and sympathetic innervation (β-adrenergic) from L1-L4 via the hypogastric nerve (facilitating relaxation). Afferent (sensory) information from stretch receptors in the bladder wall travels via the pelvic nerve to the spinal cord. Sensory information is also transmitted via the hypogastric nerve when overdistension of the bladder occurs. Afferent information from the urethra is transmitted via the pudendal nerve.

267.2 CLINICAL SIGNS OF LOWER URINARY TRACT DISEASE

Dogs with LUT disease most commonly have signs of inflammation or irritation of the bladder and urethra (such as dysuria, pollakiuria, or stranguria), discolored urine (due to hematuria), urinary incontinence, or inability to effectively void urine. Refer to Chapters 29 to 31 for an overview of these clinical syndromes. Dogs with clinical signs that suggest localization to the LUT (e.g., dysuria, pollakiuria and stranguria) may also have disease of the upper urinary tract such as extension of lower urinary tract infection (UTI) to the ureter, renal pelvis, and renal parenchyma.

Animals with rupture of the bladder or urethra often have systemic signs of uremia (anorexia, lethargy, vomiting, and diarrhea), along with indications of fluid accumulation in the abdomen or subcutaneously. Subcutaneous urine leakage may cause tissue necrosis and sloughing of the overlying skin.

267.3 DIAGNOSTIC APPROACH TO LOWER URINARY TRACT DISEASE

The reader is referred to Chapter 257 for an overview of the diagnostic approach to dogs with urinary tract disease and Chapter 188 for neoplasia of the urinary tract. For dogs with signs of LUT disease, the *minimum* diagnostic evaluation should include history, physical examination, and urinalysis. If possible, the initial evaluation should also include urine culture, complete blood count (CBC), serum biochemistry profile, abdominal radiographs, and ultrasound of the urogenital tract. A thorough history should include frequency and volume of urination, estimated daily water intake, color of urine, any abnormal odor of the urine, evidence of straining or pain during urination, and evidence of urinary incontinence including age of onset, when incontinence occurs (awake, asleep, or continuous), and frequency of incontinence. The physical examination of dogs with signs of LUT disease should include abdominal palpation, digital rectal examination, visual and digital examination of the external genitalia, and neurologic examination of the pelvic limbs and perineal region.

267.3.1 Cystoscopy

If a cause of LUT disease has not been determined from routine diagnostic evaluation, transurethral cystoscopy (also termed *urethrocystoscopy*) should be considered. Cystoscopy is becoming an integral part of the diagnostic evaluation of dogs with recurrent or persistent LUT disease.[2] Although minimally invasive, cystoscopy does require general anesthesia to minimize movement. Cystoscopy is more sensitive than excretory radiography for identification of ectopic ureters and associated anatomic defects (Figure 267-1).[3] Cystoscopy is also useful for diagnostic evaluation of dogs with recurrent urinary tract infection (UTI) to evaluate for anatomic defects and to obtain biopsies for cytology, histopathology, and microbiologic culture.

Cystoscopy is useful for documenting the extent and location of LUT neoplasia and for obtaining biopsies for cytology and histopathology from lesions within the bladder or urethra. Using cystoscopy allows the source of gross hematuria to be localized to the genital tract, urethra, bladder, and left or right kidney and ureter with more certainty than by attempting to predict the source of hematuria based on when this is noted during voiding. Box 267-1 lists indications for cystoscopy.[4]

267.3.1.1 Diagnostic Imaging

Abdominal radiographs are an integral part of the diagnostic evaluation of dogs suspected of having LUT disease. Abdominal radiographs should include the entire urinary tract from the diaphragm to the caudal most portion of the urethra. Although the common anatomic landmark for distal collimation of abdominal radiographs is the coxofemoral joint, this is inadequate for evaluation of the urethra caudal to the pelvis, especially in male dogs (Figure 267-2). Failure to include the entire urethra may result in failure to diagnose uroliths in the urethra and potentially ineffective therapy such as incomplete surgical removal of uroliths. Abdominal ultrasound examination of the urogenital tract is a useful complement to abdominal radiographs when available to the practitioner although this modality has the limitation that, unless transrectal ultrasonography is also preformed, the urethra will not be visualized.

Figure 267-1 Cystoscopy showing an ectopic ureter opening in the proximal urethra along with abnormal urethral confirmation.

267.3.1.1.1

Box • 267-1 Indications for Cystoscopy

Localization of source of hematuria

Urinary tract neoplasia

Determine extent and location of neoplasia

Obtain biopsy for cytology and histopathology

Recurrent urinary tract infections (UTIs)

Conduct examination for anatomic abnormalities uroliths

Obtain biopsies for cytology, histopathology, and culture

Urinary tract trauma

Examine for perforations, ruptures, and patency of urinary tract

Urinary incontinence

Examine for ectopic ureters and/or urethral anomalies

Give periurethral injection of bulk-enhancing agents for treatment

Urolithiasis

Confirm and remove small uroliths from bladder or urethra

Obtain uroliths for quantitative analysis and culture

Retrieve uroliths from bladder or urethra using stone forceps or stone basket

Fragment urocystoliths with electrohydraulic or laser lithotripsy

Flush bladder using Ellik evacuator to remove small uroliths or urolith fragments

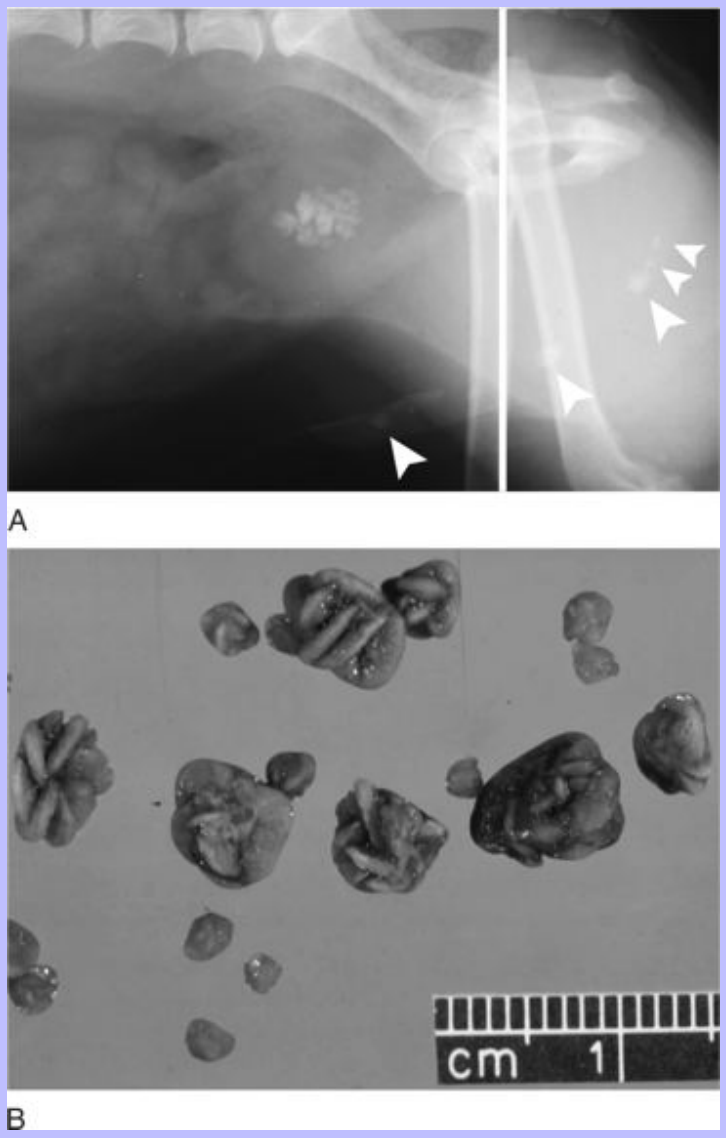
Abdominal ultrasound examination of the urogenital tract (combined with cystoscopy) reduces the use of contrast radiographic evaluation of LUT disease. However, contrast radiographs are still required for evaluation of some animals. Positive-contrast urethrocystography is the preferred technique for urethral defects such as delineating the extent and location of urethral strictures or extramural compressive lesions that preclude passage of the cystoscope. Positive-contrast urethrocystography is the preferred technique for diagnosis of pelvic bladder and rupture of the LUT (if cystoscopy is not available). Double-contrast cystography is the preferred technique for evaluation of the bladder for detection of radiolucent uroliths and mass lesions.

267.3.1.2 Urodynamics

Urodynamic evaluation is indicated for evaluation of dogs with refractory urinary incontinence, although urodynamic equipment is only available at selected referral hospitals. Urethral pressure profilometry can confirm a diagnosis of urethral incompetence.[5,6] Cystometrography may be used to diagnose detrusor instability (so-called overactive bladder), which may be due to a variety of inflammatory diseases of the LUT or may be idiopathic.[7] Some dogs with refractory urinary incontinence may have mixed incontinence

caused by both urethral incompetence and concurrent detrusor instability. Urodynamic testing allows for identification of the type and severity of urethral or detrusor dysfunction.[5]

Figure 267-2 **A,** Abdominal radiographs from a dog with calcium oxalate urocystoliths and urethroliths. Reader should note that if the radiographs were collimated at the coxofemoral joints *(solid white line)*, only one of the five urethroliths *(arrowheads)* would have been detected. **B,** Calcium oxalate uroliths from the dog in **A**. Uroliths were removed by retrograde urohydropropulsion and cystotomy.



267.4 UROLITHIASIS

267.4.1 Urolith Kinetics—Formation and Growth of Uroliths

A prerequisite for urolith formation is that urine is supersaturated, at least intermittently, with that compound. The point at which saturation of water with the pure chemical components of the crystal occurs is referred to as the *thermodynamic solubility product* (K_{sp}). However, the concentration of most urolith components in urine is actually greater than this, which can only be accomplished because urine contains inhibitors of crystal formation, which allow higher concentrations of solute to be held in solution. These solutions are described as being metastable (Figure 267-3). As the concentration rises still further, a point is reached at which the substance can no longer be held in solution; this is the formation product for the crystal (K_f). Because the concentrations of most urolith components in urine are in the metastable range, the question we should ask is not why some animals form uroliths, but why most do not. The ability of urine to hold more solute in solution than pure water is due to the many interacting ions that form soluble complexes, effectively reducing the free ionic concentration of each of the components.

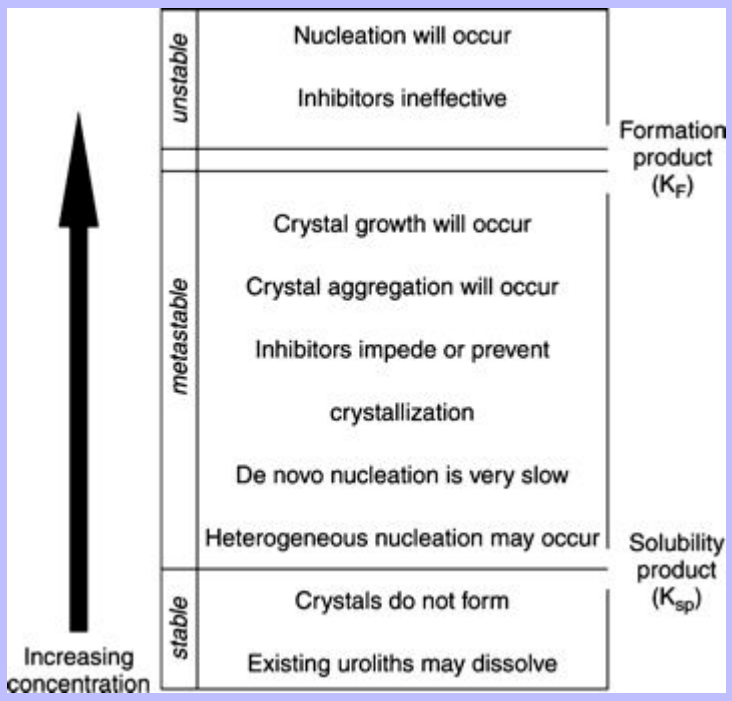
Urolith formation is initiated by the precipitation of a submicroscopic crystal nucleus in the form of a mineral lattice. If the crystal forms from a pure solution, this event is termed *homogeneous nucleation*. It is, however, probably more common for heterogeneous nucleation to occur in urine, with the crystal nucleus forming on existing surfaces (such as cell debris, urinary casts, or other crystals) because this requires a lesser degree of supersaturation.[8] If the growth of one type of crystal occurs on the surface of another, this is termed *epitaxial growth*.

Once a crystal nucleus has formed it has the potential to develop into a urolith of the same composition, with direct crystal growth occurring whenever the urine is supersaturated for that substance. Crystal growth requires a lesser degree of supersaturation than crystal nucleation. Direct crystal growth is a relatively slow process and unlikely to account for the development of most uroliths, particularly nephroliths, which must form in the time that it takes the urine to pass along the renal tubule. It is proposed that a combination of crystal growth and crystal aggregation occurs in most humans that develop uroliths.[8] In contrast to direct crystal growth, aggregation of crystals can occur rapidly. Humans that develop nephroliths excrete large crystal aggregates, whereas the urine of nonstone formers contains only small crystals.[9]

A final important factor in the development of uroliths is the retention of crystals or aggregates of crystals within the urinary tract. Crystalluria is a normal phenomenon in dogs; the exit of crystals from the urinary tract must be delayed for uroliths to develop.

In summary, the known causes of urolith formation can be divided into those that favor nucleation; those that promote crystal growth, aggregation, or both; and those that retain the urolith within the urinary tract so that further growth may occur. The importance of each of these mechanisms depends on the type of the urolith that is forming. Formation of some types of uroliths occurs principally (although not exclusively) because the concentration of solutes in urine is much higher than normal (e.g., struvite, cystine, and urate uroliths). Prevention of these types of uroliths is primarily directed at reducing the amount of solute excreted and promoting its solubility in urine (e.g., by manipulating urine pH). On the other hand, formation of calcium-containing uroliths (principally calcium oxalate) is much more complex.

Figure 267-3 States of saturation related to the formation of crystals in urine.



Urine is probably always supersaturated with respect to these compounds. Although increased urinary excretion of calcium or oxalate does play a role in the pathogenesis of urolithiasis, factors that complex calcium or oxalate in solution, reducing their effective concentrations (e.g., citrate) and that inhibit growth or aggregation of crystals (e.g., Tamm-Horsfall mucoprotein) are of much greater importance in preventing urolith formation. These individual mechanisms are discussed in more detail in the section on calcium oxalate formation.

267.4.2 Role of Matrix

Uroliths are composed of a crystalline component and variable quantities of matrix. The exact role of matrix in urolith formation in humans and dogs is unknown. Although numerous proteins and glycosaminoglycan have been detected in human nephroliths, it is unknown which ones may contribute to urolith formation versus simply being trapped in layers of the growing urolith. Occasionally, canine uroliths develop that are composed solely of matrix.[10]

267.4.3 *In Vitro* Assessment of Urolith Formation

The *gold-standard* assessment of dietary or other therapeutic interventions involves a clinical trial measuring the rate of *in vivo* formation or dissolution of uroliths. However, the protracted time course of such trials and the difficulty in studying the effect of a single intervention in isolation has resulted in the development of *in vitro* methods for evaluating the effects of urine composition on urolith formation or dissolution. The two

methods that have been used most frequently in veterinary medicine are the determination of relative supersaturation (RSS) and activity product ratios (APRs).

RSS is determined by measuring the concentration of various analytes (including calcium, oxalate, sodium, potassium, magnesium, ammonium, citrate, phosphate, pyrophosphate, and sulphate) in the urine, together with the urine pH, and then entering these values into a computer program that calculates a value for the ion activity product in the urine sample. The ratios of these activity products to the *thermodynamic solubility products* (K_{sp}) of their respective salts yield the RSS values. A RSS value less than one represents a urine sample that is undersaturated, whereas a RSS value greater than one represents a sample that is oversaturated, with respect to the compound being evaluated. Limitations of this method are that the computer program was optimized for calculations using human urine and that influence of promoters and inhibitors of crystal formation, growth, and aggregation on the measured free ion concentration cannot be included in the calculations. This technique has been applied to the analysis of urine from both dogs and cats.[11]

APRs are obtained by calculating ion activity products in the urine using a computer program in a similar manner to that used for determination of RSS. The difference with this method is that the measurements are made before and after incubation, with a seed crystal of the urolith type being investigated. The activity products will increase or decrease with incubation of the seed crystal depending on whether the urine is supersaturated or undersaturated with respect to the mineral being evaluated.[12]

267.4.4 Crystalluria

By convention, microscopic mineral precipitates within urine are called *crystals*, and macroscopic precipitates are called *uroliths* or *calculi*. The presence of crystalluria is not synonymous with disease, although it does signify that the urine is supersaturated with the mineral compound and is evidence that a risk exists for the development of uroliths. However, crystals may be found in the urine of dogs that do not have, and never develop, uroliths. This is particularly true of struvite and calcium oxalate crystals in all breeds and urate crystals in dalmatians. Conversely, some crystal types are not a normal finding and warrant further investigation even in the absence of uroliths. These include cystine, xanthine, and (in breeds other than dalmatians) urate crystals.

Crystals that were not present *in vivo* while the urine was in the excretory pathway, often form *in vitro* as the urine cools below body temperature.[13] Ideally, urinalysis should be performed as soon as possible without refrigeration of the sample when attempting to determine if crystalluria is present.

In dogs with urolithiasis, the type of crystals found in urinalysis may be helpful for predicting the mineral composition of the uroliths, although several caveats exist. If the dog's diet has been changed between the time of urolith formation and diagnosis, the crystals present at the time of diagnosis may be different from the mineral component of the urolith. Likewise, development or resolution of UTI with urease-producing organisms during the urolith formation and growth can change the type of crystal present in the urine.

267.4.5 Diagnosis of Urolithiasis

Uroliths are usually diagnosed based on results from radiography or ultrasonography. Occasionally, dogs have a history of voiding uroliths. Although uroliths may be palpated in the bladder or urethra, palpation is not a sensitive technique for ruling out urolithiasis. When uroliths are detected anywhere in the urinary tract, the entire urinary tract should be imaged with radiographs and ultrasound (or contrast radiography) to determine if uroliths are present in other locations (see Figure 267-2). Palpation of the external portion of the urethra and

digital rectal examination of the pelvic urethra should also be performed to examine for urethroliths. Although most uroliths are radiopaque and are visible on survey abdominal radiographs, some uroliths are radiolucent (or strictly speaking have the same radiopacity as the surrounding soft tissues), and some radiopaque uroliths are too small to be detected. In one *in vitro* study, failure rates for detection of uroliths by survey radiography were between 2% and 27%, depending on the size and composition of the uroliths.[14] In contrast, the radiographic procedures with greatest sensitivity were pneumocystography, double-contrast cystography, and ultrasonography using a 7.5 MHz transducer with false-negative results of 11%, 10%, and 6%, respectively.[14] Therefore precise determination of the location, presence or absence of uroliths requires either ultrasonography or contrast radiography. Ultrasonography is preferred, if available, because of relative ease, lack of requirement for urethral catheterization, and it also permits simultaneous evaluation of the upper urinary tract for nephroliths or ureteroliths.

Once the number and location of uroliths is determined, the next step is to attempt to determine the type of urolith present to formulate a treatment plan. Catheter-assisted retrieval of uroliths or mechanical removal during cystoscopy provides urocystoliths for quantitative analysis. Because qualitative analysis methods are unreliable, the preferred quantitative analysis methods are optical crystallography, x-ray defraction, and infrared spectroscopy.[10,15]

If uroliths are not available for analysis (or pending the result of quantitative analysis), the chemical composition can often be correctly predicted from signalment, and results of urinalysis, urine culture, and radiographs (Table 267-1).[16,17] Two additional imaging approaches for determining urolith composition can be used. Weichselbaum and colleagues[18,19] reported an *in vitro* method of comparing urolith opacity to various concentrations and depths of iodinated contrast solutions to predict urolith composition.

1853 1856

Table • 267-1 Characteristics of Common Canine Uroliths

COMPOSITION	RADIOGRAPHIC DENSITY	SURFACE CHARACTERISTICS	URINE pH	CRYSTALLURIA	URINARY TRACT INFECTION	COMMONLY AFFECTED BREEDS*	OTHER
Calcium oxalate monohydrate (COM) and/or calcium oxalate dihydrate (COD)	Moderately to markedly radiopaque (see Figure 267-2)	Sharp projections, mulberry shaped or smooth round uroliths (see Figure 267-2); COD may appear jackstone shaped	Acidic to neutral	Calcium oxalate dihydrate crystals (square envelope) or calcium oxalate monohydrate crystals (dumbbell or picket-fence shapes)	None or secondary urinary tract infection (UTI) with common uropathogens	Miniature schnauzer, Lhasa Apso, Yorkshire terrier, Bichon frise, Pomeranian, Shih Tzu, Cairn terrier, Maltese, miniature poodle, Chihuahua	Often multiple small uroliths in bladder; multiple nephroliths if present
Struvite (magnesium ammonium phosphate hexahydrate)	Moderately to markedly radiopaque; larger uroliths appear more radiopaque (see Figure 267-7)	Single—may be smooth or speculated, may assume shape of bladder lumen (see Figure 267-8); multiple—smooth surfaces where uroliths contact each other, often pyramidal shape	Alkaline	Struvite or "triple phosphate" crystals ("coffin lid" appearance)	Urease-producing organisms *Staphylococcus*, *(Proteus*, mycoplasma); sterile struvite uroliths in cocker spaniels	Miniature schnauzer, Shih Tzu, Bichon frise, miniature poodle, cocker spaniel, Lhasa Apso	Uroliths >10 cm diameter are likely to be struvite; nephroliths are often staghorn shaped
Urate/xanthine	Radiolucent to faintly radiopaque	Multiple smooth uroliths	Acidic	Ammonium urate crystals (yellow-brown "thorn apple" or spherical shapes) or amorphous urate crystals	None or secondary UTI with common uropathogens; rarely, urease-producing organisms	Dalmatian, English bulldog, miniature schnauzer, Shih Tzu, Yorkshire terrier	PSS or other liver dysfunction; yellow-green urolith color
Cystine	Faintly to moderately radiopaque	Multiple smooth round uroliths in bladder and/or urethra; nephroliths may be staghorn shaped if present	Acidic	Cystine crystals (hexagonal shape) Cystine crystalluria always abnormal	None or secondary UTI with common uropathogens	Mastiff, Australian cattle dog, English bulldog, Staffordshire bull terriers, Newfoundland, dachshund	Positive urine cyanide-nitroprusside test; metabolic screening of urine available; males >> females
Calcium phosphate	Moderately to markedly radiopaque	Hydroxyapatit—multiple small uroliths with variable shape; brushite—multiple smooth round or pyramidal uroliths	Alkaline to neutral pH for hydroxyapatite, acidic for brushite	Amorphous phosphates or calcium phosphate crystals (thin prisms)	None or secondary UTI with common uropathogens	Yorkshire terrier, miniature schnauzer, Bichon friese, Shih Tzu, springer spaniel, Pomeranian, miniature poodle, cocker spaniel	Hypercalcemia is a predisposing factor

Silica	Moderately radiopaque	Classic jackstone appearance	Acidic to neutral	None	None or secondary UTI with common uropathogens	German shepherd, Old English sheepdogs, Labrador retriever, golden retriever, miniature schnauzer, cocker spaniels, Shih Tzus, Bichon frises	Males >> females

The breeds listed are those from which uroliths are most frequently submitted for mineral analysis; due to differences in breed popularity, this is not necessarily the same as the breeds that are at increased risk for stone formation.

Information from computerized tomography (CT) may eventually provide more objective means of predicting urolith composition in dogs. The peak attenuation measurements (termed *Hounsfield units*) of canine uroliths determined *in vitro* by noncontrast CT was significantly correlated with chemical composition in one study, confirmation of these findings *in vivo* is required.[20] In humans, CT has become the gold standard imaging technique for detection of uroliths,[8] and urolith composition can often be predicted from attenuation values obtained by micro CT scans *in vitro* and helical CT *in vivo*.[21]

267.4.6 Urolith Removal Techniques

Uroliths that may be medically dissolved include struvite, urates, and cystine.[22–24] For dissolution to occur, the urolith should be surrounded by undersaturated urine to allow the crystals to go back into solution. Therefore the location also affects the ability to medically dissolve uroliths; urocystoliths and nephroliths are amenable to dissolution but ureteroliths and urethroliths are not.[24] Urethroliths may be flushed back into the urinary bladder by retrograde urohydropropulsion for medical dissolution or mechanical removal.[25]

267.4.6.1 Cystotomy

Surgical removal of uroliths by cystotomy is the traditional method of mechanical removal of canine urocystoliths. However, use of newer, nonsurgical techniques for removal of smaller urocystoliths is increasing. It is notable that open surgical removal of uroliths is used in only 0.3% to 4% of human patients.[26]

267.4.6.2 Laparoscopic-Assisted Cystotomy

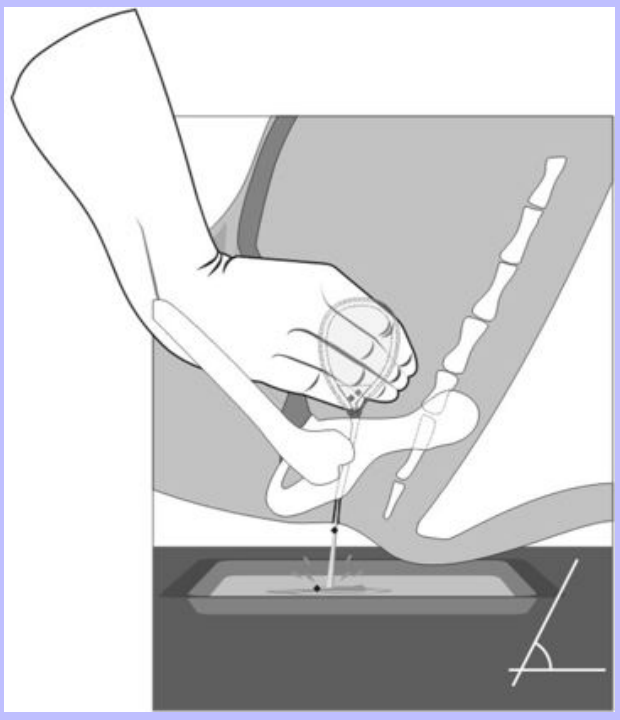
A recent report demonstrated that laparoscopic-assisted cystotomy may be used to remove urocystoliths that are too large to pass though the urethra.[27] This approach minimizes surgical trauma and may become more commonly used as veterinarians become more familiar with laparoscopic surgery.

267.4.6.3 Voiding Urohydropropulsion

Voiding urohydropropulsion is the removal of smaller urocystoliths by inducing voiding while the dog is positioned vertically so that urocystoliths pass with the voided urine (Figure 267-4).[28] Although the technique may be performed with the dog awake, general anesthesia facilitates complete urethral relaxation,

preventing development of high intravesicular pressures that could cause iatrogenic trauma to the bladder wall. Cystoscopy may be performed immediately prior to voiding urohydropropulsion to evaluate the urethra for strictures that would interfere with urolith passage. If the bladder is not distended with urine, it is distended with sterile saline via cystoscopy or urethral catheterization. The dog is positioned so that the spine is roughly 25 degrees caudal to a line perpendicular to the effects of gravity, such that a line drawn through the urethra into the bladder is vertical (see Figure 267-4). The bladder is agitated, and time is allowed for the urocystoliths to settle in the trigone. The bladder is palpated, and the intravesicular pressure is gradually increased by manual compression of the bladder to initiate a detrusor contraction. Once voiding begins, the bladder is compressed more firmly to attempt to maintain maximum urine flow rates, dilate the urethra, and flush out the urocystoliths. The bladder is refilled with sterile saline through a cystoscope or urinary catheter and the process is repeated until no urocystoliths are passed with the expelled fluid. Then postprocedural radiographs or cystoscopy are performed to confirm complete removal of the urocystoliths. Although periprocedural antibiotics are sometimes recommended to prevent iatrogenic UTI, this is not required provided proper aseptic technique is observed. If significant urethral leakage occurs when the dog is positioned vertically, inadequate bladder distention may prevent effective voiding of the uroliths. If this occurs, a Foley catheter is placed in the urethra with the balloon used to obstruct the trigone and the bladder is distended with saline. After agitation of the bladder to allow the urocystoliths to settle in the trigone, the Foley catheter balloon is deflated, the catheter is removed, and voiding urohydropropulsion is performed as described previously.

Figure 267-4 Diagram of a dog positioned for voiding urohydropropulsion. Reader should note that the trigone of the bladder is perpendicular to the effects of gravity, whereas the spine is approximately 25 degrees caudal this perpendicular line.



267.4.6.4 Retrograde Urohydropropulsion

Retrograde urohydropropulsion is the flushing of urethroliths into the urinary bladder, usually performed to relieve urethral obstruction.[25] General anesthesia is usually required for successful retrograde urohydropropulsion. If necessary, the dog or cat should be treated by decompressive cystocentesis and fluid therapy to correct acid-base and electrolyte imbalances before anesthesia to minimize the anesthetic risk. If the urinary bladder is overdistended, the bladder is gently decompressed by cystocentesis using a 22-gauge needle connected to a 60 mL syringe by extension tubing and a three-way valve. This lowers the urethral pressures proximal to the urethroliths to allow their retrograde movement. The largest urinary catheter possible is gently passed to the level of the distal calculus. An assistant compresses the urethra against the pubis via rectal palpation. A 2:1 mixture of sterile saline and sterile aqueous lubricant is rapidly flushed into the urethra distal to the obstructive calculus while compressing the urethral orifice around the catheter to prevent fluid leakage from the penis. An estimate of the total volume of flush required is 5 mL/kg of body weight or 60 mL, whichever is less. Once the urethra begins to dilate, the proximal (rectal) compression is released while flushing continues. If the urethroliths pass retrograde, the catheter is gently advanced to the trigone. If the calculus does not move retrograde, the degree of bladder distention should be assessed prior to repeating retrograde urohydropropulsion. If necessary, the bladder may be decompressed by cystocentesis before repeating the process. Subsequent retrograde flushes are done with sterile saline alone, because the urethra is well lubricated from the first attempt and saline can be more rapidly flushed through the catheter. Successful retrograde movement of all urethroliths should be confirmed by cystoscopy or radiography.

1856 1857

The aim of retrograde urohydropropulsion is to flush the uroliths into the bladder, not to push them with the urinary catheter. Pushing against urethroliths with rigid polyethylene catheters may result in excessive mucosal trauma, the catheter being forced through the wall of the urethra, or the catheter being passed round the urolith providing a route for temporary urine drainage but without moving uroliths back into the bladder. Catheter-induced trauma predisposes the dog to future urethral stricture formation.

267.4.6.5 Catheter-Assisted Retrieval

Catheter-assisted retrieval of uroliths may be used to collect small urocystoliths for mineral analysis.[29] A urinary catheter is placed with the tip located within the trigone and the bladder is distended with urine or sterile saline. Next the bladder is vigorously agitated to suspend the smaller uroliths in the urine while rapid aspiration through the urinary catheter results in removal of the suspended uroliths along with the urine. If the dog tolerates urethral catheterization, this procedure may be performed without sedation or anesthesia.

267.4.6.6 Ellik Evacuator

During cystoscopy with a rigid cystoscope the telescope is removed, leaving the cystoscope sheath in place in the urethra with the tip of the sheath just inside the trigone. An Ellik evacuator is attached to the cystoscope sheath, and the bladder is rapidly lavaged to flush sterile saline into and out of the bladder using the bulb attachment. The design of the Ellik evacuator allows the aspirated uroliths to gravitate to the bottom chamber while fluid in the top chamber is flushed into and out of the bladder several times (Figure 267-5). This technique can be used to collect uroliths smaller than the diameter of the cystoscope sheath, and thus it allows for removal of larger uroliths than a standard urinary catheter. This technique may be

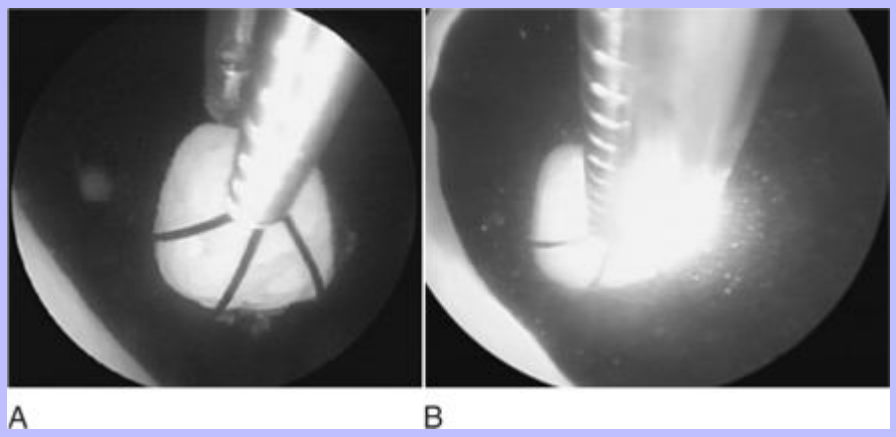
used to completely remove small uroliths from the urinary bladder or to obtain smaller uroliths for quantitative analysis and culture.

267.4.6.7 Stone Baskets

Stone baskets may be used to remove uroliths from the LUT provided the uroliths are smaller than the dilated urethra. Stone baskets are usually passed through the working channel of the cystoscope, the basket is opened, and once the urolith is engaged in the basket, the basket is closed around the urolith and positioned at the end of the cystoscope (Figure 267-6, *A*). The cystoscope and basket containing the urolith are then slowly withdrawn through the urethra with direct visualization to ensure the urothelium does not bulge around the urolith edges, which may indicate the urolith is becoming wedged in the urethra. This technique may be safely used to remove some uroliths that will not readily pass during voiding urohydropropulsion; however, caution is required to avoid getting the urolith wedged in the urethra.

Figure 267-5 An Ellik evacuator attached to a cystoscope sheath used for flushing small uroliths from the bladder. Reader should note the uroliths in the bottom chamber.

Figure 267-6 Fragmentation and removal of calcium oxalate monohydrate urocystoliths by electrohydraulic lithotripsy (EHL). **A,** Urocystolith held in a stone basket for fragmentation by EHL. The electrohydraulic electrode is visible dorsal to the basket. **B,** The electrohydraulic electrode has been activated generating a spark on the surface of the urolith.



267.4.6.8 Electrohydraulic Lithotripsy

Electrohydraulic lithotripsy (EHL), the fragmentation of urinary uroliths with hydraulic shock waves generated within the bladder lumen, has been successfully used to fragment and remove urocystoliths in dogs (see Figure 267-6).[30] The procedure requires an EHL generator and cystoscopic equipment with a 5F working channel for the electrohydraulic electrode. The average treatment time is more than 1 hour to adequately fragment urocystoliths, which are then removed by use of an Ellik evacuator. Large urocystoliths may take several hours to completely fragment by EHL.

267.4.6.9 Laser Lithotripsy

In humans, laser lithotripsy using the holmium laser has become the lithotrite of choice for fragmentation of large bladder calculi, ureteroliths, and nephroliths.[26,31,32] In humans, holmium laser lithotripsy has largely replaced EHL because it is faster and safer than EHL. The holmium laser is absorbed in 0.5 mm of fluid, allowing it to safely fragment uroliths within the urethra or ureter.[26,31] Also, because of the small diameter of the laser fibers, laser lithotripsy can be performed through small-diameter flexible endoscopes. Recent *in vitro* studies confirm that the holmium laser can efficiently fragment uroliths from dogs regardless of chemical composition.[14] Implanted urethroliths in male dogs were safely fragmented by laser lithotripsy using a holmium laser.[8] As holmium lasers become more widely available in veterinary medicine, this technique may replace cystotomy and urethrotomy for removal of uroliths.

267.4.6.10 Extracorporeal Shock Wave Lithotripsy

Extracorporeal shock wave lithotripsy (ESWL) is fragmentation of uroliths using shock waves that are generated outside the body. Although ESWL is better suited for fragmentation of uroliths fixed in one location such as nephroliths or ureteroliths, urocystoliths have been successfully fragmented using ESWL. Because the urocystoliths tend to move out of the focal spot of the lithotriptor, uniform fragmentation does not occur consistently. In treating 14 dogs using ESWL, urocystoliths were fragmented into pieces small enough to be removed through the urethra in 8 of the dogs in one ESWL session. If the fragments are too large to be removed through the urethra, ESWL may be repeated or a secondary procedure may be required to remove larger urocystolith fragments.

267.5 CALCIUM OXALATE UROLITHIASIS

Calcium oxalate uroliths are usually composed of 100% calcium oxalate, although some also contain varying amounts of calcium phosphate.[35,36] Calcium oxalate is a common component of many compound uroliths. Calcium oxalate occurs as two crystalline forms: (1) calcium oxalate monohydrate (whewellite) or (2) calcium oxalate dihydrate (weddellite). Calcium oxalate monohydrate occurs more commonly than calcium oxalate dihydrate in canine uroliths. Some dogs have both forms in different layers of the same urolith.[10] The only clinically relevant difference between these forms is that calcium oxalate dihydrate uroliths are more easily fragmented by shock waves than calcium oxalate monohydrate uroliths.[26,37] Calcium oxalate uroliths are radiopaque and often occur as multiple smaller uroliths in the LUT (see Figure 267-2). The surface characteristics vary; uroliths may be smooth, mulberry-shaped, or have sharp projections (see Figure 267-2). Although calcium oxalate uroliths are not caused by infection, they may be associated with secondary UTIs because the presence of uroliths may interfere with host defenses against infection and contribute to recurrent infections. In one study, 52% of female dogs and 32% of male dogs with uroliths that contained calcium oxalate had positive urine or urolith cultures.[38] However, compound uroliths that were made up of less than 50% calcium oxalate were included in the study, and only about half of the uroliths were cultured, which may have resulted in an overestimation of the prevalence of UTI. Other studies do not support an association of calcium oxalate uroliths with UTI.[39]

267.5.1 Epidemiology of Calcium Oxalate Urolithiasis

The percentage of canine uroliths submitted to the Minnesota Urolith Center that are composed of calcium oxalate has increased from approximately 5% in 1981 to 35% in 1997, making it the second most common urolith in dogs.[10,40] This is similar to the increased incidence of calcium oxalate uroliths and decreased incidence in struvite uroliths in cats over the same time period[10] and in humans over the last 50 years.[8] The exact reasons for the shift in prevalence of calcium oxalate uroliths in dogs is unknown. Better medical management of struvite uroliths may be decreasing the percentage of struvite uroliths, but this does not adequately explain the shift because a concurrent relative increase has not occurred in the percentage other types of uroliths.[10] Alternatively, increased use of diets designed to minimize the risk for struvite uroliths maybe increasing the risk for calcium oxalate uroliths (see section on diet, following). In humans, calcium oxalate uroliths occur most commonly in the upper urinary tract, whereas in dogs and cats they occur much more commonly in the LUT.[8,41]

Calcium oxalate uroliths occur more commonly in male dogs (68% to 71% of calcium oxalate uroliths submitted to two urolith centers) than female dogs (26% to 32%).[40,42] Similarly, in humans, men are affected three times more often than women; this has been hypothesized to be due to estrogen-induced reduction in urinary oxalate and increase in urinary citrate excretion in females.[8] Neutered male dogs have increased risk of calcium oxalate uroliths compared with intact dogs.[43] Obese dogs are more likely to form calcium oxalate uroliths, which is similar to cats and humans.[8,43] Breeds at increased risk for calcium oxalate uroliths include the miniature schnauzer, Lhasa Apso, Yorkshire terrier, Bichon frise, Pomeranian, Shih Tzu, Cairn terrier, Maltese, miniature poodle, and Chihuahua.[42–44] In one study, golden retrievers, German shepard dogs, and cocker spaniels had decreased risk of calcium oxalate uroliths.[43] Dogs that produce lower urine volumes and urinate less often may be more likely to have calcium oxalate urolithiasis.[45]

267.5.2 Etiopathogenesis of Calcium Oxalate Urolithiasis

Excessive urinary calcium excretion (hypercalciuria) or oxalate (hyperoxaluria) results in increased risk of calcium oxalate urolith formation. Calcium oxalate may precipitate on existing surfaces such as epithelial cells, cell debris, or other crystals (e.g., uric acid, calcium phosphate). This process, known as *heterogenous nucleation*, occurs at lower urine saturation for calcium oxalate than is required for homogenous nucleation. In humans, increased uric acid excretion (hyperuricosuria) often contributes to formation of calcium oxalate urolithiasis.

Urinary excretion of uric acid was slightly higher in miniature schnauzers with calcium oxalate urolithiasis than normal beagles[46]; however, because dogs have much lower serum and urine uric acid concentrations than humans (with the exception of dalmatians and English bulldogs),[22] hyperuricosuria is less likely to contribute to calcium oxalate urolith formation in dogs.

267.5.2.1 Hypercalciuria

Increased urinary excretion of calcium (hypercalciuria) is a common contributing factor to calcium oxalate urolithiasis in humans.[8] Hypercalciuria is also a common finding in dogs with calcium oxalate urolithiasis.[46–48] Hypercalciuria is proposed to occur by one of three mechanisms: (1) *absorptive hypercalciuria,* characterized by increased intestinal absorption of calcium; (2) *renal-leak hypercalciuria,* characterized by a primary renal leak of calcium; and (3) *resorptive hypercalciuria,* characterized by increased bone demineralization.[8,49] Humans and dogs with *absorptive hypercalciuria* have increased intestinal absorption of calcium with the excess calcium excreted in the urine (hypercalciuria).[8] The mildly increased serum calcium (from increased intestinal absorption) causes an increased filtered load of calcium in the glomerular filtrate and reduced tubular reabsorption of calcium due, in part, to suppression of parathyroid hormone (PTH) levels by high normal serum calcium concentrations. The combination of increased filtered calcium and reduced tubular reabsorption causes hypercalciuria. The increased intestinal absorption occurs in the jejunum and is accompanied by increased intestinal absorption of oxalate, which contributes to concurrent hyperoxaluria. Approximately 50% of humans with absorptive hypercalciuria have increased concentrations of 1,25-dihydroxycholecalciferol, causing increased intestinal calcium absorption.[8,50] In one study, five of six miniature schnauzers with calcium oxalate urolithiasis were classified as having absorptive hypercalciuria.[46]

1858

1859

Renal-leak hypercalciuria is due to impaired renal tubular reabsorption of calcium.[8] Renal calcium loss reduces the serum ionized calcium, which causes increased PTH and 1,25-dihydroxycholecalciferol. Increased 1,25-dihydroxycholecalciferol causes increased intestinal absorption of calcium (and phosphorus), which returns the serum calcium to normal. The increased PTH also causes increased mobiliza-tion of calcium from bone, which could contribute to bone demineralization over time if dietary calcium intake is not adequate. Humans and dogs with renal-leak hypercalciuria have high serum PTH concentrations, normal serum calcium concentrations, and high fasting urinary calcium excretion.

Resorptive hypercalciuria and *hypercalcemic hypercalciuria* are closely related. Resorptive hypercalciuria is a subtle, normocalcemic version of primary hyperparathyroidism, whereas serum calcium is elevated with hypercalcemic hypercalciuria.[8] In humans, the most common cause of hypercalcemic hypercalciuria resulting in calcium oxalate urolithiasis is primary hyperparathyroidism. Other causes in humans include malignancy-associated hypercalcemia, hyperthyroidism and sarcoidosis, and other granulomatous diseases, although these have not been reported associated with calcium oxalate urolithiasis in dogs. In dogs, calcium oxalate uroliths have been reported secondary to primary hyperparathyroidism.[51,52] Dogs with hyperparathyroidism may form calcium phosphate, calcium oxalate, or mixed calcium oxalate and calcium phosphate uroliths.[51,53]

267.5.2.2 Hyperoxaluria

Urinary concentration of oxalate is an important factor in calcium oxalate crystallization and urolithiasis, because on a molar basis, increases in urine oxalate concentration have a greater effect on urinary saturation of calcium oxalate than equivalent increases in urinary calcium concentration.[8,48] Oxalate is freely filtered at the glomerulus and undergoes bidirectional transport in the renal tubules with net tubular secretion. Urinary oxalate is derived mainly from endogenous production in the liver from metabolism of ascorbic acid, glyoxylate, and glycine with lesser amounts from dietary intake of oxalate. Dietary meat protein intake contributes the amino acids hydroxyproline and tryptophan, which are metabolized to oxalate. In humans, rats, and pigs, some of the normal dietary oxalate is degraded in the intestines by normal bacterial flora including *Oxalobacter formigenes*.[8] Some humans with calcium oxalate nephrolithiasis have deceased intestinal *Oxalobacter formigenes*, which may be caused by chronic antibiotic therapy for concurrent medical conditions.[54] The potential role of a paucity of intestinal *Oxalobacter formigenes* in calcium oxalate urolithiasis in dogs has not been evaluated.

Varying degrees of hyperoxaluria is present in up to 50% of humans with calcium oxalate urolithiasis;[8] however, hyperoxaluria has not been detected in dogs with calcium oxalate urolithiasis.[46] Primary hyperoxaluria is a rare genetic disorder of humans that causes either oxalate nephrosis or recurrent calcium oxalate urolithiasis. Primary oxaluria has been reported in both dogs and cats, but was associated with oxalate nephrosis rather than calcium oxalate urolithiasis.[55,56]

267.5.2.3 Water Source

The mineral content of water may be a potential factor in calcium oxalate urolithiasis in humans, although the data are conflicting.[8] It has been proposed that increased sodium or calcium content or absence of trace minerals such as zinc, which chelates calcium, might increase risk of calcium oxalate urolithiasis. In one epidemiologic study in cats, the source of water (e.g., bottled, municipal) did not appear to affect the risk of

calcium oxalate urolithiasis.[57] No reports exist on the effects of mineral content of water on calcium oxalate urolithiasis in dogs.

267.5.2.4 Modifiers of Calcium Oxalate Crystal System

In humans the degree of saturation of urine for calcium oxalate overlaps between normal subjects and those who form uroliths. The reason some humans form uroliths and others do not is that urine normally contains several natural inhibitors of urolith formation and growth. Inhibitors are either organic or inorganic substances in urine that inhibit crystal formation, aggregation, or growth and if defective or deficient, may contribute to urolith formation. In humans, inhibitors of calcium oxalate include citrate, magnesium, pyrophosphate, glycosaminoglycans, nephrocalcin, and Tamm-Horsfall mucoprotein.[8] Although little is known about these inhibitors of calcium oxalate in dogs, they may play a similar role in dogs in determining which dogs form uroliths and which do not.

Two important inorganic inhibitors of calcium oxalate are (1) citrate and (2) magnesium. In urine, citrate forms complexes with calcium that are more soluble than calcium oxalate, lowering the ionic calcium concentration. Citrate inhibits both spontaneous and heterogenous nucleation of calcium oxalate crystals.[8] In humans, citrate is filtered by the kidneys and approximately 75% is reabsorbed by the tubules, with the major determinant of the amount reabsorbed being the acid-base status. Metabolic acidosis reduces urinary citrate excretion by augmenting tubular reabsorption of citrate, whereas metabolic alkalosis decreases tubular reabsorption and increases urinary citrate excretion.[8,58] In dogs, urinary citrate excretion is much lower than humans with less than 1% of filtered citrate normally excreted in the urine, although urinary citrate excretion increases dramatically with metabolic alkalosis.[58] Hypocitraturia has been reported in 15% to 63% of humans who form calcium oxalate nephroliths, with metabolic acidosis being the most important cause of decreased urinary citrate excretion.[8,59] In dogs, mean urinary citrate excretion was not significantly different between six miniature schnauzers with calcium oxalate urolithiasis and normal beagles; however, some individual miniature schnauzers appeared to have decreased urinary citrate excretion compared with the normal beagles.[46] Because hypocitraturia only affects 15% to 63% humans with calcium oxalate nephroliths, and because too few dogs have been evaluated to accurately define what level of daily urinary citrate excretion constitutes hypocitraturia in dogs, a role for hypocitraturia in calcium oxalate urolith formation in some dogs is possible, although unproven.

Similar to citrate's role with calcium, magnesium complexes with oxalate, reducing the urine saturation for calcium oxalate.[8] Deficient urinary magnesium concentration results in more oxalate being available to combine with ionic calcium; therefore lower dietary magnesium may predispose to calcium oxalate urolithiasis, a proposal which was supported by two recent epidemiologic studies.[39,60] Citrate and magnesium play complimentary roles by complexing calcium and oxalate respectively and lowering the urine saturation for calcium oxalate.

Pyrophosphate in the urine is another inhibitor of calcium oxalate. The amount of pyrophosphate in the urine is related to dietary phosphorus intake. Although the role of pyrophosphate in canine urine is unknown, diets low is phosphorus have been shown to increase the risk for calcium oxalate urolithiasis in dogs, which could be due to lowering of urinary pyrophosphate along with other factors (see Role of Diet, following).[39,60]

Nephrocalcin, synthesized by renal proximal tubular cells and the medullary thick ascending limb, is a potent inhibitor of calcium oxalate monohydrate crystal aggregation.[61] Urine from humans who form calcium oxalate uroliths contains nephrocalcin that lacks γ-carboxyglutamic acid and is tenfold less effective at inhibiting calcium oxalate monohydrate crystal aggregation than nephrocalcin from normal urine.[61] Lulich and colleagues[40] reported that urine from dogs with calcium oxalate contained different fractions of nephrocalcin than urine from normal beagles, which could also support a role for lack of this inhibitor in the pathogenesis of calcium oxalate urolith formation in dogs.

1859

1860

Tamm-Horsfall mucoprotein, synthesized by the medullary thick ascending limb and the distal tubule, is another potent inhibitor of calcium oxalate aggregation.[8,62] The self-aggregated form of Tamm-Horsfall mucoprotein, which is the predominant form of this protein in the urine from humans with calcium oxalate nephroliths, is a less effective inhibitor of calcium oxalate crystal aggregation and may even promote calcium oxalate crystallization.[63] The role of Tamm-Horsfall mucoprotein in dogs with calcium oxalate uroliths is unknown.

267.5.2.5 Concurrent Medical Conditions

Hyperadrenocorticism is associated with calcium oxalate urolithiasis in humans and dogs.[8,64] In humans, glucocorticoid excess leads to hypercalciuria secondary to increased mobilization of calcium from bone.[8] Glucocorticoids may also decrease tubular resorption of calcium, resulting in hypercalciuria and increasing the risk of calcium oxalate urolithiasis. Chronic metabolic acidosis may contribute to calcium oxalate urolithiasis in humans and dogs.[8,65] The proposed mechanism is buffering of excess hydrogen ions by bone phosphorus and carbonates. The calcium concurrently released from the bone during buffering is excreted in the urine, resulting in hypercalciuria. Acidosis also reduces the urinary excretion of citrate, a potent inhibitor of calcium oxalate.

267.5.3 Treatment of Calcium Oxalate Urolithiasis

Calcium oxalate uroliths are not amenable to medical dissolution; therefore they must be mechanically removed from the urinary tract (see previous section for details). Once urolith removal is performed, postprocedural radiographs or cystoscopy should be performed to document complete urolith removal so that the efficacy of preventative measures can be accurately assessed. Incomplete surgical removal of uroliths has been reported in up to 20% of dogs in one series.[66]

267.5.4 Prevention of Calcium Oxalate Urolithiasis

Calcium oxalate uroliths tend to recur in most dogs, with recurrence rates of up to 50% within 3 years of initial diagnosis.[67,68] Therefore preventative measures such as diet and medications should be used to reduce the risk of recurrence. Once all uroliths have been removed and before initiation of preventative measures, a baseline database should be obtained, including serum biochemistry profile (to examine for hypercalcemia, metabolic acidosis, or support for concurrent hyperadrenocorticism) and urinalysis (to determine urine specific gravity [USG], pH and crystalluria). Dietary changes should be attempted, and the clinician should add medications if persistence of calcium oxalate crystalluria or recurrence of calcium oxalate urolithiasis is noted.

267.5.4.1 Role of Diet

Increased water intake though feeding a canned diet or by adding water to the diet may be the most important recommendation to help prevent recurrence of calcium oxalate urolithiasis in dogs.[39,40,42] Increased water intake is also a long-standing recommendation for prevention of urolithiasis in humans.[8] Increased water intake results in dilution of calculogenic substances in the urine and increases the frequency of voiding, which helps remove any free crystals that form in the urinary tract. In normal miniature schnauzers, increasing dietary moisture from 7% to 73% increased net daily water intake and reduced urine calcium oxalate RSS, which is suggested to reflect decreased risk of calcium oxalate urolithiasis.[69] In an epidemiologic study, canned canine diets significantly reduced the risk for calcium oxalate urolithiasis compared with dry diets.[39,60] Addition of water to the diet or changing to a predominantly canned diet should be implemented as the first step in prevention of calcium oxalate urolithiasis in dogs.

The ideal diet for prevention of calcium oxalate urolithiasis in dogs is unknown, and most dietary recommendations have been made based on surrogate end points (such as changes in urine concentration of calcium, 24-hour urinary calcium and oxalate excretion or calcium oxalate RSS), rather than reduction of urolith recurrence rates. The dietary factors thought to contribute to calcium oxalate urolithiasis in dogs are undergoing substantial change, with several conflicting recommendations in the literature. Previously, dietary factors hypothesized to decrease the risk of calcium oxalate urolithiasis in dogs included reduced dietary levels of protein, sodium, and oxalate precursors and higher dietary water, calcium, phosphorus, and potassium content.[16,42] In contrast, recent epidemiologic studies indicate that dietary factors in dogs associated with an decreased risk of calcium oxalate urolithiasis included increased dietary water, protein, calcium, phosphorus, magnesium, sodium, potassium, chloride and decreased dietary carbohydrate content.[39,60] In addition, dry diets that resulted in increased acidification of the urine were associated with an increased risk of calcium oxalate urolithiasis.[39,60] These were epidemiologic studies of commercial diets; thus there may have been significant confounding effects such that an apparent benefit from one factor, such as increased dietary protein, could actually have been due to other factors, such as increased phosphorus or potassium content of the diet rather than the protein content per se, because diets high in protein also tend to be high in phosphorus and potassium. Likewise, these associations do not prove cause and effect.[70]

Although diets designed for dogs with renal failure have been recommended previously for prevention of calcium oxalate urolithiasis, because these diets are phosphorus restricted, the authors do not recommend their use for this purpose. Reduced dietary phosphorus was associated with increased risk of calcium oxalate urolithiasis in dogs.[39,60] Dietary phosphorus restriction promotes increased intestinal absorption of calcium, with the excess calcium excreted in the urine. The increased intestinal calcium absorption occurs because dietary phosphorus binds calcium making it less available for absorption. Deficient dietary phosphorus also increases renal production of calcitriol, which promotes intestinal absorption of calcium and phosphorus.[40] Additionally, increased dietary intake of phosphorus is thought to increase urinary excretion of pyrophosphate, an inhibitor of calcium oxalate crystallization.[40]

Because humans and dogs with absorptive hypercalciuria have reductions in urinary calcium when dietary calcium is restricted, it was previously recommended to restrict dietary calcium. However, recent studies in humans and dogs indicate that dietary calcium restriction actually increases the risk of calcium oxalate

urolithiasis.[39,60,71] The proposed mechanism for this apparent paradox is that reduced dietary calcium results in increased dietary absorption of oxalate because less calcium is present in the intestinal lumen to bind oxalate. Increased intestinal oxalate absorption causes greater urinary oxalate excretion, which increases the risk of calcium oxalate urolithiasis. Therefore calcium oxalate preventative diets should not be calcium restricted. Although diets should be replete in calcium, calcium supplements between meals should be avoided because they may promote hypercalciuria and increase the risk of calcium oxalate urolithiasis.[72]

Because dry diets designed to maximize urine acidity were associated with a threefold greater risk of calcium oxalate urolithiasis and some authors have reported an association of acidic urine pH with calcium oxalate urolithiasis,[39,42,60] calcium oxalate preventative diets should not be maximally acidifying. Some diets recommended for prevention of calcium oxalate urolithiasis (e.g. Prescription diet u/d, Hill's Pet Nutrition) contain potassium citrate for the purpose of alkalinizing the urine, whereas other diets do not (e.g., Waltham® Canine S/O Lower Urinary Tract Support Diet, Waltham). Some authors have recommended targeting a urine pH of 6.5 to 7.5,[42,65] whereas others suggest urine pH of 5.5 to 6.0.[47] The solubility of calcium oxalate is not greatly influenced by urine pH, but because of the potential for acidosis promoting hypercalciuria, the authors currently recommend a target urine pH of at least 6.5 to 7.0. Urine pH greater than 7.5 may promote formation of calcium phosphate uroliths and should be avoided.[53]

1860

1861

Currently the ideal protein content of diets for prevention of calcium oxalate urolithiasis in dogs is not known. Although dietary protein restriction has been recommended in the past,[65] the recent epidemiologic association of higher levels of dietary protein with decreased risk of calcium oxalate urolithiasis has caused re-evaluation of this recommendation.[39,60] The apparent benefit of increased dietary protein could have been due to other factors in the higher protein diets such as higher phosphorus content. In humans, increased dietary protein intake increases the risk of calcium oxalate urolithiasis through increased urinary uric acid excretion and contributes to increased bone buffering of acid derived from catabolism of the excess amino acids, thus promoting hypercalciuria.[8] Because dogs have lower urine uric acid concentrations and because the net acidification of canine diets can be controlled independent of protein content, dietary protein may not have the same effects on recurrence of calcium oxalate urolithiasis in dogs compared with humans.

The ideal dietary sodium content for prevention of calcium oxalate urolithiasis is also controversial. Dietary sodium restriction has previously been recommended based on the hypothesis that minimizing natruresis would concurrently minimize hypercalciuria.[65] However, recent epidemiologic studies associated higher dietary sodium with decreased risk of calcium oxalate urolithiasis.[39,60] In another study using normal dogs, increased dietary sodium (0.3 g of sodium per 100 kcal) reduced urine calcium oxalate RSS, compared with a low sodium diet (0.05 g of sodium per 100 kcal).[47,69] These authors have suggested that calcium oxalate preventative diets should not be sodium restricted or overly sodium supplemented. In a different study in normal dogs, increased dietary sodium increased total urinary calcium and sodium excretion per day, but it decreased the urinary calcium *concentration* because of the diuretic effects of increased dietary sodium.[60] Because crystallization risk is more affected by urinary concentration of calcium and oxalate than the amount excreted per day, the dilutional effects of higher dietary sodium may offset the tendency toward hypercalciuria.

The commercial diets most often recommended to reduce the risk of calcium oxalate urolithiasis include Waltham® Canine S/O Lower Urinary Tract Support Diet and Hill's Prescription diet u/d®.[47,65,67,73] Diets with high fat content such as Prescription diet u/d® should be avoided in dogs with history of pancreatitis,

obesity, diabetes mellitus, or hyperlipidemia. An alternative diet suggested for these animals is Hill's Prescription diet w/d® with supplementation of oral potassium citrate to achieve a urine pH of 6.5 to 7.0.[67] Urine RSS was substantially reduced when 17 dogs with calcium oxalate urolithiasis were fed Waltham® Canine S/O Lower Urinary Tract Support Diet.[73] Reduced RSS is suggested to reflect decreased risk of calcium oxalate urolithiasis; however, this is a surrogate end point with the ideal end point being an actual reduction in the urolith recurrence rates. Clinical trials demonstrating reduction of recurrence rates of calcium oxalate urolithiasis are needed to verify efficacy of currently recommended diets.

267.5.4.2 Medications

Dietary therapy alone will not uniformly prevent calcium oxalate urolith recurrence. If calcium oxalate uroliths recur despite dietary therapy, if calcium oxalate crystalluria is persistent, or if both occur, medications should be considered.

267.5.4.3 Thiazide Diuretics

Thiazide diuretics are proven to reduce urinary calcium excretion and reduce the recurrence of calcium oxalate urolithiasis in humans.[8,74] In normal dogs, administration of chlorothiazide did not reduce urinary calcium excretion, although these dogs were water loaded, which may have prevented the hypocalciuric effects.[75] In contrast, administration of hydrochlorothiazide decreased urinary calcium excretion and urine calcium concentration in dogs with calcium oxalate urolithiasis.[76] The reduction in urinary calcium was greatest in dogs with the highest pretreatment urine calcium concentrations and when combined with dietary therapy using Prescription diet u/d®.

Hydrochlorothiazide (2 mg/kg orally every 12 hours) should be considered in dogs that have persistence of calcium oxalate crystalluria or recurrence of calcium oxalate urolithiasis despite diet therapy. Thiazide diuretics cause subclinical volume depletion resulting in increased proximal tubular reabsorption of sodium and calcium.[76] This effect may be blunted or prevented by increased dietary sodium content and increased water intake. Therefore the benefit of hydrochlorothiazide needs to be evaluated in conjunction with canned diets with higher sodium content.

267.5.4.4 Potassium Citrate

Potassium citrate supplementation has been shown to reduce recurrence of calcium oxalate uroliths in humans either when given specifically for hypocitraturia or when done empirically without 24-hour urine collection to determine if hypocitraturia is present.[59] In humans, oral potassium citrate increases urine pH, which causes decreased tubular resorption of citrate, thus increasing urinary citrate excretion.[8]

In the veterinary literature, conflicting opinions exist concerning the utility of potassium citrate for prevention of calcium oxalate urolithiasis in dogs. Potassium citrate supplementation has been recommended at a dose of 50 to 75 mg/kg orally every 12 hours if the urine pH is acidic or if calcium oxalate crystals are still present despite dietary therapy.[42,77] In one study with normal dogs, potassium citrate supplementation did not significantly increase the mean urinary citrate excretion; although in three miniature schnauzers, supplementation did increase urinary citrate excretion and lowered the urinary relative calcium oxalate supersaturation.[78] In another study, potassium citrate also did not increase mean

urinary citrate concentration but it did cause a dose-dependent increase in urine pH.[77] Potassium citrate supplementation would be expected to have the greatest effect on urinary citrate excretion in dogs with hypocitraturia or metabolic acidosis; however, this has not been reported. The effectiveness of potassium citrate supplementation for reducing recurrence of calcium oxalate urolithiasis in dogs has also not been reported. Nonetheless, once dietary and hydrochlorothiazide therapy have been implemented, if calcium oxalate crystalluria is persistent or calcium oxalate uroliths recur, the authors recommend potassium citrate given to effect to achieve a urine pH of 6.5 to 7.0 using a starting dose of 50 to 75 mg/kg orally, every 12 hours. If the urine pH is already above 7.0 to 7.5, then potassium citrate should not be added. The serum potassium should be initially monitored monthly during potassium citrate supplementation and the dose reduced if hyperkalemia occurs.

267.5.4.5 Vitamins

Supplementation of vitamin C or vitamin D should be avoided in dogs with calcium oxalate urolithiasis. Because vitamin C is converted to oxalate, excessive vitamin C may contribute to hyperoxaluria and increased risk of calcium oxalate urolithiasis.[8] Vitamin D supplementation increases intestinal absorption of calcium, thereby promoting hypercalciuria and increased risk of calcium oxalate urolithiasis.[8,67] Although vitamin B_6 has been recommended, no data support any benefit from vitamin B_6 for prevention of calcium oxalate urolithiasis in dogs.

1861

1862

267.5.4.6 Management of Recurrent Calcium Oxalate Urolithiasis

Because calcium oxalate uroliths recur in approximately 50% of dogs within 3 years,[68] appropriate surveillance methods should be used to document recurrences before the uroliths become too large to pass through the urethra. If recurrent urocystoliths are diagnosed early enough, many recurrences may be managed using nonsurgical methods. Although some dogs with recurrent calcium oxalate urocystoliths may be asymptomatic for extended periods of time, removal of urocystoliths is recommended to prevent urethral obstruction.

267.6 STRUVITE UROLITHIASIS

Struvite uroliths are usually composed of 100% magnesium ammonium phosphate hexahydrate, although some also contain varying amounts of calcium phosphate (termed *calcium apatite*) or calcium carbonate phosphate (termed *carbonate apatite*).[10,24,79] Struvite uroliths are commonly referred to as *infection stones* or *urease stones* because they are usually caused by UTI with urease producing organisms.[8,24] Struvite uroliths are moderately to markedly radiopaque (Figure 267-7). Although struvite uroliths may assume multiple shapes (e.g., smooth spherical, discoid) or conform to the shape of the bladder or renal pelvis, they are often faceted or pyramidal when multiple urocystoliths are present because the adjacent surfaces are smooth and flattened (see Figure 267-7; Figure 267-8). Large urocystoliths are most commonly composed of struvite. Large solitary urocystoliths may have sharp spiculated projections and assume the shape of the bladder lumen (see Figure 267-8).

267.6.1 Epidemiology of Struvite Urolithiasis

Although the incidence of calcium oxalate urolithiasis in dogs continues to increase, struvite remains the most common urolith type in dogs.[10] In 1997, 45% of all uroliths submitted to the Minnesota Urolith Center were

composed of struvite and 35% were composed of calcium oxalate.[10] Struvite uroliths are more commonly located in the LUT (95%) than the upper urinary tract (5%).[24] Struvite uroliths occur more commonly in female dogs (71% to 85% of struvite uroliths submitted to two urolith centers) than male dogs (15% to 29%).[24,42] Female dogs are affected more commonly because they are more likely to have UTIs than males.[24] Breeds most commonly affected with struvite uroliths include mixed breed dogs, miniature schnauzers, Shih Tzus, Bichon frises, miniature poodles, cocker spaniels, and Lhasa Apsos.[24] It is notable that all of these breeds except cocker spaniels and mixed breed dogs are also predisposed to calcium oxalate urolithiasis.

Figure 267-7 Abdominal radiographs from a dog with struvite urocystoliths. Reader should note the smooth surfaces where the urocystoliths contact each other.

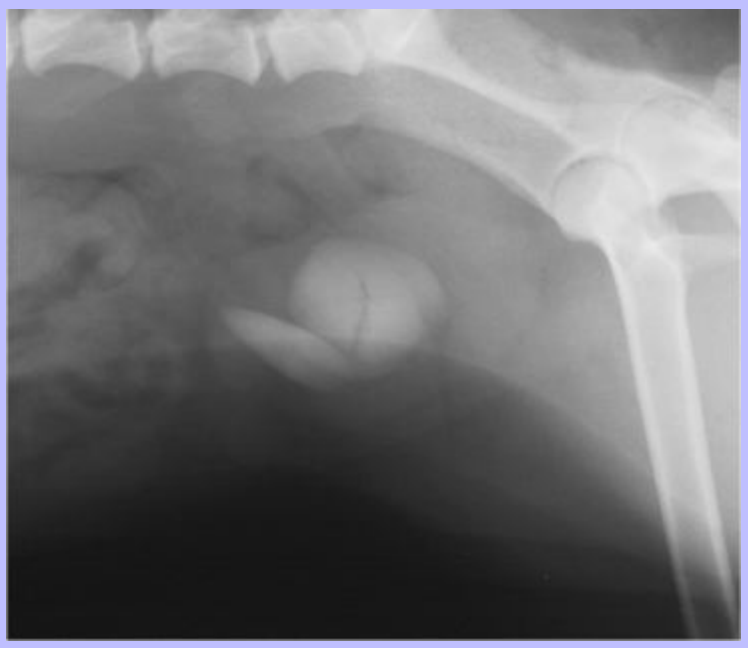


Figure 267-8 Examples of canine struvite uroliths. **A,** Spiculated solitary urocystolith. **B,** Staghorn nephrolith. **C,** Wafer-shaped urocystolith. **D,** Smooth solitary urocystolith. **E,** Pyramidal-shaped urocystoliths with smooth flat adjoining surfaces and distinct layers.

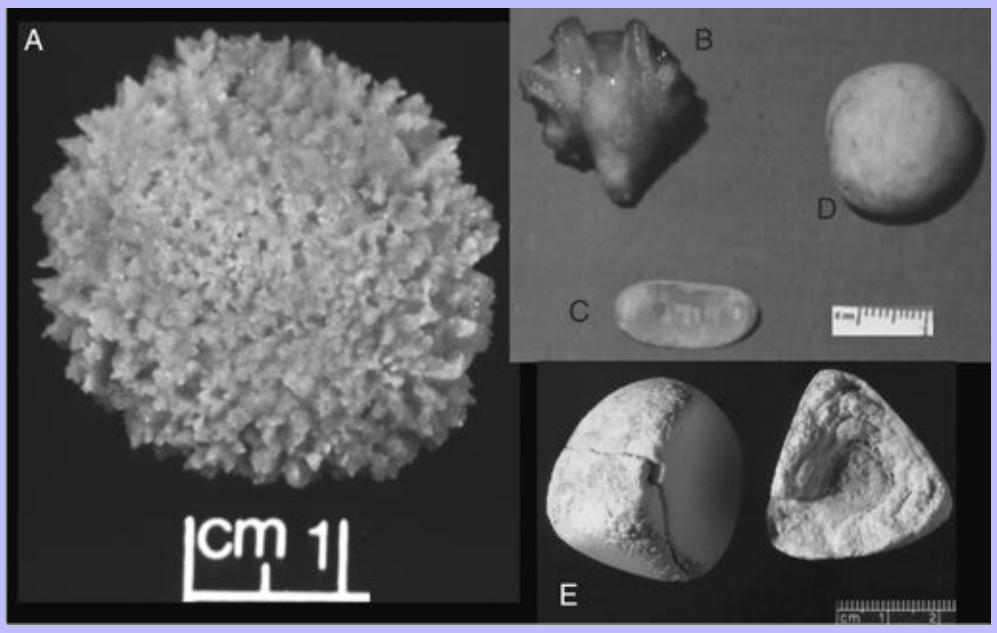


267.6.2 Etiopathogenesis of Struvite Urolithiasis

Most struvite uroliths in dogs are caused by UTI with urease-producing organisms.[24] Although recurrent, sterile struvite urolithiasis has been reported in related cocker spaniels,[80] sterile struvite uroliths are uncommon in dogs. In dogs, *Staphylococcus* spp. are the most commonly urease-producing organisms causing struvite uroliths, whereas *Proteus* spp. are the most common cause in humans.[8,24] Other urease-producing organisms that infrequently cause struvite uroliths include *Pseudomonas* spp. and *Klebsiella* spp.[24] Urease-producing mycoplasmas (termed *ureaplasma*) such as *Ureaplasma urealyticum* may also cause struvite urolithiasis.[24]

1862

1863

Urease cleaves urea (which is abundant in urine) to form ammonia and bicarbonate. The ammonium is available to combine with magnesium and phosphate, which are normally present in the urine, to form magnesium ammonium phosphate hexahydrate (struvite) crystals. The bicarbonate increases the urine pH, which decreases the solubility of struvite crystals. The ammonium also damages the urothelial glycosaminoglycan coating. This allows struvite crystals and bacteria to attach to the urothelium and may promote production of an organic matrix for crystal-matrix interaction. Attached crystals have more time to aggregate and grow into uroliths before being flushed from the urinary tract with the urine; therefore damage to the glycosaminoglycan layer promotes struvite urolith formation. Increased dietary protein increases the

urine concentration of urea and phosphorus. However, unlike in cats where struvite uroliths may occur solely due to diet, UTI with a urease-producing organism is required in most dogs.[24]

Viable bacteria are trapped in the interstices of the layers of infection-induced struvite uroliths as they grow.[8,24] Bacteria have been cultured from the core of struvite uroliths that have been stored in formalin for years.[8] Therefore dissolution or fragmentation of struvite uroliths release viable bacteria into the urinary tract and will cause reinfection unless appropriate antimicrobials are used.[8,24] Antimicrobial penetration into struvite uroliths is limited; therefore as long as struvite uroliths are present anywhere in the urinary tract, resolution of UTI is unlikely and relapses usually occur within days of discontinuation of antibiotic therapy.

267.6.3 Treatment of Struvite Urolithiasis

Treatment options for struvite urolithiasis include medical dissolution or mechanical removal. The reader is referred to the section on urolith removal techniques. It is important that the underlying UTI be controlled with appropriate antimicrobials prior to manipulation or fragmentation of infection induced struvite uroliths to minimize the risk of urosepsis. Medical dissolution of urocystoliths in male dogs is associated with a risk of urethral obstruction once the urocystoliths are small enough to pass into the urethra. Therefore the clinical signs of urethral obstruction should be thoroughly explained to the owner if medical dissolution is used. The risks and benefits of mechanical removal versus medical dissolution should be discussed with the owner before concluding which approach is best for the individual patient.

Medical dissolution of struvite urocystoliths requires a combination of appropriate antimicrobial and calculolytic dietary therapy. Antimicrobial selection should be based on urine culture and antibiotic-susceptibility testing from urine obtained by cystocentesis prior to antimicrobial therapy. Antimicrobial therapy must be given throughout the entire dissolution period because viable bacteria are contained within the interstices of each layer of struvite uroliths. Two commercial calculolytic diets are available for dissolution of struvite uroliths in dogs: (1) Hill's Prescription diet s/d® and (2) Waltham® Canine S/O Lower Urinary Tract Support Diet. Hill's Prescription diet Canine s/d® has been proven to be effective for dissolution of struvite uroliths in dogs.[24] Waltham® Canine S/O Lower Urinary Tract Support Diet was effective for dissolution of canine struvite uroliths in an *ex vivo* model, although *in vivo* efficacy has not been reported.[81] Antimicrobial and dietary therapy should continue approximately 1 month beyond radiographic resolution of struvite urolithiasis because uroliths too small for radiographic detection may still be present.

Five to 7 days after initiation of antimicrobial therapy, urine should be obtained by cystocentesis for urinalysis and culture. Urinalysis should reveal decrease of the urine pH to less than 7.0, and the urine culture should be negative for bacterial growth. If the UTI is persistent, antimicrobial therapy should be changed based on antibiotic-susceptibility testing. Monitoring of dissolution therapy should consist of abdominal radiographs and urinalyses every 4 weeks. If bacteriuria, pyuria, or inappropriate alkaline urine pH are present, the urine should be cultured for aerobic bacteria and mycoplasma. If Hill's Prescription diet Canine s/d® is being fed, several changes on the serum biochemistry profile are common. Because of the low-protein content of this diet, serum urea nitrogen (SUN) concentrations should be low or low-normal, which confirms owner compliance with the dietary recommendations. Mild decreases in serum albumin and phosphorus concentrations are commonly present within 1 month of dietary therapy.[82] Mild increases in serum alkaline phosphatase activity have also been reported in some dogs consuming this diet.[24] These changes in the serum biochemistry profile are not expected with Waltham® Canine S/O Lower Urinary Tract Support Diet.

Average time for dissolution of canine infection-induced struvite urocystoliths is approximately 3 months.[24] Even large struvite urocystoliths may be medically dissolved, although larger urocystoliths take longer to dissolve than smaller uroliths because they have less surface area relative to their volume. Many of the symptoms of LUT inflammation (dysuria and pollakiuria) resolve during the first 10 days of therapy despite the presence of the urolith, which is likely attributable to control of the UTI.[24]

A common cause of failure to effectively dissolve struvite uroliths is inadequate control of the UTI. Therefore if therapeutic attempts fail or cease, urinalysis and urine culture should be repeated. Another common cause of dissolution failure is that if the struvite urolith contains layers of calcium apatite, carbonate apatite, or calcium oxalate, this may prevent dissolution of the struvite component of the urolith.[24,42] If any of the layers of the urolith contain more than 20% of nonstruvite minerals, dissolution is unlikely to occur.[42] Another common cause of failure to dissolve suspected struvite uroliths is that the urolith is composed of another mineral other than struvite.[24,42] If medical dissolution is unsuccessful, mechanical removal of the urolith should proceed with quantitative analysis of the retrieved uroliths.

Sterile struvite urocystoliths in dogs have been successfully dissolved using calculolytic dietary therapy alone or using urinary acidifiers without calculolytic diets.[24,80] Antibiotic therapy is not required for dissolution of sterile struvite uroliths. Sterile struvite uroliths dissolve more quickly (3 to 6 weeks) than infection-induced uroliths.[24,80]

267.6.3.1 Medications

Acetohydroxamic acid (AHA; Lithostat®) is a competitive and noncompetitive enzyme inhibitor of urease. Inhibition of microbial ureases prevents the breakdown of urea to form ammonium and bicarbonate, thereby lowering the urine pH and the concentration of ammonium. AHA has been used as an adjunct to dietary and antimicrobial therapy to promote dissolution of refractory struvite uroliths at a dose of 12.5 mg/kg orally, every 12 hours. However, AHA commonly causes side effects in dogs including hemolytic anemia, anorexia, vomiting, hyperbilirubinemia, and bilirubinuria.[24] Therefore the authors do not recommend AHA therapy unless mechanical removal of the struvite uroliths also poses a significant risk. Because AHA is renally excreted, it should not be administered to dogs in renal failure. In addition, AHA should not be administered to pregnant dogs because it is teratogenic.[24]

Urinary acidifying agents such as ammonium chloride are not necessary in management of struvite urolithiasis provided a calculolytic diet and antimicrobials are used. Persistence of an inappropriately alkaline pH of the urine is usually due to failure to control the urease-producing bacterial infection. Therefore the addition of urinary acidifying drugs to the dietary therapy is unlikely to reduce the urine pH and may cause metabolic acidosis.

1863

One report exists of dissolution of sterile struvite nephroliths in two dogs using an amino acid preparation, most likely through production of acidic urine pH.[83] Dissolution of struvite urocystoliths in dogs using this amino acid preparation has not been reported.

1864

267.6.4 Prevention of Struvite Urolithiasis

The key to prevention of infection-induced struvite urolithiasis is resolution of the underlying UTI and prevention of recurrent UTI. Antibiotic therapy should be continued for 3 to 4 weeks after mechanical removal or radiographic evidence of urolith dissolution. Then urine culture should be repeated 5 to 7 days after discontinuation of antibiotic therapy. If the urine culture is negative, another urine culture should be obtained 3 to 4 weeks later to confirm resolution of the UTI. If recurrent UTIs occur, prophylactic therapy with antibiotics administered at bedtime may prevent reinfection. The reader is referred to Chapter 262 for treatment of UTI.

The role of dietary therapy for prevention of struvite urolithiasis in dogs is complex. For dogs with sterile struvite urolithiasis, dietary therapy should be used long-term to prevent urolith recurrence; however, sterile struvite uroliths are uncommon in dogs. For dogs with infection-induced struvite urolithiasis, dietary therapy designed to prevent recurrence of struvite is likely unnecessary.[42] Prevention and control of recurrent UTI is usually effective regardless of diet.[42] Many of the breeds predisposed to struvite urolithiasis are also predisposed to calcium oxalate urolithiasis. In these breeds, dietary therapy to prevent struvite urolithiasis that includes urinary acidification and magnesium restriction could potentially contribute to formation of calcium oxalate urolithiasis later in life. Diets currently available for prevention of struvite urolithiasis in dogs include Waltham® Canine S/O Lower Urinary Tract Support Diet and Hill's Prescription diet c/d®. The authors only recommend struvite preventative diets such as Hill's Prescription diet c/d® for approximately 1 month after removal or dissolution of struvite uroliths while the UTI is monitored for recurrence. Once the UTI has been resolved, the dog can be changed to a commercial adult maintenance diet. Alternatively, Waltham® Canine S/O Lower Urinary Tract Support Diet may be fed long-term in breeds predisposed to both calcium oxalate and struvite urolithiasis because it is theoretically designed for prevention of both struvite and calcium oxalate urolithiasis.

267.6.5 Dogs with Calcium Oxalate and Struvite Urolithiasis

Certain breeds of dogs are predisposed to both calcium oxalate and struvite urolithiasis including miniature schnauzers, Shih Tzus, Bichon frises, miniature poodles, and Lhasa Apsos.[24,40,43] Some of these dogs form compound uroliths with different layers composed of both calcium oxalate and struvite. Other dogs form struvite uroliths in one urolith episode and then form calcium oxalate uroliths later in life or vice versa. In both of these situations, the struvite urolith usually forms as a result of UTI with urease-producing bacteria, whereas the calcium oxalate urolith forms due to patient metabolic predispositions such as hypercalciuria. Therefore management of these dogs is by control of the struvite component via control of the UTI and designing the long-term dietary and medication recommendations to prevent calcium oxalate urolith recurrence. It has been hypothesized that these dogs may be deficient in some inhibitors of crystal formation, aggregation, or both, which predisposes them to both urolith types.[24]

267.7 PURINE UROLITHIASIS

Naturally occurring canine purine uroliths consist of uric acid (and its various salts) and xanthine. Xanthine and uric acid are successive biodegradation products in the metabolism of purines (Figure 267-9). Purine uroliths may be of pure (100%) composition, or less commonly, may contain varying amounts of other minerals. For the purposes of the following discussion, unless otherwise stated, the term *urate* includes uric acid, ammonium urate,

and the other salts of uric acid (principally sodium acid urate, sodium calcium urate, and ammonium calcium urate).

Ammonium urate is, however, by far the most commonly encountered of the urate uroliths, accounting for 86% of these uroliths,[10] and so recommendations for diagnosis, treatment, and prevention are skewed toward the management of this urolith type.

Urate uroliths are typically small, smooth, round or ovoid uroliths that are greenish-brown in color. Frequently multiple urate uroliths are present. Cutting urate uroliths in cross-section reveals concentric laminations. Xanthine uroliths are typically similar in size and shape to urate uroliths; however, they are usually yellow to brown in color. The majority of urate (97%) and xanthine (94%) uroliths that are submitted for analysis have been removed from the LUT[22]; however, nephroliths and ureteroliths may be underrepresented due to the difficulty in removing uroliths from the upper urinary tract. The size and smoothness of purine uroliths explains the relative frequency with which they cause urethral obstruction.

Urate and xanthine uroliths are generally characterized as radiolucent or only slightly radiopaque on survey radiographs (see Table 267-1). Positive-contrast studies may be required to visualize these uroliths: using an *in vitro* model, approximately 20% of ammonium urate and sodium urate uroliths were not detected on survey radiographs, although detection rates were improved if uroliths less than or equal to 1 mm in diameter were excluded from the analysis.[14] Detection rates using high-frequency (5 or 7.5 MHz) sector ultrasound scanning are better than with survey radiographs, although enumeration of uroliths is poor.[14]

267.7.1 Epidemiology of Purine Urolithiasis

Purine uroliths (predominantly ammonium urate) accounted for 8.0% of canine uroliths analyzed at the Minnesota Urolith Center between 1981 and 1997, making it the third most common type of urolith in dogs.[10] Purine uroliths may be retrieved from dogs of any age but are most frequently found in young to middle-aged animals; the average age of dogs with urate uroliths is reported to be approximately 4 years.[22] Naturally occurring xanthine uroliths are rare; most xanthine uroliths are retrieved from dogs that have been treated previously with allopurinol. Urate uroliths are most frequently retrieved from dalmatian dogs, in a recent study 61% of ammonium urate and 91% of sodium and calcium urate uroliths submitted for analysis were from dogs of this breed.[22] Pure urate uroliths occur more often in males than females.[22,35,84] This may at least in part be due to their propensity for causing urethral obstruction; it is possible that some urate uroliths are voided by bitches without being detected.

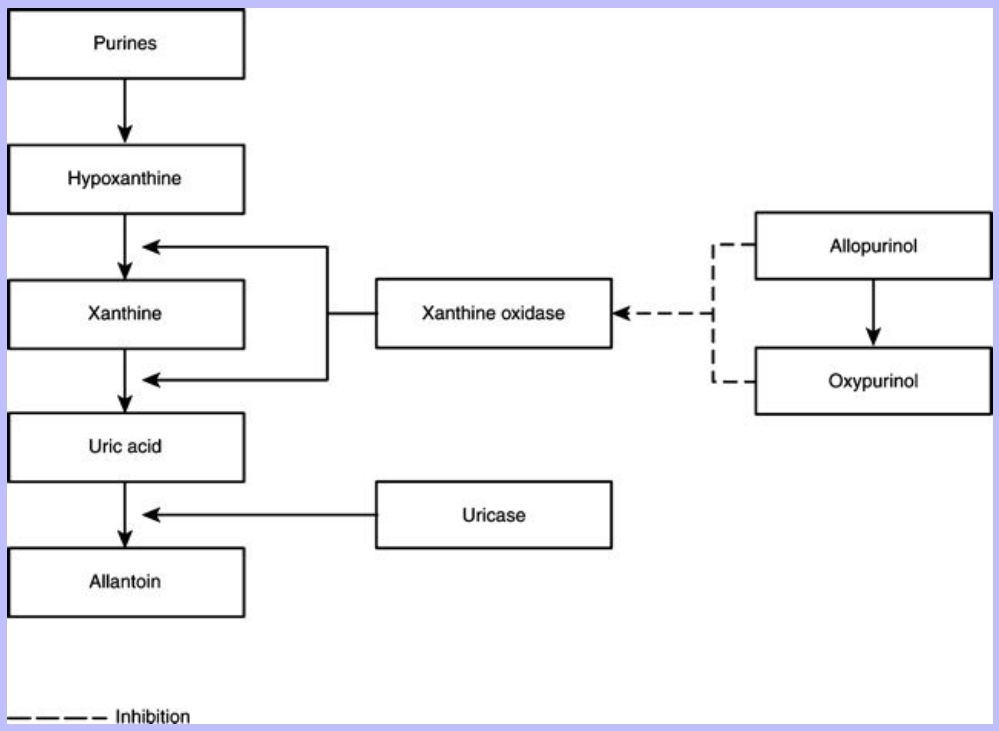
267.7.2 Etiopathogenesis of Purine Urolithiasis

The solubility of the purine metabolites, uric acid and xanthine, is much lower than that of allantoin. If urine is oversaturated with these substances, uroliths may form. Formation is promoted by a high dietary intake of purines and purine precursors and by the production of acidic urine. Production of alkaline urine decreases the risk of urate urolith formation by two mechanisms; increased solubility of uric acid and decreased production of ammonium ions.[85,86]

In human beings, infection with urease-producing bacteria may promote the formation of urate uroliths, due to the increase in ammonium ion concentration that results from hydrolysis of urea.[87] Although infection with urease-producing bacteria has been reported to occasionally contribute to formation of urate urolithiasis in

dogs, in most dogs, UTIs probably occur as a result of urolith-induced trauma or as a consequence of urinary catheterization, rather than as the cause of urolith formation.[22]

Figure 267-9 Metabolic pathway of purine degradation to allantoin showing site of action of allopurinol.



267.7.3 Dalmatian Dogs

Dalmatian dogs are predisposed to the development of urate urolithiasis due to the reduced rate at which they convert uric acid to allantoin compared with other breeds of dog, which results in 10 to 60 times greater daily urinary excretion of uric acid.[88] The uricase enzyme responsible for conversion of uric acid to allantoin is present in the liver of dalmatians in amounts comparable to those found in other breeds.[89] It is hypothesized that the reduced purine metabolism in dalmatians occurs because of a defective hepatic cell membrane transport system for uric acid.[90] The excretion of uric acid by dalmatians is increased further due to a reduced proximal tubular reabsorption of uric acid compared with other dogs.[91] Although all dalmatians excrete relatively large quantities of uric acid in their urine, not all form urate uroliths. Whether the risk for urolith formation in dalmatian dogs is solely related to the concentration of uric acid in the urine, or whether additional factors such as decreased crystallization inhibitors play a role, has yet to be definitively established. In one study, stone-forming dalmatian dogs had significantly lower urinary concentrations of Tamm-Horsfall protein than dalmatian dogs that had not formed uroliths.[92]

267.7.4 Hepatic Dysfunction

Severe hepatic dysfunction due to any cause may result in urate uroliths formation; however, the incidence of urate urolithiasis appears to be higher in dogs with portal vascular anomalies than with other causes of hepatic dysfunction.[93] Urate urolithiasis has also been reported in three miniature schnauzers with microvascular dysplasia.[22] The predisposition of dogs with hepatic dysfunction to urolith formation is presumably due to hyperammonuria and hyperuricuria, which result from a reduced ability to convert ammonia to urea and uric acid to allantoin, respectively.

267.7.5 Non-Dalmatian Dogs

Approximately 30% to 60% of urate uroliths submitted for analysis are retrieved from dogs other than dalmatians.[22,44] Many of these dogs do not have detectable hepatic dysfunction, and the reasons for lithogenesis are unknown. The breeds of dogs that, in addition to the dalmatian, are reported to have an increased incidence of urate urolith formation are English bulldogs, miniature schnauzers, Shih Tzus, and Yorkshire terriers.[44,84,94]

267.7.6 Xanthine Uroliths

The most common cause of xanthine uroliths in dogs is therapy with allopurinol, particularly if the dietary consumption of purines is high.[95,96] Xanthine is an intermediary in purine metabolism that is converted to uric acid by the action of the enzyme xanthine oxidase. This enzyme, which also catalyzes the conversion of hypoxanthine to xanthine, is inhibited by allopurinol (see Figure 267-9). Hereditary xanthinuria is a rare disorder that occurs in human beings with a deficiency in xanthine oxidase. Spontaneously occurring xanthine uroliths have been described in Cavalier King Charles spaniels and dachshunds, which were suspected, but not proven, to have a deficiency of xanthine oxidase activity.[97,98]

267.7.7 Treatment of Purine Uroliths

Urate uroliths are amenable to medical dissolution; however, in some circumstances this will not be the most appropriate mode of therapy, and direct surgical or nonsurgical removal of the uroliths is preferable. Obstruction of the urinary tract (if present) has to be relieved before medical dissolution can be attempted, and owners must be counseled that the risk of reobstruction is high.

1865

1866

267.7.8 Dietary Modification

Dietary modification may promote dissolution of urate uroliths in four ways: (1) decreasing the urinary excretion of uric acid, (2) decreasing the urinary excretion of ammonium ions, (3) urinary alkalinization, and (4) augmentation of urine volume. Reduced excretion of uric acid is achieved by feeding a diet that has a very low content of purine and purine precursors. Diets designed for urate dissolution are therefore restricted in protein content and more specifically contain no fish or glandular organs, which are particularly high in purine content. Protein sources that are relatively low in purine precursors include eggs and dairy products. Restricting protein content also reduces ammonium ion excretion by decreasing the amount of urea generated. In one study in normal beagles, increasing the protein content of the diet by adding casein, a protein source

low in purines, doubled the urine saturation with ammonium urate.[99] Diets containing very low-protein content are unsuitable for feeding to growing, pregnant, or lactating animals. Homemade diets[22] and modifications of commercially available diets[100] have been published and may be more appropriate for feeding to growing animals, but the effectiveness of these diets in dissolving urate uroliths has not been systematically evaluated.

Alkaline urine contains very low concentrations of ammonia and ammonium ions, thus reducing the risk of ammonium urate formation. Production of alkaline urine is favored by eating a diet that is low in protein content.[101] The target urine pH for dissolution of urate uroliths is approximately 7.0. To achieve this goal, in addition to consumption of a low-protein diet, urinary alkalinizing agents are generally required. The agents that are most often used are sodium bicarbonate (25 to 50 mg/kg every 12 hours) and potassium citrate (50 to 150 mg/kg every 12 hours) with the dose titrated to produce the desired urine pH. Producing urine that has pH greater than 7.5 is not desirable because this may favor the formation of calcium phosphate uroliths.

For dissolution of urate uroliths, as with all urolith types, feeding a canned diet in preference to dry, or adding supplemental water to the diet is likely to be beneficial due to the resulting increase in urinary volume. Feeding a protein-restricted diet also impairs urine-concentrating capacity by decreasing the medullary concentration gradient (due to the low urea concentration). Other methods for augmenting urine volume are controversial. Adding salt to the diet increases urine output but has not been routinely recommended due to concerns that it increases urinary calcium excretion and may promote the formation of calcium-containing uroliths; however, recent studies refute this view (see the section on calcium oxalate urolithiasis).

Only one commercial diet is marketed specifically for the dissolution of urate uroliths: Prescription Diet Canine u/d®; Hill's Pet Nutrition. This diet has very low-protein content (10% to 13% dry matter, 2.4 to 2.8 g/100 kcal of metabolizable energy) and contains potassium citrate and calcium carbonate for urinary alkalinization, resulting in a urine pH of 7.0 to 7.5. Further alkalinization of this diet is generally not required. In a clinical study of 25 dogs with ammonium urate uroliths fed this diet and treated with allopurinol according to a previously published protocol,[102] complete dissolution occurred in nine dogs (36%), partial dissolution in eight dogs (32%), and no dissolution occurred in eight dogs (32%).[22] Similar results were reported when this diet was used for dissolution of sodium urate uroliths. Feeding of this diet has infrequently been associated with the development of dilated cardiomyopathy in dalmatians.[103]

The risk for development of cardiomyopathy may be increased in some non-dalmatian breeds of dogs, particularly English bulldogs, perhaps through development of carnitine deficiency.[22] Until further information is available, severely protein-restricted diets should only be used cautiously and fed for as short a period as possible in English bulldogs.

267.7.9 Xanthine Oxidase Inhibitors

Allopurinol is a synthetic isomer of hypoxanthine that inhibits the action of xanthine oxidase resulting in decreased uric acid production (see Figure 267-9). Allopurinol has a dose dependent half-life of 2.5 to 3.0 hours in dogs, although its major metabolite, oxypurinol, which is also an effective inhibitor of xanthine oxidase, has a longer half-life of 3 to 5 hours.[104,105] The bioavailability of allopurinol is not altered by administration with food.[104] The recommended dose of allopurinol for the dissolution of urate uroliths is 15 mg/kg every 12 hours.[106] Allopurinol and its metabolites are excreted via the kidney, so the dose should be reduced in patients with renal failure.

A variety of adverse reactions to allopurinol have been reported in humans. These are commonly minor and self-limiting, including gastrointestinal (GI) disturbances, pruritus, and development of a rash, but occasionally a life-threatening hypersensitivity reaction develops, characterized by fever, eosinophilia, hepatitis, renal failure, and erythema multiforme or toxic epidermal necrolysis.[107] Most human patients that develop the hypersensitivity syndrome have evidence of renal impairment prior to treatment with allopurinol, so this drug should be used cautiously in dogs with known renal insufficiency. Rare reports of adverse reactions in dogs receiving allopurinol exist, including hemolytic anemia and trigeminal neuropathy in one dog[108] and cutaneous erythema in a dalmatian receiving allopurinol and ampicillin.[22] Discontinuation of the ampicillin but not the allopurinol resulted in resolution of the skin lesions.[22]

The most commonly reported adverse effect of allopurinol therapy in dogs is development of xanthine uroliths, either in pure form or due to an outer shell of xanthine forming around pre-existing urate uroliths.[96,106] Xanthine urolithiasis is likely to occur if dogs are treated with allopurinol while receiving a nonpurine-restricted diet. Clinicians can sometimes dissolve xanthine uroliths by discontinuing allopurinol and instituting a low-purine diet.[106]

267.7.10 Portal Vascular Shunts

The surgical amelioration of portal vascular anomalies is expected to resolve hyperuricuria and hyperammonuria with the resultant dissolution of ammonium urate uroliths. However, no systematic studies have been performed to determine how frequently dissolution occurs after surgical correction of portovascular shunts. Similarly, although anecdotal reports of dissolution of uroliths in dogs with portovascular shunts fed low-protein diets exist, no controlled studies have determined how frequently dietary therapy alone is successful.

267.7.11 Evaluating Response to Medical Therapy

Owner compliance with dietary therapy can be evaluated by checking urine pH (should be ≥7.0), USG (should be <1.015), blood urea nitrogen (BUN) concentration (<10 mg/dL in previously nonazotemic animals), urine sediment examination (no urate crystals should be seen) and monitoring urolith size and number. Use of urine uric acid/creatinine ratios in randomly collected urine samples is not recommended because the measurements correlate poorly with 24-hour uric acid excretion.[109]

267.7.12 Prevention of Purine Urolithiasis

Urate uroliths recur frequently after urolith removal or dissolution. Preventative therapy after dissolution of uroliths is directed at minimizing the urine concentration of ammonia and uric acid by feeding a low-protein diet and by urinary alkalinization. The risk of urate urolith formation may decline with age. Prophylactic treatment with allopurinol is not recommended routinely due to the risk of xanthine urolith formation.

1866
1867

Although the feeding of prescription diets to all dalmatian dogs in the absence of a documented episode of urate urolithiasis is not recommended, it is prudent to ensure that diets that favor uric acid and ammonium ion excretion (such as those high in protein, particularly fish and meat, or that are acidifying) are routinely avoided in this breed of dog.

267.8 CYSTINE UROLITHIASIS

Cystine is composed of two molecules of the amino-acid cysteine, linked by a disulfide bond. Dogs that develop cystine uroliths have cystinuria, a disease in which increased amounts of cystine (and to a variable extent other amino acids), are excreted in the urine. The solubility of cystine in the urine is low; therefore dogs with cystinuria are predisposed to urolith formation. Most canine cystine uroliths are pure, but a few contain other minerals, including struvite, urate, silicate, oxalate, or calcium apatite.[10,110,111]

Cystine urocystoliths are typically ovoid and smooth, and light-yellow to reddish-brown in color. The size of cystine uroliths is variable, but they are often small, and multiple uroliths may be present.[23] Cystine uroliths that are submitted for analysis have generally been removed from the LUT, and this urolith type is relatively frequently associated with urethral obstruction.[23] It is reported that Newfoundlands have a relatively high incidence of cystine nephroliths,[112] although this urolith type does not appear to be over-represented in nephrolith submissions as a whole.[23,113]

Although the *in vitro* radiopacity of cystine uroliths is similar to that of struvite and silica; small cystine uroliths are often difficult to visualize in giant breed dogs. If cystine uroliths are of sufficient size, they can be detected by survey radiography. Small uroliths are detected more reliably by double-contrast cystography or ultrasonography.[14]

267.8.1 Epidemiology of Cystine Urolithiasis

The prevalence of cystine urolithiasis is highly dependent on geographic location. The prevalence in the United States is only 1% to 2%,[10,110] whereas the prevalence in Europe is reportedly as high as 8% in Sweden and 26% in central Spain.[111,114]

Cystine urolithiasis occurs predominantly (98%) in male dogs,[23] although cystinuria may occur in dogs of either gender.[112] The typical age at which cystine uroliths are first diagnosed is 3 to 8 years.[115] Somewhat surprisingly, cystine uroliths are not common in very young dogs.[10] Cystine uroliths have been reported in many breeds of dog, those that are reportedly over-represented include Mastiffs, Australian cattle dogs, English bulldogs, Chihuahuas, Newfoundlands, pit bull terriers, and dachshunds.[84,110] Cystine uroliths are also found frequently in mixed breed dogs, although they are not over-represented.[23,110]

267.8.2 Etiopathogenesis of Cystine Urolithiasis

In the normal animal, cystine is freely filtered at the glomerulus and then actively reabsorbed in the proximal tubules; in cystinuric animals the carrier proteins responsible for reabsorption are defective. The disease in dogs is quite heterogeneous; with differences in both the type and quantity of amino acids excreted in the urine. The dibasic amino acids that may be lost, in addition to cystine, are ornithine, lysine, and arginine (COLA).[116] Although absorption of these amino acids from the intestine may also be reduced, this does not appear to be of any practical consequence, and clinical signs are limited to those of urolithiasis.

The mode of inheritance for cystinuria is reported to be autosomal recessive in Newfoundlands.[112] In Newfoundlands the molecular basis of the defect has been identified as a nonsense mutation in exon 2 of the

SLC3A1 (amino acid transport) gene.[117] However, in other breeds of dog with cystinuria this defect was not observed, indicating that the molecular pathogenesis of cystinuria in the dog is heterogeneous, similar to humans. Some forms of cystinuria in humans are incompletely recessive, resulting in a complex pattern of inheritance.

Cystinuria may be suspected by detection of characteristic crystals in urine, which are flat, colorless, and hexagonal, although these are not always present. If the concentration of cystine in urine is sufficiently high, the colorimetric cyanide-nitroprusside test may be used to confirm the diagnosis. The Metabolic Screening Laboratory, Section of Medical Genetics, University of Pennsylvania will perform this test on urine samples and will perform genetic screening in Newfoundlands using ethylenediamine tetra-acetic acid (EDTA) blood samples.

267.8.3 Treatment of Cystine Urolithiasis

Cystine uroliths are amenable to medical dissolution. This may be accomplished by maneuvers to reduce the concentration of cystine in the urine and to increase cystine solubility. As with all uroliths, augmenting urine volume is likely to be beneficial. Additionally, the solubility of cystine can be increased by increasing the urine pH to approximately 7.0 to 7.5, either by dietary therapy or by treatment with potassium citrate.

Feeding of a diet that is markedly protein restricted (Hill's Prescription diet canine u/d®) has been recommended because, among other potentially beneficial effects (alkalinization, sodium restriction, reduced urine concentration), this results in a 20% to 25% decrease in cystine excretion, presumably due to a reduced content of cystine precursors.[23] Feeding high-protein diets, particularly those rich in methionine, a cystine precursor, should be avoided in cystinuric dogs. However, the degree of protein restriction that is advisable is controversial because of the risk of carnitine deficiency and associated dilated cardiomyopathy in cystinuric dogs fed low-protein diets.[118] Dissolution of cystine uroliths has been reported without dietary protein restriction.[115]

Thiol-containing drugs react with cystine, resulting in its conversion to a more soluble compound by a disulfide exchange reaction; essentially, the drug is substituted for one of the cysteine residues of the cystine molecule. The prototypical thiol-containing drug used for this purpose is D-penicillamine, but this is associated with a high incidence of side effects, which effectively limits its use. Instead, the drug N-(2-mercaptopropionl)-glycine (2-MPG, Thiola; Mission Pharmacal Co, San Antonio, Texas), also known as *tiopronin*, is now more frequently used. Treatment with this drug at a dose of 20 mg/kg twice daily resulted in dissolution of approximately 60% of uroliths in one study, with the time required for urolith dissolution ranging from 1 to 3 months.[115] Unfortunately, a relatively high incidence of side effects has also been reported with this drug, including behavioral aggression, myopathy, proteinuria, anemia, thrombocytopenia, elevations of liver enzymes, and dermatologic changes.[23,115]

267.8.4 Prevention of Cystine Uroliths

Cystine uroliths frequently recur after surgical removal, with times to recurrence ranging from 1 to 36 months.[23,115] Recurrence is reportedly more likely to occur if the amount of cystine excreted is particularly high.[115] Treatment with 2-MPG, at a dose of 15 mg/kg twice daily, was successful in preventing the reformation of cystine uroliths in 76 of 88 (86%) of dogs in one study.[115] Urinary alkalinization and moderate protein restriction is likely to also be of benefit in preventing recurrence of cystine uroliths. Preventative

therapy may be titrated to maintain a negative cyanide-nitroprusside test result.[23] Because the tendency for cystine uroliths to develop decreases with increasing age, it may be possible to discontinue preventative therapy in older dogs, particularly if it has been several years since uroliths were detected.[23,115]

A few dogs receiving treatment to prevent cystine uroliths reforming have developed struvite uroliths.[115] This possibility should be considered if a urolith forms while a dog is receiving preventative therapy, particularly if it is unresponsive to 2-MPG or if UTI is present.

267.9 CALCIUM PHOSPHATE UROLITHIASIS

Most pure calcium phosphate uroliths in dogs are composed of hydroxyapatite; brushite (calcium hydrogen phosphate dehydrate) is less common and whitlockite (calcium orthophosphate) is rare.[53] Hydroxyapatite is also a common component of uroliths predominantly composed of struvite, with the hydroxyapatite either mixed throughout the urolith or as a distinct layer (sometimes an outer shell) within the urolith. Brushite uroliths tend to occur as multiple smaller urocystoliths with either a smooth round surface or a pyramidal shape (see Table 267-1), whereas hydroxyapatite occur as multiple small uroliths with variable surface characteristics. Calcium phosphate uroliths are moderately to markedly radiopaque on abdominal radiographs, thus they can be readily diagnosed with high-quality abdominal radiographs. Because of their size and shape, they often cause urethral obstruction.

267.9.1 Epidemiology of Calcium Phosphate Urolithiasis

Pure calcium phosphate uroliths are uncommon in dogs, comprising only 0.3% to 0.6% of uroliths submitted to the Minnesota Urolith Center per year.[10,53] Breeds most commonly affected with calcium phosphate uroliths include the Yorkshire terrier, miniature schnauzer, Bichon friese, Shih Tzu, Springer spaniel, Pomeranian, miniature poodle, and cocker spaniel.[53] For pure brushite uroliths, male dogs (75%) are more commonly affected than female dogs (24%), whereas with hydroxyapatite, male dogs are only slightly more commonly affected (52%) than female dogs (48%).[53]

Although pure calcium phosphate uroliths are uncommon, calcium phosphate occurs as a part of many uroliths that are predominantly composed (>70%) of struvite or calcium oxalate.[35] Viewed in this manner, calcium phosphate–containing uroliths are the third most common type of urolith.[35] However, the majority of uroliths that contain minor amounts of calcium phosphate are usually classified based on their major crystalline component of struvite or calcium oxalate.[8,10]

267.9.2 Etiopathogenesis of Calcium Phosphate Urolithiasis

Calcium phosphate saturation in the urine is affected by the concentrations of calcium and phosphate, the urine pH, and inhibitors of the calcium phosphate crystal system.[8,53] Alkaline urine pH decreases the solubility of hydroxyapatite and may contribute to calcium phosphate urolith formation. Excessive urinary alkalinization (>7.5) in an attempt to prevent calcium oxalate or other type of uroliths in dogs may contribute to the formation of calcium phosphate uroliths. Excessive urinary excretion of calcium (hypercalciuria) and phosphate (hyperphosphaturia) also results in an increased risk of calcium phosphate urolith formation.

Calcium-containing uroliths have been reported to occur in 30% to 40% of dogs with primary hyperparathyroidism.[51,52] Primary hyperparathyroidism results in hypercalcemia, hypophosphatemia, hyperphosphaturia, hypercalciuria, and alkaline urine pH.[51,52] The combination of increased urinary excretion of calcium and phosphate increases the degree of saturation of calcium phosphate predisposing to urolith formation. The increase in urine pH lowers the solubility of calcium phosphate. Uroliths from dogs with primary hyperparathyroidism may be composed of either calcium phosphate, calcium oxalate, or mixtures of calcium oxalate and calcium phosphate, with calcium phosphate being most common.[51,53]

In humans and cats, chronic hypercalcemic disorders other than primary hyperparathyroidism may cause hypercalciuria, thereby predisposing to calcium oxalate or calcium phosphate uroliths.[8,119–121] However, hypercalcemic disorders, other than primary hyperparathyroidism, that cause hypercalciuria rarely result in calcium-containing uroliths in dogs. Similarly, almost all humans with hypercalcemia who form uroliths have primary hyperparathyroidism.[8] Hypercalciuria in dogs without primary hyperparathyroidism more commonly results in calcium oxalate urolithiasis.

Although renal tubular acidosis is a common contributing factor to formation of calcium phosphate uroliths in humans, this has not been documented in dogs.[8,53,122] Struvite urolithiasis has been reported in two dogs with renal tubular acidosis.[122]

Dogs with urinary tract hemorrhage may develop blood clots that become mineralized with calcium phosphate.[53] These may not be true calcium phosphate uroliths even though the mineral component is composed of calcium phosphate, because they probably do not contain the same matrix proteins or ultrastructure as typical calcium phosphate uroliths.

267.9.2.1 Inhibitors of Calcium Phosphate

Urine contains substances that act to inhibit precipitation or growth of calcium phosphate crystals including pyrophosphates, citrate, magnesium, and nephrocalcin.[53] In urine, citrate forms complexes with calcium that are more soluble than calcium phosphate, lowering the ionic calcium concentration. The reader is referred to Inhibitors of Calcium Oxalate in this chapter for additional information on these inhibitors.

267.9.3 Treatment of Calcium Phosphate Urolithiasis

Calcium phosphate uroliths have been reported to dissolve in a few dogs after parathyroidectomy for treatment of primary hyperparathyroidism.[53] How frequently this occurs is unknown. Because calcium phosphate uroliths are frequently multiple small uroliths, waiting for spontaneous resolution of urocystoliths does carry an inherent risk of urethral obstruction. Therefore urolith removal by surgical or nonsurgical methods should also be considered.

267.9.4 Prevention of Calcium Phosphate Urolithiasis

The emphasis in prevention of calcium phosphate uroliths should initially be to diagnose and treat any underlying or predisposing conditions. The patient should be evaluated for evidence of primary hyperparathyroidism, hypercalcemia, hypercalciuria, hyperphosphaturia, or inappropriately alkaline urine pH. If dietary therapy, potassium citrate therapy, or sodium bicarbonate therapy have been used previously to

alkalinize the urine and prevent another type of urolith, a neutral urine pH should be the target. However, the urine should not be acidified because this increases the risk of calcium oxalate urolith formation, which is more common in dogs.

The optimal preventative diet for prevention of calcium phosphate uroliths in dogs is unknown. As with all urolith types, increasing net water intake through feeding a canned diet is likely to be the most important dietary factor. At present, the authors offer similar dietary recommendations to those for prevention of calcium oxalate urolithiasis for dog with calcium phosphate uroliths. The main caution is to avoid excessive alkalinization of the urine, which may occur with some diets used for prevention of calcium oxalate uroliths.

267.10 SILICA UROLITHIASIS

Silica (silicon dioxide) uroliths are relatively infrequently diagnosed, accounting for just 0.9% of specimens submitted to the Minnesota Urolith Center.[10] The mean age of affected dogs was 7.2 ± 3.1 years (range 1 to 17 years) and most (93%) of the affected dogs were male. Silica-containing nephroliths are rarely encountered in dogs from the United States,[10,113,123] although a very high prevalence of silica-containing nephroliths without accompanying cystoliths has been reported to occur in native Kenyan dogs.[124] Although many silica uroliths are pure, some are composed of multiple distinct layers, with oxalate and struvite being the most common additional minerals.[123] This observation has relevance when breed risks are considered; German shepherd dogs and Old English sheepdogs are at increased risk for developing silica uroliths, and when these develop they are typically pure, whereas additional breeds that are over-represented (including the miniature schnauzer, Shih Tzu, Lhasa Apso, and Yorkshire Terrier) are recognized to be at high-risk for development of uroliths generally, and they commonly form uroliths that are multilayered and incorporate other mineral types.[123]

1868

1869

Most silica uroliths have a “jackstone” configuration unless an outer layer of mineral (typically struvite) masks their characteristic appearance.[125] Multiple uroliths are often present. On cross-section, silica uroliths are distinctly laminated. The radiopacity of silica uroliths is similar to that of struvite.[17]

267.10.1 Etiopathogenesis of Silica Urolithiasis

It is proposed that the development of silica uroliths occurs due to an increase in dietary intake of this mineral. Animal protein contains very low concentrations of silica. Therefore dietary sources are likely to be of plant origin or due to ingestion of soil either directly or by contamination of crops during harvesting. The plant sources that have been implicated in the pathogenesis of silica uroliths include rice and soybean hulls, which may be added to diets to provide bulk and thus aid in the management of obesity, and corn gluten feed, which is added to some poor quality pet foods as a cheap source of protein.[125] The high prevalence of silica-containing nephroliths in native dogs in Kenya is proposed to be due to either consumption of maize meal or due to a high silica content in the local groundwater.[124] Silica uroliths develop in humans that consume large quantities of antacids containing magnesium trisilicate, and this has been replicated experimentally in a beagle dog.[125]

267.10.2 Treatment and Prevention of Silica Urolithiasis

Effective protocols for the dissolution of silica-containing uroliths have not been identified. The risk of silica uroliths reforming is not well documented; in one study of silica uroliths, 12% of dogs had had a previous

episode of urolithiasis, but in most cases it was not known whether the previous urolith was also composed of silica.[123] The empiric recommendations for reducing the risk of silica uroliths reforming are to change the diet to one in which the vegetable content is limited and to avoid the ingestion of soil.[125] As with all uroliths, increased water intake should be promoted to decrease the resulting concentration of calculogenic material in urine.

267.11 UNCOMMON UROLITHS

Drugs and drug-metabolites may form uroliths of pure, mixed, or compound composition. The class of drugs that is most commonly incorporated into uroliths is the sulfonamides, although this is still a rare occurrence.[35,95] In addition, there have been single reported cases of ciprofloxacin, primidone, and tetracycline uroliths developing in dogs receiving these drugs.[95,126] A urolith composed of potassium, magnesium, and pyrophosphate (*perserite*) has been reported in a collie dog and four Persian cats.[127] The composition of this urolith is unexpected inasmuch as inorganic pyrophosphate is generally considered to be an inhibitor of urolith formation. The authors of the report speculate that formation of pyrophosphate-containing uroliths results from an enzymatic dysfunction similar to the recognized human condition of hypophosphatasia, leading to pyrophosphate supersaturation of the urine.[127]

267.12 MIXED AND COMPOUND UROLITHS

Many uroliths are impure. In fact, in one study, only 29% of specimens in females and 61% of specimens in males were composed of a single mineral substance.[35] If uroliths do not contain a predominant mineral (typically defined as >70%), they may be classified as mixed; mixed uroliths comprised 1.9% of uroliths submitted to the Minnesota Urolith Center, with an additional 6.6% of uroliths being described as compound in composition.[10] Compound uroliths are those in which distinct layers are present, with each layer having a different mineral composition. Management of compound uroliths is challenging. In principle, dissolution of compound uroliths may be achieved by first instituting protocols designed to dissolve the mineral that is predicted to form the outer layer of the urolith and then altering the protocol according to the predicted composition of the inner layer or layers. In practice, the probability that the mineral composition of each layer will be successfully predicted, and that all mineral layers will be of a type amenable to medical dissolution is quite low, thus most compound uroliths are treated surgically or removed by other nonsurgical techniques. After removal of a compound urolith, a strategy needs to be implemented to try to prevent recurrent urolithiasis. In general, the strategy is to try to prevent the reformation of whatever mineral composed the core of the removed urolith, because the outer layer or layers may not have formed had there not been a mineral substrate present on which heterogeneous nucleation could occur. Specific strategies designed to prevent the recurrence of compound uroliths of varying composition were reviewed recently.[128] The reader is also referred to the section on compound calcium oxalate and struvite urolithiasis in this chapter.

267.13 URETHRAL OBSTRUCTION

Urethral obstruction may occur due to mechanical or functional causes. Functional obstruction results from failure of coordination of urethral relaxation with detrusor contraction (reflex dyssynergia).[129,130] The reader is referred to Chapter 29 for the diagnostic approach to dogs with urinary retention.

Urethral obstruction is life threatening when complete. Dogs with urethral obstruction should be evaluated for hyperkalemia and metabolic acidosis because these may be life threatening. Common causes of urethral obstruction include urethroliths, blood clots, urethral strictures, one-way valve effects from proliferations of the urothelium such as neoplasia or proliferative urethritis, urinary bladder entrapment in perineal or inguinal hernias, and penile fractures.[25,131,132]

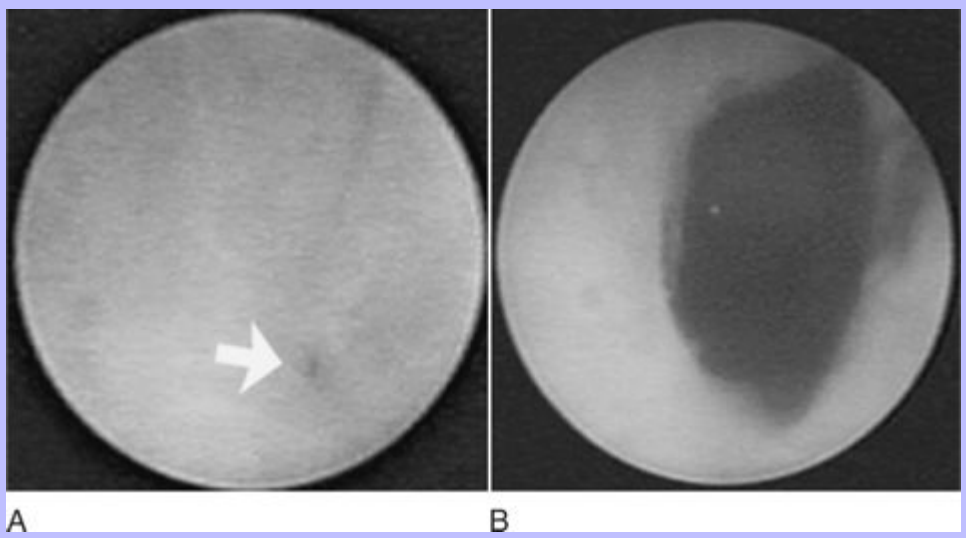
Urocystoliths small enough to fit into the urethra may become lodged in the urethra and are termed *urethroliths*. Blood clots causing urethral obstruction may originate from bleeding in the kidney or bladder.[131] Several types of neoplasia may cause urethral obstruction, including transitional cell carcinoma (most common), prostatic adenocarcinoma, leiomyoma, leiomyosarcoma, squamous cell carcinoma, myxosarcoma, and lymphoma.[133–136] The reader is referred to Chapter 188 for additional information.

Urethral strictures may form secondary to previous urethral injury from surgery, urethroliths, external trauma, or iatrogenic trauma from prior urethral catheterization. Firm polypropylene urinary catheters should not be used as indwelling urethral catheters because they often cause mucosal trauma and irritation that may lead to stricture formation.[16] Documentation of the site and extent of urethral strictures is best accomplished by positive-contrast urethrography. Although urethral strictures are often treated surgically, they may also be dilated using balloon dilation catheters in male dogs or using urethral or ureteral dilation sets in female dogs (Figure 267-10).

1869

1870

Figure 267-10 Dilation of a urethral stricture. **A,** Cystoscopic view of a urethral stricture in the proximal urethra with a diameter of less than 1 mm *(arrow)*. **B,** Cystoscopic view of the proximal urethra after dilation of the stricture to 5 mm.



Chronic inflammatory conditions (e.g., UTI, urolithiasis) may cause mucosal thickening and proliferation, which has been termed *granulomatous urethritis* or *proliferative urethritis*.[2,132] Proliferative urethritis is a more accurate description of the disease because the mucosa does not contain a granulomatous inflammatory infiltrate in all dogs, and proliferation of the urethral mucosa is commonly observed during urethrocystoscopy. The

mucosal proliferations are often bands of tissue that are connected to the urethral mucosa on each end, unlike the papillary projections of transitional cell carcinoma.[2] The mucosal proliferations cause a one-way valve effect that causes outflow obstruction but often permits retrograde passage of urethral catheters. Digital rectal palpation of dogs with proliferative urethritis reveals a thickened and firm urethra. The site of obstruction can be confirmed by voiding contrast urethrography or urethrocystoscopy. Proliferative urethritis should be differentiated from urethral neoplasia by cytology and histopathology.

Treatment of proliferative urethritis requires effective control of the UTI if this is the underlying cause. If the lesions fail to regress with adequate control of the UTI, immunosuppressive therapy with prednisone (2.2 mg/kg orally, every 12 hours) with or without cyclophosphamide may be added to antimicrobial therapy.[132] However, immunosuppression may exacerbate the underlying infection and is not consistently effective for resolving the lesions. The efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) for treatment of proliferative urethritis has not been reported. Prognosis is guarded in dogs with urethral obstruction from proliferative urethritis because some dogs fail to respond to the immunosuppressive therapy, and immunosuppression may prevent resolution of the underlying UTI. Urinary diversion via an indwelling urethral catheter or tube cystostomy may be required during initial medical therapy to bypass the urethral obstruction until the dog is able to void urine.[137,138] Surgical resection of a distal urethral obstruction and vaginourethroplasty was successful in treating proliferative urethritis in one dog.[136]

267.14 URINARY TRACT TRAUMA

Trauma to the urinary tract may be caused by blunt force (particularly in association with pelvic fractures), accidental incision during celiotomy, penetrating abdominal or perineal wounds, iatrogenic injury from improper cystocentesis technique or from rigid instruments (rigid cystoscopes, polypropylene or metal catheters), or from overdistension of the urinary bladder. Potential types of injury include contusions of the bladder or urethra, urethral tears, rupture or avulsion, urinary bladder rupture, and penile fracture.

Clinical signs of urinary tract trauma depend on the location of the trauma, duration and extent of urinary leakage, and the presence or absence of concurrent UTI. Contusions of the LUT may be asymptomatic or may cause hematuria, dysuria, and pollakiuria. Dogs with bladder or urethral rupture or urethral avulsion may be unable to urinate or may pass small amounts of bloody urine. Persistent intra-abdominal leakage of urine from a ruptured urinary bladder causes chemical peritonitis and postrenal azotemia manifested by lethargy, anorexia, vomiting, dehydration, abdominal distention, or pain on abdominal palpation. Transient urinary leakage caused by cystocentesis of an overdistended bladder, or from small rents in the urinary bladder wall as a result of overdistension during contrast cystography, does not usually cause clinical signs unless concurrent UTI is found. Bacterial peritonitis may result from even transient leakage of infected urine into the abdominal cavity.

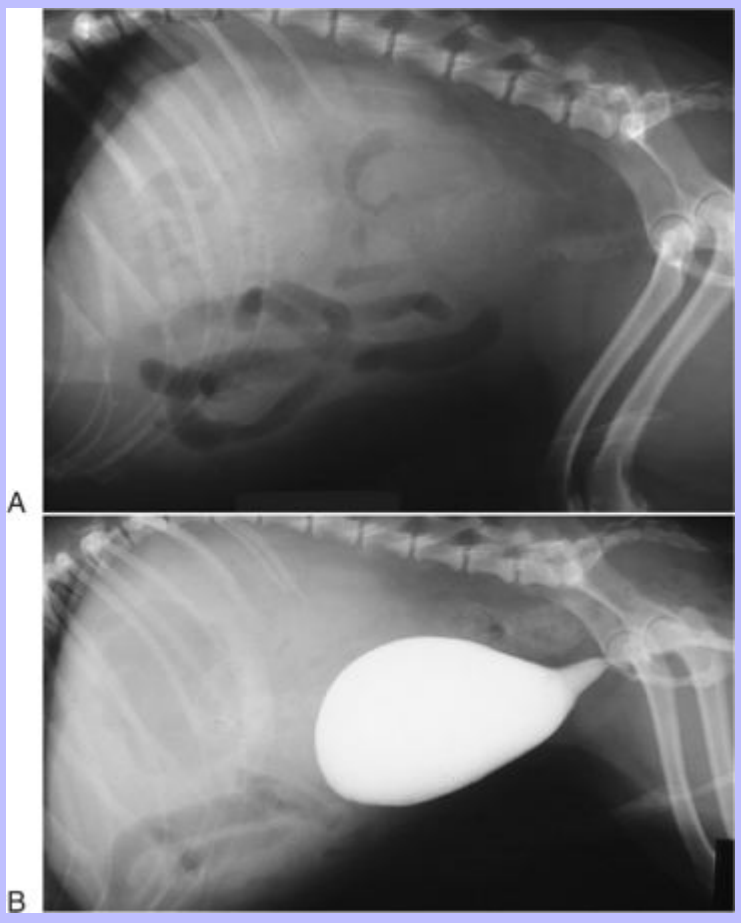
The potential for concurrent damage to the urinary tract should be considered in all dogs with abdominal, pelvic, or perineal trauma. Diagnosis of the extent and location of traumatic injury is accomplished by either positive-contrast retrograde urethrocystography or urethrocystoscopy. During contrast urethrocystography, urinary tract rupture is confirmed by either direct visualization of leakage of contrast material from the urinary tract or by increased radiopacity of the abdominal cavity compared with radiographs obtained before injection of contrast (Figure 267-11). Passage of firm polypropylene urinary catheters should be avoided if urethral tears or lacerations are suspected because the catheter tip may enlarge urethral tears. Likewise, the ability to pass a urinary catheter and obtain urine from the bladder is insufficient to rule out urethral or bladder rupture. Urethrocystoscopy allows direct visualization of the location and extent of LUT injury, but the cystoscope should only be advanced under direct visualization of the lumen. If abdominal fluid is present, determination of the creatinine concentration of the fluid and comparison to the serum creatinine concentration is recommended rather

than measurement of urea nitrogen concentrations because urea rapidly equilibrates across the peritoneum. Urinary leakage can be confirmed by finding abdominal fluid creatinine concentrations more than one and a half to twofold higher than the serum concentration.

1870

1871

Figure 267-11 Contrast urethrocystography confirming urinary leakage secondary to traumatic cystocentesis of an overdistended urinary bladder. **A,** Abdominal radiographs showing loss of intra-abdominal detail secondary to uroabdomen. **B,** Positive-contrast urethrocystogram failed to demonstrate a leak from the urinary bladder; however, the intra-abdominal fluid is more radiopaque than before filling the bladder with contrast media, confirming urinary leakage.



Surgical repair is required for treatment of large rents in the urinary bladder, urethral avulsion, and large urethral lacerations. Small tears in the urethra or bladder wall may be treated conservatively by urinary diversion using an indwelling urethral catheter or by tube cystostomy.[137,138] Such small tears usually heal within 5 to 10 days. The

healing process can be re-evaluated by positive-contrast radiography or urethrocystoscopy. Likewise, contusions of the LUT heal within 3 to 5 days and do not require specific therapy.

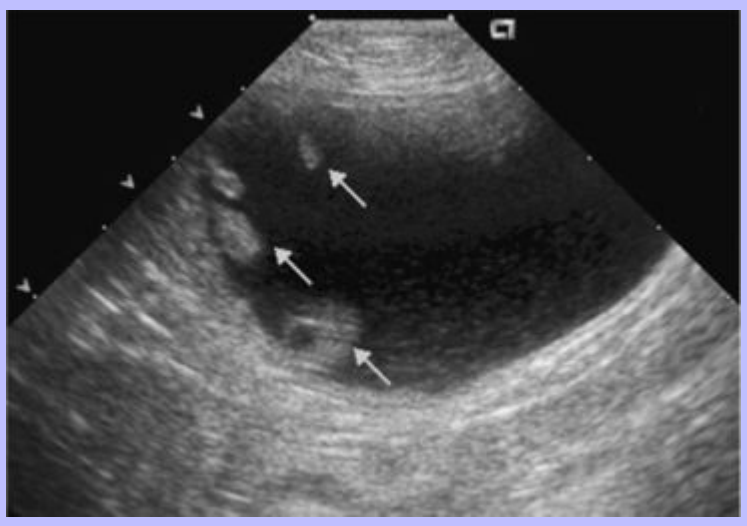
267.15 INFLAMMATORY CONDITIONS OF BLADDER AND URETHRA

Inflammation of the bladder and urethra are termed *cystitis* and *urethritis*, respectively. Most conditions causing inflammation of the LUT affect both the bladder and urethra. Clinical signs of LUT inflammation include dysuria, stranguria, pollakiuria, and hematuria. By far the most common inflammatory condition of the canine LUT is bacterial infection of the bladder and urethra. (The reader is referred to Chapter 262 for additional information about bacterial UTI.) Dogs with chronic UTI may have follicular cystitis characterized by multiple small mucosal follicles seen in the bladder, urethra, and vaginal vestibule, which are visible during cystoscopy. These follicles contain lymphoid infiltrates and they regress spontaneously with control of the UTI. Follicular cystitis must be differentiated from polypoid cystitis and neoplasia.

Fungal UTI is less commonly diagnosed than bacterial UTI, with the most common isolate being *Candida albicans*.[139] In one study, all affected dogs had concurrent illnesses or received medications that were likely to have predisposed to fungal UTI.[139] Potential reasons for development of fungal UTI in dogs include surgery or instrumentation of the urinary tract, corticosteroid administration or hyperadrenocorticism, chemotherapy, and chronic antibiotic therapy. Persistent funguria should be documented before concluding that fungal UTI is present to exclude the possibility that contamination of the sample occurred *ex vivo*. Spontaneous resolution of fungal UTI occurred in two of 13 dogs in one study.[139] Oral fluconazole, flucytosine, or both may be effective for treatment of fungal UTI caused by *Candida* spp. Although both fluconazole and flucytosine are renally excreted, some stains of *Candida* are resistant to these drugs. Unfortunately, *in vitro* susceptibility testing for antifungal drugs is not readily available. Intravesical infusions of clotrimazole may be required to resolve candidiasis of the LUT in some dogs.[140] Effective management of the underlying condition that predisposed the dog to fungal UTI is required for long-term control of infection.

Polypoid cystitis is a relatively uncommon disease of the bladder characterized by inflammation, epithelial proliferation, and development of a polypoid mass or masses without histopathologic evidence of neoplasia.[141] Polypoid cystitis probably develops due to a hyperplastic inflammatory reaction secondary to chronic irritation of the bladder from recurrent UTI or urolithiasis. Dogs with polypoid cystitis have clinical signs of hematuria or LUT inflammation such as dysuria, stranguria, and pollakiuria. Female dogs are much more commonly affected than male dogs.[141] Ultrasonographic evaluation reveals single or multiple polypoid projections into the bladder lumen without distortion of the layers of the bladder wall (Figure 267-12). Diffuse thickening of the bladder wall may occur in some cases. Cystoscopy reveals polypoid projections in the bladder, which are sometimes difficult to definitively differentiate from transitional cell carcinoma (Figure 267-13). Papillary mucosal proliferative lesions with large blood vessels that extend to the tip of the projection are more characteristic of TCC than polypoid cystitis. Polypoid cystitis occurs more commonly in the cranioventral portion of the bladder, whereas transitional cell carcinoma occurs more commonly in the trigone of the bladder; however, the location and appearance of polypoid masses alone is insufficient for differentiating these diseases. Therefore biopsies of all polyps and papillary masses should be obtained for cytology and histopathology.

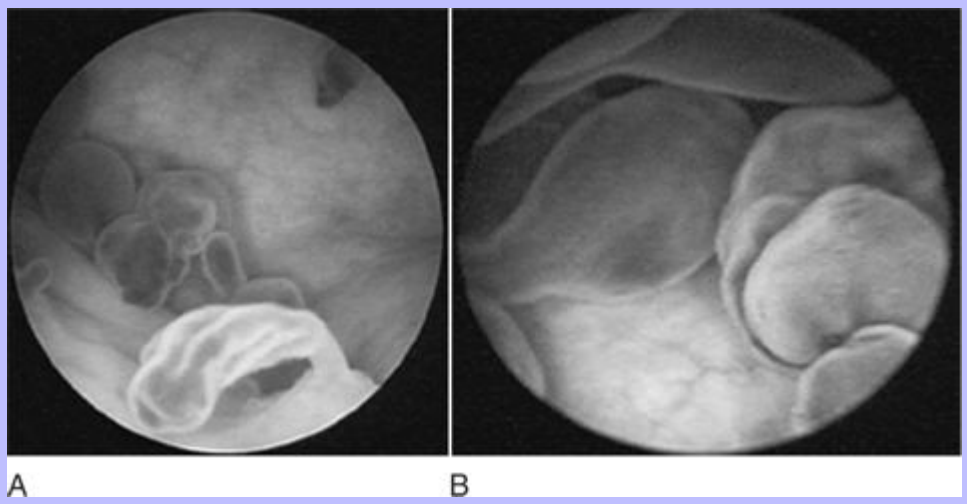
Figure 267-12 Ultrasonographic image of polypoid cystitis in a dog showing multiple polypoid projections *(arrows)* along the cranioventral portion of the bladder.



1871

1872

Figure 267-13 Polypoid cystitis and transitional cell carcinoma of the urinary bladder are sometimes difficult to differentiate visually. **A,** Cystoscopic image of polypoid cystitis from the dog in Figure 267-12. **B,** Transitional cell carcinoma of the urinary bladder of a dog.



Although effective management of UTI may result in spontaneous resolution of polypoid cystitis in a few cases, removal of the polyps by surgery or cystoscopy is required in most dogs. Surgical options include excisional biopsy of the polypoid masses or partial cystectomy of areas that are diffusely affected.[141] Cystoscopic resection of the isolated polyps may be performed using biopsy forceps, electrocautery loops, or the holmium laser.

Emphysematous cystitis is an uncommon form of bacterial cystitis characterized by gas production within the layers of the bladder wall. Emphysematous cystitis usually occurs from intramural gas production from bacterial fermentation of glucose in dogs with UTI and glucosuria. Diagnosis is made based on gas accumulation in the bladder wall visible of abdominal radiographs. Treatment involves effective treatment of the UTI and control of glucosuria.

Cyclophosphamide-induced cystitis is a sterile hemorrhagic cystitis caused by urinary excretion of acrolein, a metabolite of cyclophosphamide. Administration of furosemide concurrently with cyclophosphamide reduces the risk of cystitis developing.[142] Thiazide diuretics should not be used for this purpose because they may potentiate the myelotoxic effects of cyclophosphamide.[142] Treatment consists of discontinuation of cyclophosphamide therapy, short-term symptomatic therapy (e.g., narcotics for analgesia), and treatment of secondary UTI. Parasitic cystitis, caused by mucosal or submucosal invasion by the adult stage of *Capillaria plica*, is an uncommon disease in dogs. Capillariasis may be associated with clinical signs of dysuria, stranguria, and pollakiuria. Capillariasis is diagnosed by identification of the double-operculated ova during urinalysis. Treatment with ivermectin (0.2 mg/kg subcutaneously) eliminates the infection and improves clinical signs. In dogs that cannot be treated with ivermectin, an alternative therapy is fenbendazole (50 mg/kg orally, daily for 5 days).

267.16 URINARY INCONTINENCE

Urinary incontinence is defined as loss of voluntary control of urination resulting in leakage of urine from the urinary system to the exterior of the body. Urinary incontinence occurs either when intravesicular pressure is greater than urethral pressures (due to decreased detrusor compliance or poor urethral pressures) or due to anatomic abnormalities that bypass the normal continence mechanisms (e.g., ectopic ureters). Urinary incontinence must be differentiated from inappropriate urination associated with dysuria and pollakiuria. The reader is referred to Chapter 30 for the clinical signs and diagnostic approach to urinary incontinence. Box 267-2 lists common causes of urinary incontinence in dogs.

267.16.1 Urethral Incompetence in Female Dogs

Urethral incompetence (also called *urethral sphincter mechanism incompetence*) is the most common cause of incontinence in adult female dogs and usually occurs months to years after neutering. Congenital anatomic or functional abnormalities of the urethra may also result in urethral incompetence. Urethral incompetence frequently occurs concurrently in dogs with ectopic ureters due to malformation of the urethra (see Figure 267-1) and can result in treatment failure after surgical correction of ectopic ureters.[143]

Urethral incompetence may be confirmed by documenting decreased urethral closure pressure by urethral pressure profilometry; however, urodynamic equipment is only available at some referral hospitals. Although urodynamic confirma-tion is unnecessary in most cases, urodynamic evaluation should be considered for dogs with urinary incontinence that is unresponsive to standard treatment.[144,145] Alpha-adrenergic agonists (phenylpropanolamine, ephedrine, or pseudoephedrine) or estrogen (diethylstilbestrol or estriol) are recommended for treatment of urethral incompetence in female dogs. Phenylpropanolamine (1.1 to 1.5 mg/kg

orally, every 8 hours) is effective in approximately 85% to 90% of female dogs with urethral incompetence.[6,146] Estrogen therapy increases urethral closure pressure by increasing the density and responsiveness of α-adrenergic receptors in urethral smooth muscle. Estrogen therapy is effective in approximately 50% to 65% of female dogs with urethral incompetence.[147] Excessive doses of estrogen may cause severe bone marrow suppression; therefore owners should be cautioned not to exceed recommended doses and CBCs should be monitored in dogs receiving estrogen therapy. Diethylstilbestrol is administered at 0.1 to 0.2 mg/kg orally, daily (maximum dose 1 mg/dog) for 5 days, followed by the same dose once to twice a week. The maximum maintenance dose of diethylstilbestrol is 0.2 mg/kg/wk. The minimum effective dose should be used for maintenance.

267.16.1.1

Box • 267-2 Causes of Urinary Incontinence

Urethral incompetence

Ectopic ureters

Neurologic disorders

Urge incontinence (secondary to urinary tract infection [UTI] or uroliths)

Idiopathic detrusor instability

Paradoxic (overflow) incontinence

Ureterocele

Pelvic bladder

Ureterovaginal or urethrorectal fistula

Patent urachus

Low-dose daily estrogen using estriol has recently been suggested as an alternative to diethylstilbestrol.[148] Estriol is administered at a dose of 2 mg orally, daily for 1 week, then the dose is reduced at weekly intervals to the minimal effective dose (typically 0.5 to 2.0 mg/dog given daily or every other day). In one study of 129 dogs, there was no evidence of bone marrow toxicity when estriol was administered for 42 days.[148] Although some authors suggest that low-dose daily estrogen therapy may be more effective than weekly therapy with diethylstilbestrol, the long-term safety of low-dose daily estrogen has not been reported.

Because estrogen up-regulates the α-adrenergic receptors that phenylpropanolamine stimulates, combination therapy with these medications is synergistic. Therefore female dogs that are refractory to either medication

alone may respond to combination therapy. For dogs that are refractory to combination therapy, urodynamic evaluation is recommended. Alternative therapies for dogs with refractory urinary incontinence due to confirmed urethral incompetence include cystoscopic injections of bulk-enhancing agents (glutaraldehyde cross-linked collagen) or surgical methods to increase urethral resistance.[149–151] Periurethral injection of collagen narrows the urethral lumen and allows for more effective closure of the urethra by existing urethral pressure. Periurethral injection of collagen resolved urinary incontinence in 53% of dogs with an additional 22% that were improved with concurrent administration of phenylpropanolamine.[150] In the authors' experience, repeat cystoscopic injections of collagen are required in some dogs weeks to months after initial injections. Surgical methods for treatment of refractory urinary incontinence include colposuspension and urethropexy.[149,151,152] Surgery resolves incontinence in approximately 50% of dogs, with an additional 25% to 40% being continent with concurrent administration of phenylpropanolamine.[149,151,152] However, improvement may not be sustained with a 1-year response rate of only 14% in one study.[149]

An additional medical treatment for urinary incontinence that has been reported recently is the use of gonadotrophin-releasing hormone (GnRH) analogues.[153] Improved continence was noted for several months after the subcutaneous administration of GnRH depot preparations, even though the bitches that were treated had not responded well to other treatments. This approach was investigated because of the observation that spayed bitches have very high concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) compared with intact bitches, and the treatment was shown to decrease the concentration of these hormones.

267.16.2 Detrusor Instability and Urge Incontinence

Although urethral incompetence is the most common cause of urinary incontinence, this may also occur due to detrusor contraction during storage of urine or due to low compliance of the detrusor muscle, which may be confirmed by cystometrography.[7,145] When decreased detrusor compliance occurs secondary to inflammatory conditions affecting the LUT (e.g., urolithiasis, UTI), this is termed *urge incontinence* (see Box 267-2). Clinical signs of dogs with urge incontinence may also include pollakiuria, stranguria, and dysuria. If no identifiable cause of decreased detrusor compliance is identified, this is termed *idiopathic detrusor instability*.[7] In one study of 77 dogs with refractory urinary incontinence, 10 dogs had poor bladder storage function alone and 15 dogs had both detrusor dysfunction and concurrent urethral incompetence.[145]

Treatment of detrusor instability is by anticholinergic medications (oxybutynin, imipramine, or dicyclomine) to decrease detrusor contractions during storage of urine.[7,154] Although oxybutynin (0.2 mg/kg orally, every 8 to 12 hours) has been most commonly recommended, dicyclomine appeared to have a greater effect on detrusor compliance in normal dogs than oxybutynin.[154] Clinical effectiveness of dicyclomine has not been reported in dogs with idiopathic detrusor instability. Imipramine is a tricyclic antidepressant medication that has anticholinergic effects to facilitate urine storage and also increases urethral closure pressure. Therefore imipramine may be effective for dogs with mixed incontinence due to detrusor dysfunction and concurrent urethral incompetence.[154]

267.16.3 Urinary Incontinence in Male Dogs

Urinary incontinence occurs much less commonly in male than female dogs and urethral incompetence is a less common cause in male dogs.[155] In one study, only five of 38 incontinent males dogs had urethral

incompetence.[156] Surgical procedures involving the proximal urethra and prostate are a common iatrogenic cause of urinary incontinence in male dogs, because the proximal urethra is integral in maintaining continence in male dogs.[155] Urethral incompetence in male dogs may be treated with α-adrenergic medications (phenylpropanolamine: 1.1 to 1.5 mg/kg orally, every 8 hours) or testosterone cypionate (2.2 mg/kg intramuscularly, every 30 days). Testosterone has potential side effects including prostate disease and behavioral aggression; therefore some authors discourage use of testosterone for treatment of urethral incompetence. Unfortunately, less than 50% of dogs with urethral incompetence are responsive to phenylpropanolamine.[155] Therefore surgical correction by vasopexy is recommended in male dogs with urethral incompetence that are unresponsive to phenylpropanolamine.[157] The authors have diagnosed several male dogs with idiopathic detrusor instability that were responsive to oxybutynin; therefore urodynamic evaluation is recommended prior to surgical therapy.

267.16.4 Ectopic Ureters

The reader is referred to the chapter on Diseases of the Ureter for discussion of ectopic ureters. Ectopic ureters are commonly associated with anatomic and functional abnormalities of the bladder and urethra.[3,143,158] Urodynamic evaluation of nine dogs with ectopic ureters revealed that four of nine dogs had decreased detrusor compliance and seven of nine had poor urethral function.[143] Therefore urodynamic evaluation is recommended prior to surgical correction of ectopic ureters to aid in predicting whether the dog will be continent after surgery. Anatomic abnormalities of the urethra and vaginal vestibule are common in dog with ectopic ureters (see Figure 267-1).[3] Ureteral troughs, fenestrations, and the intramural ureter in the dorsal urethral wall may all affect the ability of the urethra to generate adequate closure pressure. Therefore some authors have suggested removal of the submucosal ureteral remnants from the trigone and urethra with reconstruction of the muscular defect caused by the resection in addition to surgical correction of the location of the ureteral opening.[158] Urinary continence is improved by this more aggressive surgical approach in dogs with multiple anatomic abnormalities.[158]

267.17 ANATOMIC ABNORMALITIES

267.17.1 Ureterocele

A ureterocele is a cystic dilatation of the terminal portion of the ureter which often protrudes into the bladder lumen.[159–161] Ureteroceles are classified as either *orthotopic* (also called *intravesical*), if the ureter opening is in a normal trigonal location, or *ectopic*, if the ureter opening is distal to the normal trigonal position. Ureteroceles may cause a variety of clinical signs depending on their size and whether or not the ureter is ectopic. Urinary incontinence is the most common clinical sign of ureteroceles.[159,160] Ureteroceles may place pressure on the bladder and proximal urethra resulting in functional urinary retention, or they may cause signs of dysuria, stranguria, and pollakiuria. Dogs with ureteroceles may also present for recurrent UTI. Although ureteroceles are congenital abnormalities, some dogs with ureteroceles do not develop clinical signs until later in life.[159] Ureteroceles may be associated with developmental or acquired abnormalities of the upper urinary tract or LUT, including moderate to severe hydroureter and hydronephrosis, ectopic ureters, and urethral anomalies. Ureteroceles are diagnosed by excretory urography or ultrasonography.[160,162]

Treatment of ureteroceles depends on the type and extent of concurrent anomalies and whether or not the ureteral opening is ectopic. Excision of the ureterocele with reimplantation of the ureter is recommended for ectopic ureteroceles or ureteroceles associated with ureteral obstruction.[159] Orthotopic ureteroceles may be incised cystoscopically or by cystotomy; however, this often results in vesicoureteral reflux that could contribute to pyelonephritis if UTI is also present.

267.17.2 Urethral Prolapse

Prolapse of the urethral mucosa through the external urethral orifice is an acquired disease of male dogs, most common in English bulldogs (Figure 267-14).[163] The proposed causes for urethral prolase include excessive sexual excitement or stranguria associated with UTI or urolithiasis.[16,163] Although small urethral prolapses may resolve spontaneously in some dogs,[16] surgical correction is required in most cases. A recently reported urethropexy technique was successful in three of three dogs and is less invasive than surgical resection of the prolapsed tissue with apposition of the urethral and penile mucosa.[163]

267.17.3 Vesicourachal Diverticula

Vesicourachal diverticula are remnants of the urachal canal between the apex of the bladder and the umbilicus. Vesicourachal diverticula usually appear as an out pouching of the bladder wall near the bladder apex that can be diagnosed by contrast cystography or cystoscopy. Dogs with vesicourachal diverticula are predisposed to recurrent UTI, presumably from incomplete emptying of the urine in the dead space of the diverticula.[164,165] Vesicourachal diverticula may resolve spontaneously if the underlying cause can be corrected.[165] Surgical removal of urachal diverticula is recommended for dogs with persistent or recurrent UTIs and for dogs undergoing surgical removal of urocystoliths.

267.17.4 Urethrorectal or Ureterovaginal Fistula

Fistulas between the urethra and the rectum or between the ureter and vagina are uncommon conditions in dogs that may be congenital or acquired.[166–169] Ureterovaginal fistulas usually form as a result of ovariohysterectomy when the ureter is accidentally included in a ligature around the vaginal stump. Urethrorectal fistulas may be congenital or may be acquired after pelvic trauma. Clinical signs of urethrorectal fistulas include passing of urine from the anus during voiding or recurrent infections of the *urogenital tract*.[168,169] Urinary incontinence is the most common clinical sign of ureterovaginal fistulas in dogs.[166,167] Surgical correction of urethrorectal or ureterovaginal fistulas is recommended; however, surgical correction of urethrorectal fistulas may be complicated by intrapelvic location and by concurrent infection. Resolution of secondary UTI is essential after surgical correction of urethrorectal fistulas and may require prolonged antimicrobial therapy.

Figure 267-14 Urethral prolapse showing eversion of the distal urethral mucosa.

267.17.5 Persistent Urachus

Persistent urachus is an uncommon congenital abnormality in dogs where the entire urachal canal remains patent from the apex of the bladder to the umbilicus. The clinical signs are dribbling of urine through the umbilicus, and secondary UTI and omphalitis are common sequela. The diagnosis can be confirmed by performing contrast radiography by gently injecting iodinated contrast into the umbilicus. Treatment of persistent urachus is by surgical removal of the urachal canal.

267.17.6 Pelvic Bladder

Pelvic bladder is a term describing urinary bladders that have a blunt-shaped trigone, with the trigone located in an intrapelvic location associated with a shortened urethra.[170] Pelvic bladder is controversial as to whether or not it is a cause of urinary incontinence or an artifact of how contrast urethrocystography is performed.[170–172] The normal urinary bladder trigone tapers and connects to the urethra in an intra-abdominal location. The degree of distention affects the location of the trigone; therefore the bladder should be properly distended during contrast urethrocystography before diagnosing pelvic bladder. Pelvic bladder may also be associated with increased incidence of UTI, although this association has not been definitively proven.[170] Although some dogs with pelvic bladders do not have urinary incontinence[171,172]; other dogs with pelvic bladders have refractory urinary incontinence without any other identifiable cause. [170,173] Diagnosis of pelvic bladder is usually made by contrast urethrocystography, although the abnormal shape of the trigone can also be detected during cystoscopy, raising suspicion of the diagnosis. The authors' approach to dogs with radiographic evidence of pelvic bladder is to rule out other abnormalities that might cause urinary incontinence (e.g., urethral incompetence, ectopic ureters). If concurrent urethral incompetence is present, combination medical therapy with estrogen and α-adrenergic agonists should be attempted prior to surgical

intervention. If the dog is refractory to medical therapy, urethropexy or colposuspension are recommended to move the bladder neck cranially.[149,151,152]

268 CHAPTER • 268 Ureteral Diseases

Lori L. Ludwig

268.1 ANATOMY AND FUNCTION

The ureters are fibromuscular ducts that carry urine from the renal pelves to the bladder. The course of the ureters is retroperitoneal, adjacent to the caudal vena cava and aorta and ventral to the psoas muscle. The ureters reach the dorsolateral surface of the bladder through the lateral ligaments and turn from a caudal to a cranial direction before they enter the bladder at the cranial border of the trigone. The degree of curvature of the ureters at the trigone depends on the degree of bladder distension. Recognition of this curvature is important in the evaluation of contrast radiographic studies and for catheterization of the ureters during surgery. Upon entering the bladder, the ureters course obliquely in the submucosa toward the bladder neck. This path through the bladder wall facilitates closure of the distal ureter when the bladder is distended with urine, preventing retrograde flow of urine from the bladder (vesicoureteral reflux).

The ureteral wall is composed of an outer adventitial layer, a muscular layer, submucosa, and a mucosa of transitional epithelium. The muscular wall of the ureter consists of an outer longitudinal, middle circular, and inner longitudinal muscle layer except at the ureterovesical junction, where only longitudinal fibers are present. During diuresis, stretching of these muscle layers can result in a seventeenfold increase in the ureteral luminal diameter.[1] The normal width of the ureteral lumen in dogs is reported to be 0.07 times the length of the second lumbar vertebra.[2]

The blood supply to the ureter arises from the renal artery cranially and from the prostatic or vaginal arteries caudally. These vessels anastomose at the level of the adventitia in the ureteral wall. The ureteral veins follow the same path as the arteries. The ureters are innervated by autonomic fibers, but this innervation is not responsible for ureteral peristalsis.[2] Ureteral peristalsis occurs when urine enters the ureter, initiating electrical impulses to be conducted between smooth muscle cells. If the peristaltic activity is initiated in the renal pelvis, urine is propelled toward the bladder. However, if peristaltic waves begin when urine enters the distal ureter because of an incompetent ureterovesical junction, urine moves toward the kidney. Because ureteral peristalsis is myogenic (not neurogenic) in origin, ureteral peristalsis persists with transplantation.

Ureteral contractions in normal dogs occur three to six times per minute.[2] The frequency of contractions increases with diuresis to a maximum point. Once the maximum frequency has been reached, the ureter dilates, and urine stasis occurs. Ureteral peristalsis also is impaired by transection and anastomosis of the ureter. Two weeks after surgery, conduction of peristaltic waves returns across the surgery site.[3] In addition, physical ureteral obstruction and some bacterial toxins can inhibit ureteral peristalsis.[4]

268.2 VESICOURETERAL REFLUX

Vesicoureteral reflux is flow of urine in a retrograde direction, from the urinary bladder into the ureters, that occurs when the intraluminal bladder pressure exceeds intraluminal ureteral pressure. This condition may result in transmission of lower urinary tract infection to the kidney.[2] It may also perpetuate lower urinary tract infection, because infected urine from the bladder refluxes into the ureter and then recontaminates the bladder when it returns from the ureter. In addition, renal parenchymal damage may result from increased intrapelvic

pressure associated with ureterectasis and transmission of voiding pressure to the renal pelvis during reflux.[2] Vesicoureteral reflux is prevented in normal animals by the long, submucosal/intravesical portion of the ureter (ureterovesical valve), which collapses as pressure in the bladder increases. Factors that may affect the functioning of the ureterovesical valve include the length, diameter, pliability, and ratio of length to width of the intravesical portion of the ureter; ureteral peristalsis, detrusor muscle function, and intraluminal pressure of the ureters or urinary bladder.[2,4]

Primary vesicoureteral reflux occurs in young dogs (7 to 12 weeks old) and may be related to intrinsic maldevelopment of the ureterovesical junction.[2] The process is usually self-limiting, because the submucosal portion of the distal ureter elongates as the dog grows. Primary vesicoureteral reflux is rare in adult dogs. Secondary vesicoureteral reflux is acquired and may occur with inflammation of the vesicoureteral junction, lower urinary tract obstruction, surgical damage, neurogenic disease of the bladder, and ectopic ureters.[2]

Maximum distension and voiding cystourethrography are the techniques most commonly used to diagnose vesicoureteral reflux. A catheter is placed in the membranous or prostatic urethra, and iodinated contrast material is infused into the catheter until the bladder is distended enough to stimulate contraction of the detrusor muscle. Alternatively, external pressure can be applied to the bladder to express urine. Lateral radiographs are taken at the beginning of voiding of the contrast agent from the bladder, or voiding is monitored fluoroscopically. Vesicoureteral reflux may be seen during contrast filling of the bladder, during voiding, or both. Reflux can also be detected cystoscopically by filling the bladder with a colored dye and then watching for this dye to be excreted from the ureters after the bladder is emptied and filled with clear fluid.[2]

Treatment of patients with vesicoureteral reflux should be aimed at eradication of urinary tract infections. Surgery may be indicated to treat predisposing factors such as obstructive lesions or ectopic ureters. Vesicoureteral reflux in young dogs is usually self-limiting and therefore requires no treatment.

268.3 CONGENITAL ANOMALIES

268.3.1 Ectopic Ureter

A ureter that enters the bladder distal to the trigone is considered ectopic. Ectopic ureters result from an embryologic abnormality of the ureteral bud of the mesonephric duct. The degree of deviation of the ureteral bud from the normal position determines the location of the ectopic ureteral opening, which can be anywhere along the urethra or in the vagina or uterus. Ectopic ureters may be unilateral or bilateral and extramural or intramural. Extramural ectopic ureters bypass the urinary bladder entirely and insert at a distal location. Intramural ectopic ureters appear externally to enter the bladder at the normal dorsolateral location; however, instead of opening in the trigone, the ureter traverses below the mucosa and opens in the bladder neck, urethra, or vagina. Reported variations to the intramural ectopic ureter include ureteral troughs, double ureteral openings, multiple fenestrated openings, and two intramural ureters opening in a single orifice.[5] Ectopic ureters commonly are associated with other abnormalities of the urogenital tract, including agenesis, hypoplasia, or irregular shape of the kidneys; hydroureter; ureterocele; urachal remnants; pelvic bladder; vulvovaginal strictures; and persistent hymen.[6,7]

1875 1876

The diagnosis of an ectopic ureter is usually made in young females.[5,7] It is possible that males with ectopic ureters remain undiagnosed because the length of the urethra and external urethral sphincter may prevent urine dribbling. Intramural, bilateral ectopic ureters are most commonly reported.[7] A genetic basis for this disease

has been suggested by the documentation of ectopic ureters in litter mates and a report of a parent-offspring transmission.[7] Breeds reported to be at greater risk for ureteral ectopia include the Siberian husky, Labrador retriever, golden retriever, Newfoundland, English bulldog, West Highland white terrier, fox terrier, Skye terrier, and miniature and toy poodles.[7] Ectopic ureters have been rarely reported in cats.

Dogs and cats with ureteral ectopia most commonly present with a history of continuous or intermittent incontinence since birth or weaning. The incontinence may be more severe when the animal is in a recumbent position. Normal urine voiding may also occur. On physical examination, the perineum may be soaked or stained with urine, or perivulvar dermatitis may be noted. Male cats may have a constricted preputial orifice with dilatation of the sheath caused by urine accumulation. The results of hematologic studies and a serum biochemistry profile usually are normal unless concurrent renal disease is present. Bacterial urinary tract infections have been reported to occur in 64% of patients with ectopic ureters.[5] These patients may be at greater risk of developing infection as a result of lack or dysfunction of the vesicoureteral valve, impaired ureteral peristalsis, or stasis of urine in the lower urogenital tract.

Several modalities have been used to diagnose ureteral ectopia. Traditionally, contrast radiography has been recommended. Excretory urography allows evaluation of the size and morphology of the kidneys and ureters. To improve the accuracy of evaluation of the ureteral insertion, excretory urography should be combined with pneumocystography. The bladder should be distended with carbon dioxide or room air, which provides negative contrast around the ureter as it enters the bladder. Elevation of the caudal abdomen and oblique or dorsoventral views may be helpful for identifying the ureteral opening. Fluoroscopy can be useful in discriminating the path of the ureter as it enters the bladder. A dilated ureter is the abnormality most frequently detected with excretory urography.[6] Ureteral dilatation may result from obstruction to urine flow caused by a stenotic ureteral orifice or by functional obstruction that occurs with contraction of the urethral sphincter at the site of insertion of the ectopic ureter. In patients with infection, ureteral dilatation may also be a result of inhibition of ureteral peristalsis caused by *Escherichia coli* endotoxin.[6] In addition, a primary neuromuscular abnormality has been proposed as a cause of hydroureter. These changes may not be limited to the affected side, because chronic ascending infection and pyelonephritis may result in dilatation of the contralateral ureter and renal pelvis. Dilatation of the ureter may not be present if the ureter is only mildly displaced or has a troughlike opening. If the ureter appears to be straight as it enters the bladder, rather than forming the normal J shape, an ectopic location should be suspected.[6] An intramural ectopic ureter may appear to bypass the bladder on these studies and may be confused with an extramural ectopic ureter. Other diagnostic techniques may be required to confirm an ectopic opening because of superimposition of pelvic bones, the gastrointestinal tract, or contrast medium in the bladder and urethra. Lack of opacity of the distal ureter as a result of peristalsis or poor renal excretion may also result in a nondiagnostic study.

Other contrast radiographic procedures that have been described for the diagnosis of ureteral ectopia are retrograde urethrography and vaginourethrography.[4,7] The presence of a catheter in the urethra may obstruct the ectopic ureteral orifice, prohibiting a diagnosis with urethrography. Insertion of a Foley catheter into the vestibule and distension of the vagina and urethra with contrast may result in filling of the ectopic ureter with contrast medium, which confirms the diagnosis.

Ultrasonography has been reported to be an accurate means of determining ureteral anatomy.[4] The ureterovesicular junction is visible as a small, convex structure on the dorsal aspect of the bladder. Flow of urine from this area (“ureteral jet”) can be observed in dogs with normally positioned bladders. Distension of the bladder with fluid or administration of a diuretic may aid visualization. Reduced or absent urine flow from the distal ureter into the bladder indicates an ectopic ureter. In addition, dilatation of the ectopic ureter or renal

pelvis and thickening of the ureteral wall may be noted. One study that compared ultrasonography to contrast radiography for the diagnosis of ectopic ureters found that both techniques were accurate, with correct identification of 91% of the ectopic ureters.[4]

Direct visualization of the ureteral orifice with vaginoscopy and cystoscopy is a specific means of making the diagnosis of an ectopic ureter and for identifying abnormalities of the vagina and lower urinary tract. The vestibule and vagina can be visualized with a speculum, although ideally a rigid or flexible endoscope is used for complete evaluation of these structures, in addition to the bladder and urethra. Fluid insufflation aids visualization. The normal ureteral opening has a horseshoe-shaped, slitlike appearance when viewed endoscopically. Urine flow should be observed intermittently arising from these openings in the trigone region of the bladder. Inability to identify the normal ureteral openings should raise suspicion of an ectopic ureter. The urethra and vagina should be carefully evaluated for single or multiple ureteral openings and for a submucosal tunnel, which may appear as a slightly raised tube below the mucosal surface.

Cystometrographic studies and urethral pressure profilimetry can be used to identify functional abnormalities of the bladder and urethra in patients with ectopic ureters and may provide prognostic information.[7,8] The urethral pressure profile provides information about the pressures generated along the length of the urethra. This is often combined with the cystometrogram, which evaluates bladder capacity and compliance, and the strength of the detrusor reflex. In one study that evaluated the results of preoperative urodynamic measurements in nine dogs with ectopic ureters, reduced bladder capacity was detected in four dogs and urethral incompetence was found in six dogs.[8] Lack of response of urethral incompetence to phenylpropanolamine treatment before surgery was highly predictive of a poor postoperative outcome.[8]

Surgery is recommended for the treatment of patients with an ectopic ureter. The type of procedure performed depends on the morphology of the ureter and the functioning of the associated kidney. If the kidney is determined to be nonfunctional by preoperative evaluation, it should be removed with the ectopic ureter. Incontinence will likely persist after nephroureterectomy in patients with an ectopic intramural ureter unless the intramural segment is also removed.[7] The traditional treatment for intramural ectopic ureters has been to ligate the distal submucosal ureteral segment and create a new ureteral opening in the trigone of the bladder. Recently it was suggested that the intramural segment of ureter disrupts the functional anatomy of the internal urethral sphincter mechanism.[7] Therefore it has been recommended that the intramural segment be resected from the bladder neck and urethra and that the overlying mucosa and smooth muscle layers be apposed. A neoureterostomy is then performed by suturing the ureteral mucosa to the bladder mucosa in the region of the trigone. This trigonal and urethral reconstruction technique has been reported to result in less postoperative incontinence.[7] Extramural ectopic ureters are treated by ligating the distal end of the ureter at its attachment to the urethra, vagina, or uterus and reimplanting it into the bladder between the apex and the trigone. Because of the frequency of infection in patients with ectopic ureters, a urine culture from the bladder or renal pelvis should also be performed at surgery.

1876

1877

The most common complication after surgical correction of an ectopic ureter is persistent urinary incontinence, which occurs in 44% to 67% of patients.[7,9] Reasons proposed for persistent incontinence include the presence of a submucosal ureteral remnant in the trigone or urethra, primary sphincter mechanism incompetence, other congenital abnormalities of the urogenital tract, or urinary tract infection. Urine culture should be performed in patients with persistent or recurrent incontinence and infection treated based on susceptibility results. Some patients with postoperative incontinence respond to alpha-adrenergic drugs (phenylpropanolamine or ephedrine). Additional procedures that have been proposed for treatment of persistent incontinence include endoscopic submucosal injection of glutaraldehyde cross-linked collagen

within the urethra and additional surgical procedures, such as colposuspension and cystourethropexy.[7] Partial or complete resolution of hydroureter and hydronephrosis may be seen after surgical correction of ectopic ureters even if the dilatation was severe before surgery.[10]

268.3.2 Ureterocele

A cystic dilatation of the submucosal segment of the distal ureter near the ureteral orifice is called a *ureterocele*. The proposed embryogenic mechanisms that result in the formation of a ureterocele include persistence of the membrane that separates the ureter from the lumen of the urogenital sinus; stenosis of the ureteral orifice, resulting in obstruction and ureteral dilatation; delayed ureteral migration, resulting in retention of the dilated distal ureteral segment; and embryonic arrest of myogenesis of the distal ureter.[4] Ureteroceles are classified as orthotopic or ectopic, depending on the location of the ureterocele and the associated ureteral orifice. An orthotopic ureterocele is located in the trigone of the bladder with an opening at the normal position of the ureterovesicular junction. Ectopic ureteroceles occur in conjunction with an ectopic ureter and have an opening within or distal to the bladder neck. A grading system for canine ureteroceles was recently proposed.[11] Grade 1 ureteroceles have no evidence of associated upper urinary tract disease. Grade 2 ureteroceles are associated with ipsilateral hydroureter, hydronephrosis, or chronic renal disease, and the condition is bilateral in grade 3 ureteroceles.

Orthotopic ureteroceles may go undiagnosed unless they are large enough to cause obstruction of the urethra or of the ipsilateral or contralateral ureter or unless they are associated with infection. Clinical signs associated with large orthotopic ureteroceles include abdominal pain, hematuria, stranguria, and pollakiuria. Incontinence is seen if the ureterocele is ectopic. The diagnosis is made with contrast radiography, ultrasonography, or uroendoscopy. Excretory urography combined with pneumocystography may reveal a contrast-filled dilatation of the ureter in the bladder or urethra; this is referred to as the *cobra head sign*.[4] If the kidney associated with the ureterocele has impaired function, a filling defect is seen as contrast accumulates within the bladder or urethra. On ultrasonographic evaluation, the ureterocele appears as a rounded, thin-walled, fluid-filled cystic structure in the bladder.[4]

Cystoscopic incision is commonly used to treat ureteroceles in humans and may also be effective in dogs with orthotopic ureteroceles.[11] In addition, ureteroceles may be treated by open resection. Ectopic ureteroceles should be treated as ectopic ureters by resection of the ureterocele, neoureterocystostomy, and reconstruction of the bladder neck and urethra. Unless renal dysfunction is present prior to surgery, the prognosis for correction of an orthotopic ureterocele is good. Incontinence has been reported to persist in 33% to 50% of patients treated for an ectopic ureterocele.[11,12]

268.3.3 Agenesis or Duplication

Ureteral agenesis results from failure of development of the ureteral bud. Segmental absence of the ureter or lack of a lumen may occur in combination with other congenital abnormalities.[4] Renal agenesis may be associated with ureteral agenesis, because the ureteral bud induces the embryonic metanephric kidney to proliferate and differentiate. Unilateral ureteral and renal agenesis is usually asymptomatic unless the opposite kidney is compromised. Ureteral duplication has also been reported and occurs when more than one ureteral bud develops from the same mesonephric duct or if an abnormality exists in division of the ureteral bud.[13] A duplex kidney results as renal parenchyma is formed around each developing ureter. The ureter draining the

lower part of the duplex system enters the bladder in the normal location, whereas the ureter draining the upper part is ectopic, terminating in the urethra.

268.4 ACQUIRED DISEASES

268.4.1 Ureteral Trauma

Ureteral injury can result from blunt abdominal trauma, penetrating wounds, or iatrogenic damage during surgery. Trauma to the ureters has been rarely reported in dogs and cats. Ureteral injury resulting from blunt trauma accounted for only 0.01% of the small animal hospital population in a recent report.[14] In humans, ureteral injuries, which usually result from gunshot wounds, are also uncommon, representing 5% of all patients with genitourinary trauma.[15]

The diagnosis of ureteral injury is often delayed for 3 or more days because of the rarity of this condition and the nonspecific clinical signs, which are often masked by hypovolemic shock, pain, and multiple organ injuries caused by the traumatic incident.[13] If the retroperitoneum is intact, urine accumulation is confined to this space, and several days may pass before an increase in the serum creatinine or potassium concentration is detected. Uroabdomen is present if retroperitoneal disruption occurs or with injury at the ureterovesicular junction. Uroabdomen may also result from concurrent urinary bladder rupture. Hematuria is not consistently present in patients with ureteral trauma alone.[14,15] If hematuria, abdominal pain, or uroabdomen is present, further evaluation of the urinary tract is indicated. Although the diagnosis of ureteral injury may not be made for days, this delay in humans has not been associated with increased mortality, loss of renal function, or the necessity for ureteronephrectomy.[15]

Radiography may reveal loss of peritoneal or retroperitoneal detail. Increased density, widening, and streaking of the retroperitoneum are indications of fluid accumulation but are not specific for urine.[4] Excretory urography can be performed if the patient is hydrated, normotensive, and not significantly azotemic. Extravasation of contrast medium from the site of rupture and renal pelvic or ureteral dilatation may be seen in affected animals. One report of ureteral trauma in small animals found excretory urography to be diagnostic in all four animals in which it was used; however, in humans with ureteral trauma, it has been reported to be less than 50% accurate.[14,15] Potential reasons for inaccuracy included poor urine output, a poor quality study, and radiographs taken at only one time period. Ultrasonography may demonstrate fluid accumulation in the retroperitoneal space but does not allow differentiation between a hematoma and extravasation of urine. Additional diagnostic tests that may be helpful include retrograde pyelography, computed tomography (CT), or magnetic resonance imaging. The diagnosis of ureteral trauma can be made at surgery, but direct inspection of the ureters after a traumatic incident is often complicated by the presence of retroperitoneal blood and fluid. Catheterization of the ureter from the bladder may aid identification of the site of ureteral rupture. In addition, intravenous injection of methylene blue increases visualization of urine coming from the proximal ureteral segment; however, this technique should be used with caution, because it has been associated with Heinz body anemia and renal failure. If intraoperative fluoroscopy is available, excretory urography can also be performed at surgery.

The goal of initial treatment should be to stabilize the patient for definitive surgery. Hypovolemic shock, hyperkalemia, and respiratory compromise must be treated prior to administration of anesthesia. If uroabdomen is present and the patient is not stable for surgery, a large-gauge, fenestrated catheter (e.g., peritoneal lavage catheter) can be placed intra-abdominally for drainage.

Definitive surgical treatment of the injured ureter depends on the severity and location of the injury and the functioning of the contralateral kidney. Ureteronephrectomy has been reported as the most common treatment in small animal patients.[14] This likely is due to the severity of ureteral damage and the technical difficulties of ureteral surgery. The prognosis with ureteronephrectomy is good if the other kidney is functional; however, ureteronephrectomy is considered a salvage procedure in humans and should not be performed if doubt exists about the function of the remaining kidney.

Successful ureteral anastomosis requires an adequate blood supply, good apposition of ureteral ends, and minimal tension. Urine diversion via a nephrostomy catheter or ureteral stent may also be helpful. A ureteral wound less than 50% the circumference of the ureter seals in 48 hours with adequate urine diversion.[3] Injuries to the proximal one third of the ureter may be treated by primary anastomosis. Injuries to the middle or distal one third may be treated by primary anastomosis or reimplantation of the ureter into the bladder (ureteroneocystostomy). If the ureter is reimplanted, the bladder may be advanced cranially (psoas cystopexy) or the kidney freed and moved caudally (renal descensus) to alleviate tension. Risks of primary repair and reimplantation include urine leakage, dehiscence, and stricture formation. Additional surgical techniques that have been described include bladder flap ureteroplasty and transureteroureterostomy.[13]

268.4.2 Iatrogenic Injury

Injury to the ureters can result from iatrogenic damage, which occurs most commonly during ovariohysterectomy. Inadvertent ligation and transection of the ureters has been reported.[16] The most common location for inadvertent ligation is near the uterine body. This may result in complete obstruction, with associated hydronephrosis, hydroureter, and eventually permanent renal damage if not corrected within 7 days.[13,16] An additional complication that has been reported to occur as a result of incorporation of the ureter into a uterine or vaginal ligature is ureterovaginal fistula.[17] The fistula may develop within 1 to 2 weeks of ovariohysterectomy and is associated with urinary incontinence. Treatment of ureterovaginal fistula involves ligation of the fistula and ureteral reimplantation into the bladder or ureteronephrectomy. Pyelonephritis is another complication that can occur with ureteral ligation and excision during ovariohysterectomy.

268.4.3 Urinoma

A paraureteral pseudocyst, or urinoma, forms when urine that has leaked from a ureter into the retroperitoneum becomes encapsulated in a thick, fibrous wall. The proposed mechanism of formation involves chronic, low-grade urine leakage from the ureter after trauma or obstruction, which causes necrosis of the surrounding fat and infiltration of round cells.[18] This inflammatory reaction results in the creation of a fibrous capsule over 3 to 6 weeks. A paraureteral pseudocyst was recently reported in a cat 3 weeks after an automobile-related accident.[19] Inadvertent ureteral transection during ovariohysterectomy was also reported to cause urinoma in a dog.[18] A preoperative diagnosis of a paraureteral pseudocyst is made by the identification of contrast accumulation in the pseudocyst during excretory urography or by visualization of hydronephrosis and hydroureter with a fluid-filled cavitary mass on ultrasonography.[4] Ureteronephrectomy has been the reported treatment.[18,19]

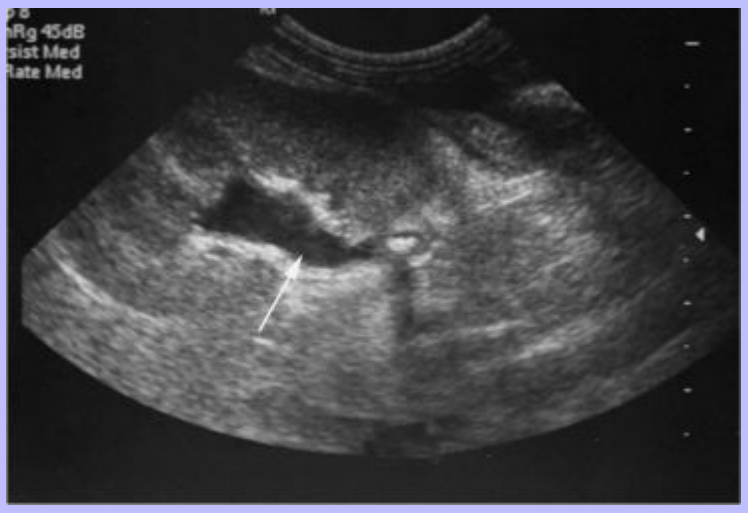
268.4.4 Ureteral Obstruction

Ureteral obstruction can result from intraluminal, intramural, or extramural causes. Intraluminal obstruction can occur as a result of a blood clot or calculus. Intramural fibrosis, stricture, or neoplasia may also obstruct urine flow. Extramural compression may occur from a retroperitoneal mass or bladder neoplasm or from a ligature placed inadvertently during surgery. Clinical signs of obstruction may not be apparent unless bilateral obstruction or concomitant infection of the urinary tract is present. Clinical signs may be mild, including dysuria, abdominal pain, vomiting, anorexia, and lethargy. On the other hand, patients with complete, bilateral obstruction are anuric and may be collapsed at presentation. Complete, bilateral obstruction that persists for 3 days or longer is fatal without appropriate treatment.[13]

It may be difficult to distinguish between obstructing and nonobstructing causes of ureteral dilatation. However, this distinction is important, because pyelonephritis may cause ureteral dilatation and would not warrant surgery. Conversely, an obstructing calculus or mass would necessitate early surgical intervention. Obstructing ureteral calculi in cats may be small and difficult to visualize on plain radiographs. Excretory urography is helpful for identifying ureteral dilatation to the point of obstruction and may show a filling defect or stricture if the associated kidney is functional and the patient is not severely compromised. With severe compromise of renal function, opacification of the kidneys and ureters is poor, resulting in a nondiagnostic study.[4] In addition, adverse systemic reactions and the potential for further damage to the kidney make this procedure less than ideal in dehydrated or severely azotemic patients.[4,13]

Percutaneous antegrade pyelography is an accurate diagnostic test for patients in which excretory urography is nondiagnostic, or when concern exists about the adverse effects of systemic contrast administration (Figure 268-1).[20] Fluoroscopy or ultrasonography can be used to guide needle or catheter placement into the dilated renal pelvis. Urine is aspirated from the renal pelvis and submitted for analysis and culture. Iodinated contrast material is then injected into the needle or catheter at a volume equal to one half the aspirated urine volume. *1878* The flow of contrast is monitored with fluoroscopy or with radiographs taken immediately after contrast *1879* injection. This technique is easily performed and has minimal complications, such as hematuria and leakage of contrast material or urine into the abdomen. Fluid diuresis is recommended with this procedure to prevent blood clot formation, which may result in obstruction.[20]

Figure 268-1 Percutaneous antegrade pyelography. Under ultrasound guidance, a needle was placed into the renal pelvis of a cat presenting with azotemia and anuria. Injection of contrast material allowed the diagnosis of complete, bilateral, distal ureteral obstruction by ureteroliths that were not evident on plain radiographs.



Ultrasonography is noninvasive, allows limited morphologic assessment of the renal parenchyma, and may allow diagnosis of ureteral obstruction. Although ureteral dilatation alone is not a specific sign of obstruction, visualization of focal hydroureter to the level of obstruction can be diagnostic.[4] In some patients it may be difficult to follow the entire course of the ureter because of its size and because of interference by other organs. In these cases, absence or reduced amplitude and duration of ureteral flow at the ureterovesicular junction can be used as an indirect sign of obstruction.[4] Additional noninvasive imaging that can be used to evaluate patients with ureteral obstruction are CT and renal scintigraphy. Renal scintigraphy allows evaluation of renal function in dogs with ureteral obstruction but does not predict what function will be after the obstruction has been relieved.[21]

Once the diagnosis has been made, rapid surgical intervention is indicated, because recovery of renal function is inversely related to the duration of obstruction.[13] If patency of a completely obstructed ureter is restored within 7 days of obstruction, renal function can return to normal.[13,21] If the obstruction persists for 2 weeks prior to correction, the affected kidney will regain approximately 50% of its preobstruction function. Complete loss of renal function does not occur until complete ureteral obstruction is present for longer than 4 weeks. If the patient is not stable for definitive surgical correction, a nephropyelostomy catheter can be placed to divert urine flow and preserve renal function. If hemodialysis is available, it can be useful for stabilization of severely uremic patients before they undergo long surgical procedures to remove the source of obstruction. The definitive surgical treatment depends on the cause and duration of obstruction.

268.4.5 Calculi

Calcium oxalate calculi are the most common type of uroliths found in the kidneys and ureters of cats.[21] Potential risk factors for the formation of these stones include hypercalcemia, feeding a urine-acidifying diet or a single brand of cat food, an indoor only environment, and being of the Persian breed.[22] Struvite and calcium oxalate calculi most frequently cause ureteral obstruction in dogs.[23] If ureteral calculi are diagnosed by plain radiography and are not associated with significant obstruction, serial radiographs should be taken to monitor calculi movement. Medical dissolution of ureteroliths is unlikely to be successful, because calculi in the ureter are not continually bathed in urine, and calcium oxalate calculi are not amenable to dissolution. Intravenous fluid diuresis, with or without diuretics, may encourage movement of calculi to the bladder. Failure of calculi to progress down the ureter on subsequent radiographs is an indication for surgical intervention. Currently there is no recommendation on the appropriate amount of time for which patients should be monitored for the passage of ureteroliths. An experimental study of artificial calculi in dogs has shown that solid spheres 2.8 mm in diameter become firmly impacted in the ureter; however, spheres 2.3 mm in diameter pass within 1 to 24 hours.[13] A clinical report of 11 cats with ureteroliths found that the calculi did not move toward the bladder in any patient monitored for a mean of 19 days.[21] Furthermore, fibrosis of the ureteral wall and ulcers of the ureteral epithelium at the site of obstruction demonstrated that the stones were immobile in these patients. Because even partial obstruction of the ureter results in decreased renal blood flow, decreased renal function, and potentially irreversible renal damage, early surgical intervention is indicated if there is evidence of obstruction.[21]

Options for surgical treatment of ureteroliths include ureterotomy; retrograde flushing of calculi into the renal pelvis, followed by pyelolithotomy; resection of the affected portion of the ureter, followed by primary anastomosis or reimplantation into the bladder; and ureteronephrectomy. Complications of ureteral surgery include urine leakage, dehiscence, and stricture formation. Placement of a nephrostomy catheter after surgery may be helpful for diverting urine flow until the ureter heals.

Extracorporeal shock wave lithotripsy (ESWL) is an alternative treatment for nephrolithiasis and ureterolithiasis in dogs. ESWL was reported to be effective in two dogs with ureterolithiasis and in one dog that developed ureteroliths after treatment for nephrolithiasis.[23] In humans, ESWL is reported to be less effective for ureteroliths than for nephroliths because of attenuation of shock wave energy by surrounding muscle and bone, difficulty with patient positioning, difficulty identifying ureteroliths by fluoroscopy or ultrasonography, and adherence of the ureterolith to the ureteral mucosa, which prevents fragments from passing during lithotripsy.[23] Disadvantages of ESWL in dogs include lack of availability, the need for general anesthesia, and the potential need for multiple treatments. ESWL is contraindicated in patients with coagulopathies, pacemakers, pregnancy, and obstruction distal to the calculi, which prevents removal of urolith fragments. Lithotripsy was reported to be successful in only one of five cats treated for ureterolithiasis.[21]

268.4.6 Neoplasia

Primary ureteral neoplasia is rare in dogs and has not been reported in cats. Transitional cell carcinoma has been the most frequently reported tumor type and is seen most commonly in females.[24] Other tumor types

include leiomyoma, leiomyosarcoma, and benign papillomas.[13,24] In a small number of patients, a good prognosis was reported for ureteronephrectomy of neoplasms confined to the ureter.[24]

269 CHAPTER • 269 Problem-Oriented Differential Diagnosis of Autoimmune Skin Diseases

Karen A. Moriello

Immune-mediated skin diseases are uncommon in clinical veterinary practice; they accounted for fewer than 1.5% of all skin diseases seen in a university referral dermatology service (Figure 269-1). Nonetheless, they are problematic to the clinician because they can appear similar to other skin diseases that are more common.

Immune-mediated skin diseases are divided into two major categories: *primary autoimmune diseases,* in which the disease is the result of attack against self-antigens, and *secondary immune-mediated diseases,* in which the disease is the result of an attack against a foreign antigen. The most common foreign antigens are drugs, bacteria, and viruses that trigger an immunologic reaction, causing tissue damage. This chapter provides an overview of the more common autoimmune skin diseases and highlights key features that may narrow the list of differential diagnoses or may answer the question, “Should I be thinking of an autoimmune skin disease?”

269.1 CLINICAL CLUES IN THE HISTORY AND PHYSICAL EXAMINATION FINDINGS

Two major clinical presentations are seen in pets with autoimmune skin diseases (ASDs). One is the textbook presentation of the disease, which includes an acute onset of severe lesions. These patients are rarely problematic to the clinician with regard to diagnosis, because suspicion is high from the onset. The clinician suspects something serious, and an aggressive diagnostic evaluation is shortly underway. In the other clinical presentation, the disease manifests itself in a less obvious way, waxes and wanes, partially responds to treatment for a different disease, is a mild form of the ASD, or occurs concurrently with another chronic skin disease (e.g., atopic patients that develop pemphigus). The following points should raise suspicion of a possible immune-mediated skin disease:

269.1.0.1 Historical Clues

- Any severe skin disease with an acute or rapid onset
- Reports that the lesions wax and wane, especially in relatively short cycles of 7 to 10 days
- Intermittent episodes of depression, fever, and anorexia, especially if they coincide with the development of lesions
- Lack of response to seemingly appropriate therapy. For example:
  - A routine case of otitis externa that does not respond to therapy, with evidence emerging of primary lesions on the inner pinnae
  - Patients that continue to develop pustular lesions despite appropriate antibiotic therapy, especially if therapy has continued for longer than 3 weeks
  - Continued development of oral lesions on gums after appropriate dental therapy
- Difficulty eating or drinking (an early historical finding in dogs with oral ulcers)

269.1 Suspicious Physical Examination Findings

- Pruritus (variable in ASD, and its presence does not rule out ASD; evidence of pruritus may come from the history or may be obvious on examination [e.g., excoriations, observed self-trauma])
- Symmetry of skin lesions
- Skin disease (mild or moderate) with concurrent signs of systemic illness (fever, depression, anorexia)
- Large numbers of easily found, intact primary lesions all in the same stage, especially pustules, vesicles, or bullae
    - Intact or recently ruptured pustules on the inner pinnae
    - Intact pustules near the mammae of cats
    - Intact, flaccid pustules spanning several hair follicles, often yellow-green in color
- Thick, adherent crusting on the body
    - Crusting only on the face and/or footpads
    - Crusting that includes the face, footpads, and body
- A strong, offensive odor, with exudation and serum accumulation on the trunk, causing matting of the haircoat, especially if oily seborrhea is not present
- Ulcerations or erosions. For example:
    - Oral ulceration and/or erosions with or without halitosis and drooling
    - Mucocutaneous ulcerations and/or erosions, matting of the haircoat in these areas, and odor (often prominent findings)
    - Ulcerations and erosions in the axillary and/or inguinal region
- Depigmentation of the nose or mucocutaneous junctions

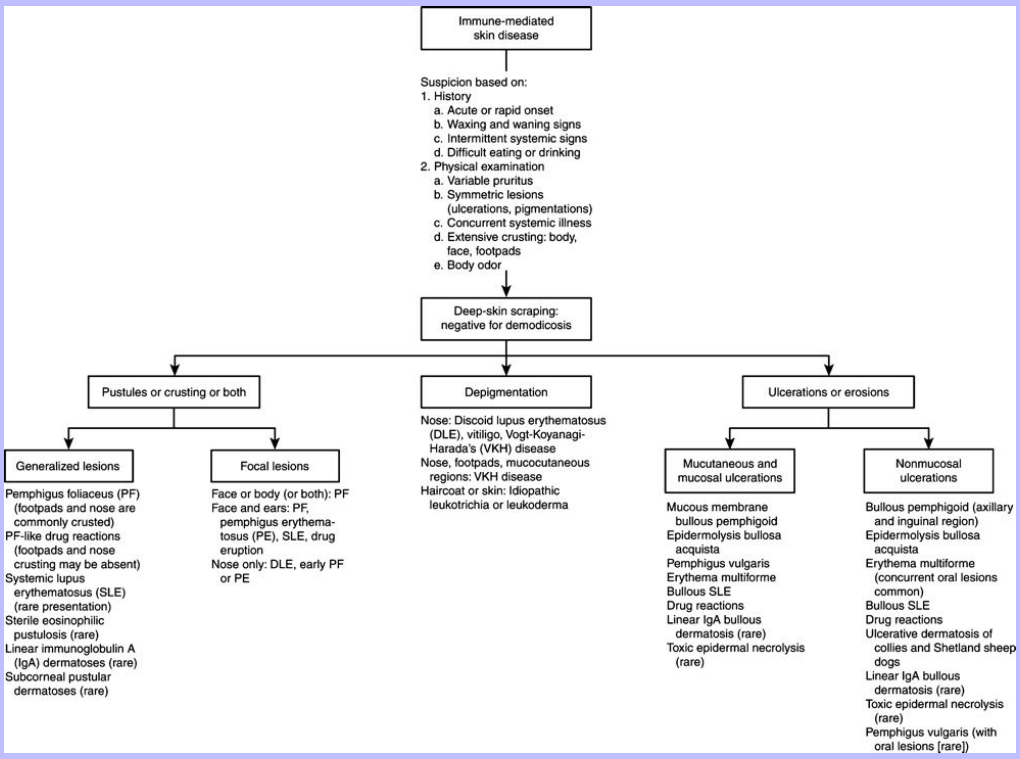
269.2 PROBLEM-ORIENTED APROACH TO DIFFERENTIAL DIAGNOSIS

The dermatologic problems most commonly associated with ASD are pustular eruptions, crusting and scaling, mucocutaneous ulcerations, nonmucocutaneous ulcerations, depigmentation, and miscellaneous problems, such as noninflammatory focal alopecia. Box 269-1 presents a problem-oriented list of differential diagnoses for autoimmune skin disorders. Because of the variation in clinical signs, some diseases fit into several categories.

Box 269-2 is a summary of the key diagnostic findings for skin biopsy and immunologic tests in various ASDs that help confirm the diagnosis. Skin scrapings and dermatophyte cultures should be negative in ASD. However, mite infestations and/or dermatophytosis can develop secondary to immunosuppressive disorders and occasionally occur concurrently. Adult-onset demodicosis can precede the development of an autoimmune skin

disease. In a "classic" ASD case, bacterial cultures of intact pustules should be reported as "no growth" or "scant" growth. If heavy growth of bacteria is found, this may indicate that the pustular disease is bacterial in origin, that bacteria have colonized skin lesions caused by the ASD, or that staphylococcal bacteria from the clinician's fingers contaminated the culture. In some cases skin biopsies are diagnostic, and in other cases a trial of antibiotic therapy or a review of previous therapies may answer the question. Cytologic specimens may also show concurrent *Malassezia* overgrowth. It is important to rule out candidiasis in patients with mucocutaneous or ulcerative dermatoses. This is best done by fungal culture at a reference laboratory (a swab is submitted) and by cytologic examination of exudate (unfixed, unstained slides of debris scraped from the lesion margins are submitted).

Figure 269-1 Algorithm for diagnosis of immune-mediated skin disease.



269.2.1 Box • 269-1 Differential Diagnosis of Autoimmune Skin Diseases

269.2.1.1 Generalized Pustular Eruptions and/or Crusting Dermatoses (Involving the Body, Head, Face, or Feet)

- Pemphigus foliaceus (PF) (footpad and nose commonly are crusted)
- Pemphigus-like drug reactions (nasal and footpad crusting may be absent)
- Systemic lupus erythematosus (rare presentation)

- Sterile eosinophilic pustulosis (rare disease)
- Linear IgA pustular dermatosis (rare disease)
- Subcorneal pustular dermatosis (rare disease)

269.2.1.2 Focal Pustular Eruptions and/or Focal Crusting

- Face and/or footpads: PF
- Face and ears only: PF (early), pemphigus erythematosus (PE), drug eruptions, lupus erythematosus
- Nasal only: Discoid lupus erythematosus, PE (early), PE

NOTE: Pustules are quite transient, and many of the generalized pustular diseases also present as generalized, malodorous, crusting dermatoses. The major differential diagnoses here are bacterial pyoderma, dermatophytosis, severe seborrhea, and zinc deficiency. Bacterial pyoderma rarely affects the head, and dermatophytosis is a nonsymmetric skin disease. Most cases occur in young animals (dermatophytosis) or sled dogs (zinc deficiency). Severe, oily seborrhea may also appear as a crusting dermatosis and can mimic PF if nasal and digital hyperkeratosis is present; the major differentiating factor is that primary seborrhea starts out at a young age. Zinc-responsive skin diseases may present as widespread or focal crusting dermatoses and can mimic PF.

269.2.1.3 Mucocutaneous and Mucosal Ulcerations

- Pemphigus vulgaris (may also have oral ulcerations)
- Mucous membrane bullous pemphigoid
- Epidermolysis bullosa acquisita
- Erythema multiforme (target lesions, cutaneous ulcerations also may be present)
- Bullous systemic lupus erythematosus
- Drug reactions
- Linear IgA bullous dermatosis (rare)
- Toxic epidermal necrolysis (rare)

Note: The primary lesions in these diseases are vesicles and bullae, which are quite transient and rupture, leaving erosions and ulceration. The adjacent haircoat becomes matted and odorous. The major differential diagnoses of concern are candidiasis, ulcerative mucocutaneous bacterial pyoderma, and cutaneous lymphoma.

269.2.1.4 Nonmucosal Ulcerations (Axillae, Inguina, Pinnae, or Other Haired Areas)

- Bullous pemphigoid

- Epidermolysis bullosa acquisita
- Linear IgA bullous dermatosis
- Bullous systemic lupus erythematosus
- Canine vesicular cutaneous lupus erythematosus (also called idiopathic ulcerative dermatosis of collies and Shetland sheepdogs)
- Erythema multiforme
- Toxic epidermal necrolysis
- Drug eruptions
- Pemphigus vulgaris (with concurrent mucocutaneous lesions)

NOTE: The primary lesions are vesicles and/or bullae, which are quite transient. These patients commonly present with fever, pain, a matted haircoat, and exudation. The major differential diagnoses of concern are deep bacterial pyoderma, deep pyoderma caused by demodicosis, and cutaneous deep and intermediate mycoses.

269.2.1.5 Depigmenting Skin Diseases

- Nasal only: Discoid lupus erythematosus, vitiligo-like syndrome, uveodermatologic syndrome, early PF or PE
- Nose, footpads, lips, eyelids, and mucocutaneous regions: Uveodermatologic syndrome (these animals have concurrent uveitis)
- Haircoat or skin: Idiopathic leukotrichia or leukoderma

269.2.1.6 Miscellaneous

- Focal alopecia: Alopecia areata, rabies vaccine, focal vasculitis
- Widespread noninflammatory alopecia: Alopecia areata, pseudopelade
- Erythematous target lesions: Erythema multiforme
- Nodular ulcerative lesions: Nodular panniculitis
- Purpura, hemorrhage, “punched out” lesions: Vasculitis
- Ear margin necrosis, pineal erosions: Vasculitis
- Dependent edema with erythema: Vasculitis

269.2.2 Box • 269-2 Key Diagnostic Findings in Common Autoimmune Skin Diseases

269.2.2.1 Skin Biopsy

- *Pemphigus vulgaris:* Suprabasilar acantholysis with cleft and vesicle formation; basal cells attachment to basement membrane resembles a row of tombstones.
- *Pemphigus foliaceus:* Intragranular or subcorneal pustules with acantholysis.
- *Pemphigus erythematosus:* Intragranular or subcorneal pustules with acantholysis with a lichenoid reaction.
- *Bullous pemphigoid, epidermolysis bullosa acquisita, linear IgA bullous dermatosis, mucous membrane pemphigoid,* and *bullous systemic lupus erythematosus:* Subepidermal cleft and vesicle formation, no acantholysis, and possible lichenoid reaction.
- *Systemic* or *discoid lupus erythematosus (DLE) (the histologic findings for both systemic and discoid lupus erythematosus are identical, except that pigmentary incontinence may be more prominent in DLE):* Hydropic and/or lichenoid interface dermatitis of the epidermis and possibly of the outer root sheath of the hair follicles, apoptosis of basal cells and, less commonly, subepidermal vesicles.
- *Erythema multiforme (EM) (the histologic findings with EM vary greatly; a key finding is apoptosis of keratinocytes throughout the epidermis):* Interface dermatitis with prominent single cell apoptosis of keratinocytes throughout the epidermis and outer root sheath of the epidermis.
- *Toxic epidermal necrolysis:* Hydropic degeneration of basal cells, full-thickness coagulation necrosis of the epidermis, and minimal dermal inflammation.
- *Uveodermatologic syndrome:* Lichenoid interface dermatitis with large histiocytes, as well as prominent pigmentary incontinence; hydropic degeneration of epidermal basal cells is rare.

269.2.2.2 Antinuclear Antibody Testing

- *Pemphigus erythematosus:* Weak positive titer may be seen.
- *Systemic lupus erythematosus:* Strong positive titer.
- **Direct Immunofluorescence Testing**
- *Pemphigus complex:* Positive intercellular fluorescence.
- *Pemphigus erythematosus:* Positive intercellular and basement membrane fluorescence.
- *Bullous pemphigoid (50% to 90% of cases), epidermolysis bullosa acquisita, linear IgA dermatosis, mucous membrane pemphigoid, systemic or cutaneous lupus erythematosus (50% to 90% of cases):* Positive basement membrane fluorescence.

NOTE: Direct immunofluorescence testing usually is negative in the other autoimmune skin diseases, however, this is not always the case, and nonspecific staining may be seen.

269.2.2.3 Indirect Immunofluorescence Testing

- Indirect immunofluorescence testing using a salt split-skin as a substrate is a relatively new method of differentiating the autoimmune subepidermal bullous diseases.

Cytologic examination of the contents of an intact pustule may be extremely valuable for making a diagnosis. This diagnostic test may be helpful for corroborating a diagnosis of pemphigus foliaceus (PF). Intact pustules are rare in cats, and if found, especially on the inner pinnae and near the mammae, are almost always caused by pemphigus foliaceus. In dogs, it is rare to easily find large numbers of intact pustules. The pustules of pemphigus are large, flaccid, and filled with a copious amount of pus. The specimen should be stained and examined for acanthocytes, which are round, deeply basophilic epidermal cells often present as rafts (i.e., numerous cells adhered together). In dogs these cells tend to be found in PF and in cases of severe bacterial pyoderma. Cytologic specimens should be carefully examined for eosinophils. In dogs, eosinophils can be seen in pustular specimens from PF. A finding of eosinophils should prompt the clinician to consider other differential diagnoses, such as allergic disease (small numbers of eosinophils), sterile eosinophilic pustulosis (almost pure fields of eosinophils), or parasitic diseases (variable). In cats, a finding of large numbers of eosinophils requires some thought on the part of the clinician, because many allergic skin diseases of cats can mimic ASDs.

270 CHAPTER • 270 Regenerative Anemias Caused by Blood Loss or Hemolysis

Urs Giger

Anemia is not a diagnosis in itself but is a common clinical sign and laboratory test abnormality in companion animals. Thus anemia may indicate a specific erythrocyte problem or can be associated with other organ disorders. Anemia and other hematologic abnormalities occur so frequently that a complete blood cell count (CBC) is generally requested in the diagnostic assessment of any ill dog or cat. Anemia is defined as a decrease in the red blood cell (RBC) mass as expressed by a reduction in number of circulating RBCs, hematocrit, and hemoglobin. Clinical signs of anemia result from decreased oxygen-carrying capacity, reduced blood volume, underlying disease, and the adjustments made to increase the efficiency of the erythron. Severity of clinical signs depends on the rapidity of onset, the degree and cause of anemia, and the extent of physical activity. A logical approach to the cause of anemia is usually fruitful. Anemias are classified by pathophysiologic mechanisms, bone marrow response, and RBC indices. This chapter reviews regenerative anemias caused by blood loss or hemolysis. Non-regenerative anemias will be covered in the next chapter (271) and additional details on hematologic aspects are provided in *Schalm's Veterinary Hematology* and other clinical pathology texts.[1–3]

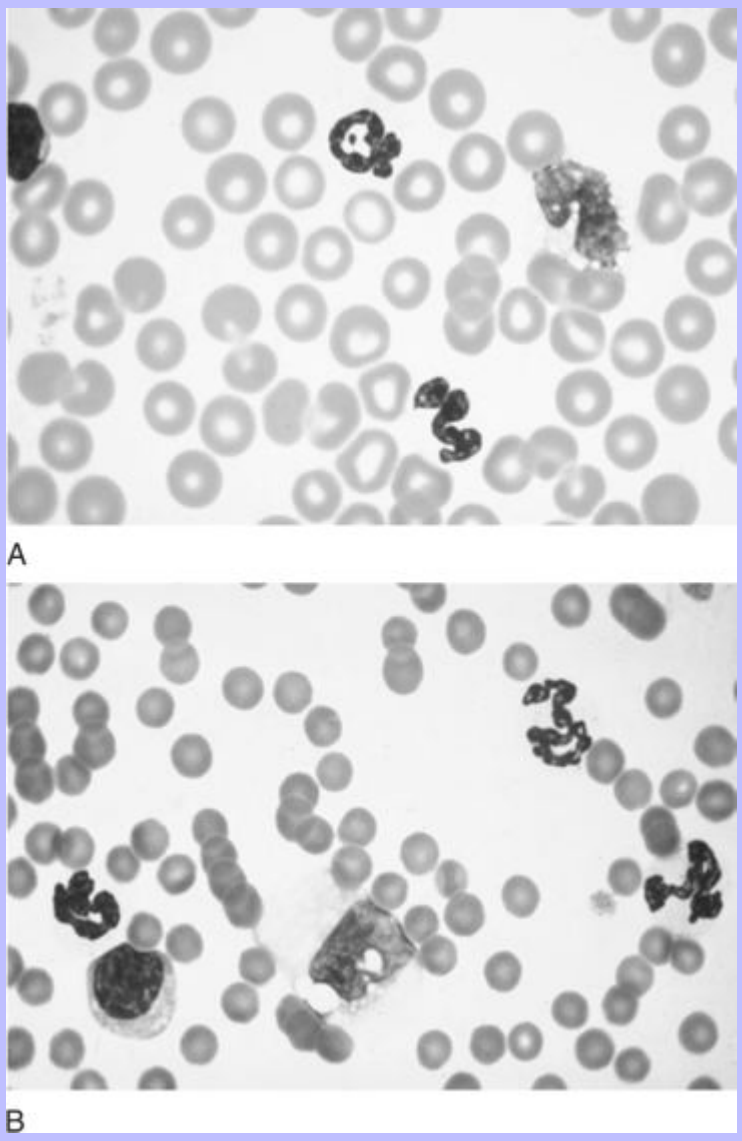
270.1 REGENERATIVE BONE MARROW RESPONSE

The number of circulating erythrocytes is the result of a dynamic equilibrium between the production and delivery of erythrocytes (Figure 270-1) and their destruction or loss. The normal homeostatic mechanisms of the body bring about recovery from anemia by accelerating erythropoiesis. The erythroid bone marrow response is primarily regulated by erythropoietin, a lineage-specific hematopoietic growth factor. Erythropoietin synthesis in the renal cortex is induced by anemia, although the actual sensor measures oxygen tension and renal hypoxia. It acts predominantly on erythroid precursor cells of the bone marrow known as *burst-forming units-erythroid* (BFU-E) and particularly colony-forming units-erythroid (CFU-E). At maximal stimulation, the bone marrow is capable of producing erythrocytes at tenfold to fiftyfold the normal rate. Erythropoietin also contributes to the maturation from the early committed erythroid precursors to fully hemoglobinized erythrocytes, which takes normally approximately 1 week.[1,3]

270.1.1 Reticulocytes

The most useful marker of accelerated erythropoiesis is an increased number of circulating reticulocytes.[1,3,4] Reticulocytes form after extrusion of the pyknotic nucleus from normoblasts and continue to mature, finally to erythrocytes, in the bone marrow and peripheral blood. Reticulocytes normally reside within the marrow for almost 2 days before they are released into the circulation. They continue to synthesize hemoglobin as long as they have functional messenger RNA, which is usually 1 day in circulation. However, during accelerated erythropoiesis, reticulocytes may be released prematurely from the marrow. The so-called stress or shift reticulocytes are macrocytic, less developed, and therefore require a longer time to mature to erythrocytes in circulation. In hemolytic disorders they contain high pyruvate kinase (PK) activity.[4] Because they contain residual RNA, which can be precipitated into a reticulum network and stained by certain supravital dyes, such as new methylene blue or brilliant cresyl blue, reticulocytes can be readily enumerated. The latter stain is particularly suitable as it is relatively free of precipitates. On a stained blood smear, the number of reticulocytes is counted per 500 to 1000 erythrocytes, and the reticulocyte result is reported as a percentage of cells examined (number per 100 cells). Some hematology instruments provide a specific count.

Figure 270-1 Normal canine **(A)** and feline **(B)** blood smear, Wright's-Giemsa staining. Reader should note the smaller size of feline erythrocytes.



1886

1887

Because canine reticulocytes contain strong aggregates, they are relatively easy to count (Figure 270-2). In contrast, cats produce two types of reticulocytes: (1) aggregate and (2) punctate. Aggregate reticulocytes correspond to the reticulocytes seen in dogs and indicate an active regenerative response. After a short maturation time of less than 1 day, these aggregate forms become punctate reticulocytes. On a blood smear stained for reticulocytes, they contain up to 10 individual blue dots, which do not coalesce. As punctate

reticulocytes circulate over a period of 1 to 2 weeks and represent a cumulative response, they can reach high percentages. It is therefore best to report either the aggregate reticulocytes only, or both separately, in cats.

The upper limit of a normal reticulocyte count is often stated as 1%; however, healthy small animals generally have less than 0.4% reticulocytes per 100 erythrocytes. This number is not only increased by enhanced hematopoiesis but also affected by anemia, because it depends on the number of circulating erythrocytes and the duration of reticulocyte maturation in circulation. Therefore various "adjustments" to reticulocyte counts are used. If the erythrocyte count is available, the absolute reticulocyte count can be calculated and is less than 40,000/µL in a healthy animal:

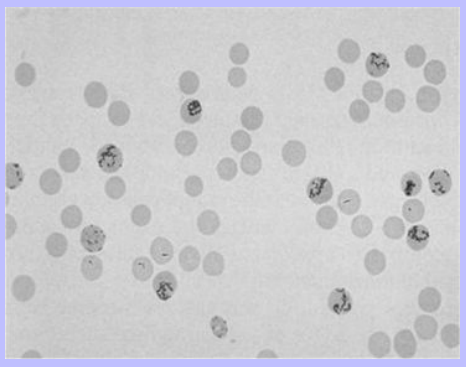
$$\frac{\%\ \text{reticulocytes} \times \text{RBC}/\mu\text{L}}{100} = \text{recticulocytes}/\mu\text{L}$$

The absolute reticulocyte count has now been adopted as the preferred expression of erythroid regeneration. Several automated hematology analyzers have incorporated staining to detect reticulocytes and provide absolute reticulocyte counts; however, some such counts may be falsely increased in the presence of Heinz's bodies, Howell-Jolly bodies, and punctate reticulocytes. If the erythrocyte count is not known, correction for anemia can be made based on the dog or cat's hematocrit compared with the average normal packed cell volume (PCV) value (dogs 45%; cats 37%) and is normally less than 0.4%.

Finally, the reticulocyte production index (RPI) also takes into consideration the extended maturation of stress or shift reticulocytes in circulation. This parameter is no longer applied clinically.

An increase in absolute reticulocyte count or corrected reticulocyte percentage provides the best evidence for a regenerative response. Although not as accurate, other hematologic manifestations such as mean cell volume (MCV) and red cell distribution width (RDW) may be used to indicate increased erythropoiesis when a reticulocyte count is not available. On a blood smear stained with Wright's stain or Diff-Quik, polychromatophilic cells represent erythrocytes recently released from the bone marrow (Figure 270-3). Because their blue-gray tint is due to the presence of RNA, their numbers correlate with the reticulocyte count. When more than one polychromatophilic cell is recognized per microscopic oil immersion field, accelerated erythropoiesis is likely. Polychromatophilic erythrocytes are often macrocytic, which indicates that these cells are released prematurely from the marrow, thereby contributing greatly to the high MCV and RDW, as well as anisocytosis of regenerative anemias. It should be noted that macrocytic anemia is not always regenerative but may indicate a maturation problem such as feline leukemia virus (FeLV) infection or folate deficiency in cats.[5,6]

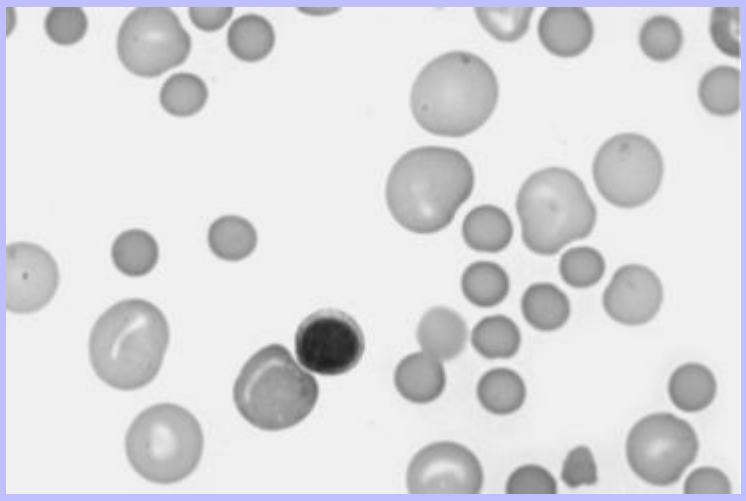
Figure 270-2 Canine reticulocytes as visualized by brilliant cresyl blue stain.



Nucleated erythrocytes (Figure 270-3) also known as *normoblasts* or *metarubricytes* with variably shrunken nuclei are rarely found in blood of healthy animals (less than 1 per 100 white blood cells [WBCs]). Depending on the hematology instrument, they may not be counted or may be under the WBCs. Large numbers may accompany a marked regenerative response in anemic pets. However, nucleated RBCs may also be seen in animals without reticulocytosis and regenerative response because of a breakdown of the barrier between marrow and vasculature. The highest numbers of normoblasts, for example, are observed in acute lead poisoning in the absence of anemia. Mild to moderate normoblastosis with nonregenerative anemia may be seen with myeloproliferative disorders, dyshematopoiesis, extramedullary hematopoiesis, hemangiosarcoma, and sepsis. Thus, normoblastosis should not be equated with a regenerative marrow response without confirmation by a reticulocyte count.

If an anemia is characterized as regenerative based on a reticulocytosis, bone marrow examination is rarely indicated. In regenerative anemia, the bone marrow cellularity is increased and the ratio of myeloid to erythroid elements in the bone marrow is generally below one. The earliest morphologically recognizable erythroid cell is a pronormoblast. An exponentially increasing number of round erythroid precursors that decrease in size to the pyknotic normoblast and are progressively more hemoglobinized indicate normal maturation. Although the erythropoietin response is lineage specific, independent stimulation of thrombopoiesis (e.g. iron deficiency) or granulopoiesis (e.g. immune-mediated hemolytic anemia [IMHA]) may also be present. Bone marrow examination rarely provides helpful information about an underlying cause or marrow iron deposition in animals with regenerative anemia that would otherwise remain undetected. 1887 1888

Figure 270-3 Polychromasia and anisocytosis with spherocytes and metarubricytes.



270.2 BLOOD LOSS ANEMIA

Blood loss anemia occurs whenever a disease process damages vascular integrity sufficiently for RBCs to escape from the intravascular space. Blood loss may be localized to one site and caused by trauma, surgery, tumor, gastrointestinal (GI) disorders, or parasites. Blood loss may be generalized in association with a hemorrhagic tendency. Surface bleeding such as petechiae and epistaxis suggests a platelet problem, whereas hematomas and

cavity bleedings indicate a coagulopathy. These primary and secondary hemostatic disorders are discussed in other chapters (see Chapters 272–274). Regardless of the cause, clinical manifestations of blood loss anemia depend on the volume of blood loss and onset (i.e., whether it is acute or chronic). Both acute and chronic blood loss are regenerative, although in the first few days after acute blood loss and in late stages of severe iron deficiency due to blood loss, such anemias are poorly regenerative.

270.2.1 Acute Blood Loss

Rapid blood loss of major proportions represents a double threat, because it decreases the total blood volume and oxygenation of tissue.[7,8] The total blood volume of dogs and cats is 8–10% and 6–8% of the body weight, respectively. Blood donations for transfusion of 4.4 mL/lb body weight, representing less than 20% of the blood volume of healthy animals, are generally well tolerated. However, when hemorrhage exceeds 20%, cardiovascular signs occur. Initial physiologic adjustments are peripheral vasoconstriction and tachycardia. Regional blood flow to skin and spleen is curtailed to protect perfusion of the brain, heart, and viscera. Thus pallor in acute blood loss anemia is caused not by thinness of blood but by reduced perfusion of the skin and is associated with a prolonged capillary refill time and dry mucous membranes. Besides the redistribution of blood to areas most vulnerable to hypoxemia, the heart rate is increased in an attempt to maintain cardiac output. This high-velocity flow is well tolerated because of the reduced viscosity of anemic blood and vasodilatation in the central and cerebral vascular beds into which most blood is diverted. As the blood loss exceeds 30% to 40% of the original blood volume, cardiac output decreases and hypotension with cardiovascular collapse ensues. The animal becomes immobile and exhibits a rapid, thready pulse, as well as cold skin and extremities. Acute blood loss exceeding 50% of the vascular volume within hours results in shock and eventually death before any changes in hematocrit and plasma protein are observed.[8,9]

If the acute blood loss is gradual, restoration of the plasma volume can occur, which in turn lowers the hematocrit. Unless fluid is administered, plasma volume expansion is a relatively slow process. After a sudden, single hemorrhagic event, albumin-containing fluid is mobilized from the extravascular space over a period of 2 to 3 days. This fluid shift reduces the skin turgor until the fluid deficit is replenished by oral or parenteral fluid intake. Because the associated fall in hematocrit is gradual, the severity of the hemorrhage may be markedly underestimated.

As the anemia is initially normocytic-normochromic and nonregenerative, it could be mistaken for a defective hematopoietic problem. Within a few hours, serum erythropoietin levels are, however, increased and erythropoiesis is stimulated. After 3 days the anemia becomes macrocytic and regenerative. A maximal reticulocyte response is seen within 4 to 7 days. The corrected reticulocyte count may reach 3% to 10% or several hundred thousands per microliter, which is somewhat less than with hemolytic anemias. In acute anemia, adequate iron stores are generally present but the marrow response may be hampered by limited iron mobilization. In cats, the transient rise in aggregated reticulocytes is followed by a marked sustained increase in punctate reticulocytes over a few weeks.

A stress leukogram may also be associated with acute blood loss. Although platelets are being consumed at the site of injury, this does not result in a clinically significant thrombocytopenia; to the contrary, after a slight dip to no less than 60,000/μL, acute blood loss is accompanied by a mild reactive thrombocytosis. In case of external blood loss, a concomitant loss of plasma proteins occurs that includes albumin and globulins. Thus the triad of anemia, hypoproteinemia, and reticulocytosis is considered a hallmark of acute external blood loss. Other test abnormalities depend on the cause of bleeding. Besides typical clinical signs of hemorrhage, examination of a blood smear for platelets and schistocytes and evaluation of an activated clotting time and

buccal mucosal bleeding time may suggest a hemostatic defect that can be confirmed by appropriate laboratory tests.

Four main objectives exist in the management of acute blood loss anemia: (1) fluid replacement, (2) prevention of further bleeding, (3) blood transfusion support, and (4) treatment of the underlying disorder. With sudden hemorrhage, the immediate effects of volume depletion are more important than the loss of circulating RBCs. Thus the first requirement is to maintain an adequate blood volume by intravenous infusion of crystalloid fluids (electrolytes), colloid solutions of plasma, hydroxyethylstarch, hemoglobin solution (Oxyglobin®), or whole blood. Fluid choice depends on the clinical setting, particularly the severity and rate of hemorrhage. With major hemorrhage leading rapidly to shock, losses are primarily from the intravascular space with little change in extra-and intracellular fluid compartments. Crystalloid fluids (isotonic saline or Ringer's lactate) are the first choice. Because crystalloids are rapidly distributed between the intra-and extravascular compartments, they need to be infused in a volume of two to four times the estimated loss. An infusion of crystalloids can rapidly restore circulation, thereby normalizing many hemodynamic parameters.

Within days, intra-and extracellular fluids shift into the intravascular space. For adequate resuscitation of a pet with hemorrhagic hypotension and shock, much larger fluid volumes must be given quickly to replete the fluid compartments and restore circulation. Colloid fluids such as 6% hydroxyethylstarch or dextran 70 solutions produce a volume expansion slightly larger than that infused and can maintain this effect for as long as a day. Because species-specific albumin solutions are not available for small animals, plasma, or whole-blood transfusions may be used for replacement therapy. Their use should, however, be discouraged unless clotting factors are needed or, because of anemia due to major blood loss, an oxygen carrier is deemed necessary. A bovine hemoglobin solution (Oxyglobin®) has become commercially available for dogs that provides oncotic pressure and an oxygen transporter. It can prove useful in the emergency management of acute blood loss and lacks immunologically important reactions and in dogs even after repeated administration.[10–12]

The depletion of RBC mass after acute blood loss may be difficult to estimate because of concurrent plasma loss and the hematocrit decreases only after total blood volume returns to normal. Thus the “transfusion trigger” can be particularly difficult to define in a hemorrhaging pet. Although a healthy normovolemic anemic animal at rest may tolerate a hematocrit as low as 5% to 10%, signs of hypoxia develop much earlier in a hypovolemic anemic animal. Thus small animals with precipitous blood loss may be deemed in need of a blood transfusion at hematocrits above 20%. Ten milliliters of whole blood per pound body weight increases the hematocrit by 10%, but fluid shifts and concomitant replacement of fluids may diminish the response. It should be noted that except for isotonic saline, fluids have to be administered through a catheter other than that used for transfusion. If venous access cannot be obtained in severely hypotensive animals, the intraosseous route may be used because RBCs and fluids rapidly reach the intravascular space. Because canine stored blood or packed RBCs have low 2,3-diphosphoglycerate (DPG) concentrations, which may hamper the oxygen release, some clinicians have advocated the use of fresh blood. However, DPGs are rapidly replenished in canine erythrocytes; therefore this may be more of a theoretic concern. Because the hemoglobin-oxygen affinity of feline erythrocytes is not DPG dependent, this is not a problem in cats; however, closed blood collection systems and blood component preparation for storage of feline blood are a problem. When hemorrhage has ceased, the recovery of the red cell mass to normal usually occurs within 1 to 2 weeks. Animals with acute blood loss anemia have adequate iron stores and generally do not require supplemental iron to reach an appropriate erythroid bone marrow response.

270.2.2 Chronic Blood Loss Anemia-Iron Deficiency Anemia

Animals have approximately 9 to 22 mg iron per lb body weight, and most of the iron is located in erythrocytes as hemoglobin (1 mg iron in 2 mL of blood).[3,13] In addition, muscle myoglobin and many important enzymes contain heme iron (e.g., cytochromes). Iron is also stored in various tissues, particularly spleen, liver, and bone marrow, as a soluble mobile fraction (ferritin) or insoluble fraction (hemosiderin), depending on the amount available. Transferrin represents the iron transport protein in the plasma and is normally 20% to 60% saturated with iron. As under physiologic conditions, iron losses through gut, urine, and skin are negligible, amounting to less than 1 mg/day in small animals. Iron balance is regulated by iron absorption. Iron is absorbed in the ferrous (Fe^{2+}) form as heme iron or nonheme iron by the mucosal cells of the proximal small intestine. The exact control mechanisms have not been elucidated, but absorption increases with diminished storage and increased erythropoietic activity. However, the maximal absorption remains rather limited—only a few milligrams per day.[14,15]

Chronic external blood loss is the major cause of iron deficiency anemia in small animals and is associated with a regenerative anemia. Iron deficiency denotes a deficit in total body iron, which occurs in varying degrees. Iron depletion is present when iron stores are depleted but serum iron and blood hemoglobin concentrations remain normal. In iron-deficient erythropoiesis, serum iron levels are also low but the anemia is only mild. *Iron deficiency anemia* refers to the most advanced stage, characterized by absent iron stores, low serum iron concentration, low transferrin saturation, and low hemoglobin and hematocrit values.

Chronic external blood loss may result from GI hemorrhage, parasitism, chronic bleeding neoplasia, and even chronic inflammatory bowel disease (IBD).[16–22] Severe flea infestation can cause substantial blood loss and mortality, particularly in kittens and puppies, because 100 fleas could potentially consume 1 mL of blood daily. Similarly, the quantity of blood loss caused by hookworms and rarely whipworms is proportional to the worm burden and may reach 100 mL/day. Hookworms burrow their heads deeply into the small intestinal wall and suck blood by peristaltic pumping. Chronic or intermittent GI blood loss may also result from hemorrhaging GI neoplasia, including leiomyoma, carcinoma, and lymphoma; bleeding intestinal aneurysm; and ulcerogenic drugs such as glucocorticosteroids, salicylates, and nonsteroidal anti-inflammatory agents. As each regular blood collection (450 mL) removes approximately 200 mg of iron from the body, overzealous blood donations and frequent phlebotomies for diagnostic purposes in small dogs and cats may lead to iron deficiency states.

In young animals the iron needed for growth may exceed the supply available from diet and body stores. Thus they are particularly at risk for developing an iron deficiency anemia. Because milk is low in iron, nursing animals may become iron deficient. However, with the general use of balanced commercial diets for growing animals, iron deficiency related to inadequate intake alone is rare. Intestinal malabsorption syndromes, such as IBD in Shar Peis, can be associated with iron deficiency states.

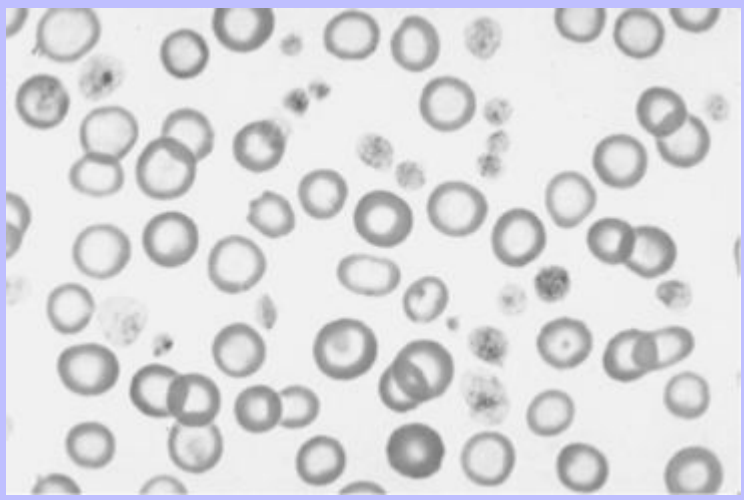
Iron deficiency anemia develops over weeks and is almost always insidious, allowing remarkably effective adaptation. Clinical signs are nonspecific and depend more on the rate of progression than the extent of anemia. Even when the hematocrit falls below 5% to 10%, clinical signs of anemia, besides pallor, may not be obvious at rest. The animals may become increasingly fatigued and exercise intolerant and, when stressed, may suddenly decompensate and die. Clinical manifestations include extremely pale mucous membranes, bounding pulses, gallop rhythm, and a systolic flow murmur. Reduced blood viscosity, vascular resistance (decreased afterload), and increased left ventricular filling (increased preload) maintain the cardiac output. Thus chronic anemia causes cardiomegaly through cardiac hypertrophy and dilation and may eventually lead

to congestive heart failure (CHF).[20] In contrast, tachypnea and dyspnea are not typical features of anemia unless the animal has pulmonary disease that impairs oxygen uptake. Pica, the craving to eat, chew, or lick unusual substances such as dirt, clay, feces, and metal, is a classical manifestation of iron deficiency. Because iron deficiency is most commonly caused by GI blood loss, melena is likely to be present, but occasionally it is intermittent or detected only by the occult fecal blood test. A positive test result for an animal receiving a commercial diet is probably clinically significant. Typical blood sweat and laboratory test abnormalities may provide the first clue to an iron deficiency anemia and possibly an occult intestinal malignancy.

Iron deficiency can produce clinical manifestations independent of anemia because depletion of iron-containing compounds in nonerythroid tissue results in impaired proliferation, growth, and function. These include reduced muscle activity, abnormal behavior, and skin and nail changes.

Severe iron deficiency anemia is characterized by a hypochromic microcytic anemia caused by decreased synthesis of hemoglobin and delayed cell maturation and extra mitosis.[1,7,16,23] On a blood smear the hypochromic cells are readily recognized by the increased central pallor (Figure 270-4) and are reflected by a decreased mean corpuscular hemoglobin concentration (MCHC). In advanced states the red cell corpuscles represent mere rings. Microcytosis is less well appreciated on a blood smear, because cell diameter is less affected than cell thickness; these flat, poorly stained cells are called *leptocytes* and have a reduced MCV. 1889
Anisocytosis is also a recognizable morphologic change and can be quantified by an increased RDW as 1890
determined by particle size counters. In addition, iron-deficient erythrocytes appear stiffer and less deformable, presumably because of oxidative damage of membrane proteins. Thus erythrocyte fragmentation, increased mechanical fragility, and accelerated lysis may occur, thereby affecting the various erythrocyte indices. However, in the osmotic fragility test, the red cells may be more resistant to destruction in hypotonic salt solutions because of their increased capacity to expand their volume.[1,14]

Figure 270-4 Hypochromasia and thrombocytosis in a dog with severe chronic blood loss anemia.



In humans, iron deficiency anemia is non-or poorly regenerative[14]; in contrast, iron deficiency in small animals is usually associated with a pronounced reticulocytosis.[16] The reticulocyte counts may reach

500,000/μL (10% corrected), presumably because of their delayed maturation. This reticulocytosis greatly contributes to the degree of anisocytosis and increased RDW.

The leukocytes are usually normal in number, but slight neutropenia may occur, whereas eosinophilia is seen in parasite-induced blood loss anemia. Interestingly, the platelet count is commonly increased to about twice normal, but may exceed $1 \times 10^6/\mu L$.[9]

Thrombocytosis associated with acute and chronic blood loss is considered reactive, but the exact mechanism remains unexplained. A search for occult blood loss is highly warranted in anemic animals with thrombocytosis. In uncomplicated iron deficiency anemia, the chemistry screening test results are unremarkable except for a low total protein related to concomitant intestinal losses of albumin and globulin.

The bone marrow is characterized by mild to moderate erythroid hyperplasia with nuclear distortions. The normoblasts appear small and have scant cytoplasm. After staining the bone marrow aspirate or biopsy section with Prussian blue, one sees dark-blue granular material scattered throughout the marrow. In iron deficiency anemia, no stainable iron in the form of deep-blue granules is found (hemosiderin appears in the unstained marrow smear as golden refractile granules). However, healthy cats normally store only small amounts of ferritin and hemosiderin in macrophages of their marrow; thus a lack of positive Prussian blue staining is not diagnostic for iron deficiency in cats, but Prussian blue–positive deposits in marrow exclude iron deficiency.

Serum iron concentrations are usually low, ranging from 5 to 60 μg/dL compared with a normal range of 60 to 230 μg/dL, depending to some extent on the method used.[13] However, serum iron concentrations are subject to many variables that may cause normal or even high results, including hemolyzed samples, iron supplementation, and recent transfusions. The iron-binding capacity is a measure of the amount of transferrin in circulating blood and may be slightly increased in iron deficiency states; thus the transferrin saturation is markedly decreased to below 20% (normal 20% to 60%). Serum ferritin concentrations would be expected to be low, but because ferritin is an acute phase protein, values are often increased by coexisting inflammation. Iron parameters can also be affected by transfusions, iron supplements, and glucocorticoid administration.

Management of chronic blood loss anemia is directed toward correction of the anemia, the iron deficiency, and treatment of the underlying disease. Transfusions with packed RBCs or whole blood are indicated only in cases of severe anemia or in preparation for anesthesia and surgery to correct the GI hemorrhage (PCV less than 15% to 20%) and clinical signs of tissue hypoxia. Because these animals are normovolemic and have increased cardiac output, transfusion volumes and rates should be conservative to avoid cardiac failure. Volume overload occurs more commonly in cats than in dogs. Correction of the anemia also results in resolution of cardiomegaly within several weeks. Although ulcerogenic drugs can be withdrawn immediately, control of ecto-and endoparasites (as well as any surgical corrections) should be undertaken only when the pets has been stabilized. Leiomyomas and leiomyosarcomas are frequent small intestinal tumors in older dogs, and their complete resection is often rewarding.

Once critical care has been provided and the underlying condition has been corrected, iron supplementation should be initiated to replenish iron stores. Iron is highly effective in treating iron deficiency. It has, however, no other legitimate therapeutic use, because it exerts no beneficial effects for other forms of anemia and may be harmful (exception: animals with chronic renal failure may in fact also experience an iron deficiency). Iron can be administered orally and parenterally. The oral route is the safest and least expensive. Ferrous sulfate in tablet or liquid form at a dose of 5 mg/lb daily along with a meal is effective, although the exact iron requirements have not been established for small animals. Iron fumarate and gluconate may be substituted, but other iron preparations are likely not to be effective, may cause gastric irritation, and hence are not

recommended. Treatment has to be continued for weeks to months to correct the iron deficiency state, but iron stores may never be completely replenished.

If oral iron replacement is deemed inappropriate or insufficient or a GI disorder prevents iron absorption, parenteral iron may be administered. Iron dextran complex containing 50 mg iron per milliliter can be given intramuscularly. After a small dose is injected deep into the muscle to test for hypersensitivity reaction, a maximal dose of 2 mL is administered daily; two thirds of the iron is absorbed from the injection site within days. Ferrous chloride is potentially available in intravenous form. As 2 mL of blood contains 1 mg iron, blood transfusions also provide an excellent source of iron, but they should be restricted to severely anemic animals.

270.3 HEMOLYTIC ANEMIAS

Once the erythrocyte has lost its nucleus and ribosomes, it can no longer synthesize proteins. Nevertheless, it survives hundreds of miles of hazardous travel through large and tiny blood vessels with its limited equipment. It is capable of sustaining adequate energy levels through anaerobic glycolysis, maintaining ionic composition, reducing methemoglobin and oxidized glutathione, and resealing its membrane if portions are lost. Despite these capacities, erythrocytes have a finite life span that may be shortened when the environment becomes hostile or when the cell's ability for self-repair becomes impaired. Accelerated erythrocyte destruction is the major mechanism in hemolytic disorders and plays a minor role in many other common anemias.[24]

The normal life span of erythrocytes averages approximately 100 to 120 days in dogs and 70 to 78 days in cats.[2,3] Although it is rarely done in clinical practice, the erythrocyte life span can be measured directly by two labeling methods. The cohort method depends on the incorporation of an isotopically labeled chemical such as radioactive iron or glycine into newly formed cells. In contrast, the random labeling methods use tracers that bind with all erythrocytes in the circulation and include radiolabeled chromium or cyanate, as well as nonradioactive biotin.[25] Because chromium elutes from cells readily, the apparent half-life is much shorter (i.e., 20 to 30 days instead of 60 days for normal canine erythrocytes and only 6 to 14 days instead of 37 days for feline erythrocytes).[26] If needed, the nonradioactive biotin-labeling method should be considered.

Although the concept of erythrocyte aging and death is well established, the precise mechanisms involved in normal cell senescence are still not clearly defined. No single marker exists to identify aged erythrocytes, but the following factors may contribute to the finite life span of erythrocytes: declining enzyme activities, change in calcium balance, diminished negative membrane charge, repeated oxidative injuries, and binding of complement or naturally occurring autoantibodies against membrane band 3 protein and galactosyl-containing glycolipid.[24,25] 1890 1891

The erythrocyte life span may be shortened as a result of some intrinsic defect, such as an erythroenzymopathy, or because of some extrinsic mechanism that leads to premature erythrocyte removal, such as antibodies against erythrocytes. These can be distinguished experimentally by cross-transfusion studies. When erythrocytes from a healthy animal are transfused to one with an extrinsic cause for hemolysis, the donated cells are destroyed as rapidly as the pet's own cells. However, if an animal's corpuscles are removed from the unfavorable environment, they survive normally. In contrast, erythrocytes with an intrinsic defect would be disposed of rapidly in either the affected animal or a healthy recipient. Such survival studies are generally not required in the evaluation of hemolytic anemias in clinical practice.

Erythrocyte destruction may take place either extra-or intravascularly.[1,3] Extravascular hemolysis predominates and is assumed to be the mode of destruction of senescent erythrocytes in healthy animals. Extravascular

destruction refers to erythrophagocytosis by macrophages of spleen, liver, and bone marrow. Damaged or senescent erythrocytes are prone to enhanced sequestration in these organs. Erythrophagocytosis may be either complete (culling) or partial (pitting). In particular, splenic environment with its low glucose concentration, mild hypoxia, hypercapnia, and relatively low pH can be deleterious to erythrocytes. Based on its structure, the canine spleen is more efficient than the feline spleen in removing erythrocytes. Macrophages destroy ingested erythrocytes through proteolytic and lipolytic enzymes.

The heme oxygenase system responsible for hemoglobin degradation is located primarily in phagocytic cells. The globin is broken down to amino acids, which are reused. In heme catabolism, iron becomes liberated, recirculates bound to transferrin in plasma back to the marrow for erythropoiesis, and the protoporphyrin ring opens. Carbon monoxide is split off, exhaled, biliverdin forms, and is subsequently reduced to bilirubin.

Unconjugated bilirubin is then released into the plasma; it is water insoluble and reversibly binds to albumin (indirect-reacting bilirubin). The albumin-bound bilirubin is readily absorbed by hepatocytes. In the liver, bilirubin is conjugated with glucuronic acid to form bilirubin diglucuronide, also known as *direct bilirubin*. The conjugated bilirubin is excreted via the bile canaliculi into the duodenum, but in the presence of massive heme breakdown, conjugated bilirubin leaks back into the plasma and is also excreted in the urine. Intestinal bacteria in the colon convert the bilirubin to urobilinogens. Most of the urobilinogen is excreted in the feces, but a small amount is reabsorbed. The reabsorbed urobilinogen is readily re-excreted by the liver (enterohepatic recirculation), with a small portion lost in the urine.

The serum bilirubin concentration is an important marker of the rate of hemoglobin metabolism and of hepatobiliary function. Normal serum values, measured by colorimetric methods, do not exceed 0.4 mg/dL, and jaundice is not appreciated until the serum bilirubin exceeds 2 mg/dL. One might predict that hemolytic disorders are associated with a greater rise in indirect bilirubin, whereas hepatic failure leads to a larger increase in direct bilirubin. However, because the process to conjugated bilirubin is highly efficient and rapid in small animals, the differential bilirubin determination in serum has not proved helpful in distinguishing hemolytic from hepatic causes of hyperbilirubinemia. Hyperbilirubinemia and hemoglobinemia can affect accurate measurements of serum liver and other chemistry screen parameters. Liver function tests are often indicated, because hemolysis may be associated with a hepatopathy. Heme can be metabolized by alternative pathways in other tissues (e.g., kidney in dogs). In any case, a rise in heme degradation results in hyperbilirubinuria because of increased urinary excretion of conjugated bilirubin. Bilirubin is readily identified by the diazo-reaction on the urine dipstick. Small amounts of bilirubin are normally found in urine from healthy dogs but not cats. Hemoglobinuria may make the bilirubin readings invalid. Bile pigment gallstones, seen in humans with hemolysis, are not observed in small animals.

Less commonly, erythrocytes are lysed within the systemic circulation as a consequence of membrane permeability changes or cellular fragmentation. With intravascular hemolysis, hemoglobin is directly released into the blood, from which it is removed by several mechanisms. Hemoglobin breaks into two alpha-beta dimers and binds to haptoglobin in plasma or further dissociates into heme to form hemopexin and methemalbumin. After these complexes are taken up by macrophages and hepatocytes, hemoglobin and heme are metabolized as described earlier in relation to extravascular hemolysis. Binding prevents excretion of hemoglobin into the urine, but during intravascular lysis, haptoglobin becomes easily depleted. Unbound plasma hemoglobin and heme may be removed by the liver or excreted through the renal glomeruli.

Proximal tubular cells reabsorb and catabolize most filtered hemoglobin and heme.

Hemoglobinuria ensues when the amount filtered exceeds the limited capacity of the tubular cells to resorb dimers. Although heme pigments may precipitate and form casts in the distal renal tubules, hemosiderinuric

tubular necrosis and acute renal failure are rarely observed in small animals with severe or chronic hemoglobinuria.

Intravascular lysis can be readily recognized by the presence of hemoglobinemia, depletion of plasma haptoglobin, and hemoglobinuria. Plasma hemoglobin levels of 10 to 20 mg/dL give plasma an amber coloration, and at 50 to 100 mg/dL the plasma appears reddish. The hemoglobinemia has to be distinguished from artifactual increases in plasma hemoglobin caused by blood collection methods that directly cause hemolysis, as well as delayed plasma separation. Plasma hemoglobin concentrations can be quantitated spectrophotometrically by an accurate and simple hemoglobinometer (HemoCue).[27] Hemoglobinuria imparts a red-brown color to the urine, reflecting both hemoglobin and methemoglobin. Because the urine dipstick identifies only heme (labeled "blood"), hemoglobinuria has to be differentiated from hematuria (whole erythrocytes) by microscopic examination after urine sedimentation. Myoglobinuria associated with massive muscle necrosis can also cause a positive test result but hardly ever occurs in small animals.

Based on the preceding mechanisms of erythrocyte destruction, the clinical features and laboratory test abnormalities of the various hemolytic disorders are similar. Besides the general signs of anemia such as pallor and weakness, characteristic signs of hemolysis are jaundice and pigmenturia. Jaundice is first appreciated on mucous membranes (gingiva and sclera) when serum bilirubin concentration exceed 2 mg/dL, whereas skin becomes icteric at slightly higher concentrations. Milder and chronic forms of hemolysis may not be associated with jaundice. Pigmenturia caused by hemolysis may be due to hyperbilirubinuria and hemoglobinuria. Hyperbilirubinuria persists in dogs with hemolytic disorders, whereas in cats it is not constant. Hemoglobinuria and hemoglobinemia are hallmark features of intravascular hemolysis and often indicate a more severe disorder.

The terms *hemolytic anemia* and *hemolytic disorder* are limited to conditions in which the rate of erythrocyte destruction is accelerated and the ability of the bone marrow to respond to the stimulus is unimpaired. As indicated in the introduction, hemolytic anemias are generally associated with accelerated erythrocyte production that is unrestricted by iron availability. In fact, the highest reticulocyte counts and most severe erythroid hyperplasias are observed in animals with hemolytic anemias. Thus hemolytic anemias are regenerative and macrocytic-hypochromic, although in the early stages and in some complicated acquired forms the erythroid response may be poor (e.g., immune-mediated hemolytic anemia). In addition, a number of common complex anemias related to insufficient erythrocyte production have a component of accelerated erythrocytic destruction such as the previously mentioned advanced iron deficiency anemia.

1891

1892

The division of hemolytic anemias into acute and chronic forms is of limited usefulness, because acute crises may develop during the course of chronic disorders. Classification based on the site of hemolysis, predominantly within the circulation (intravascular) or within tissue macrophages (extravascular), is of some help, because only a few are associated with overt intravascular hemolysis. However, intravascular lysis may occur only transiently; therefore the unique manifestations of hemoglobinemia and hemoglobinuria may be missed. Excessive destruction of erythrocytes may occur either because of an intrinsic defect in the cell itself or because of the action of extrinsic factors on normal erythrocytes. Intrinsic defects are generally inherited and extrinsic are acquired. The division into intrinsic and extrinsic or inherited, and acquired forms is of pathogenic importance and is most useful as hereditary hemolytic anemias gain greater recognition. Furthermore, some hemolytic processes are associated with acquired disorders of other organs and are covered elsewhere.

270.3.1 Inherited Erythrocyte Defects

Several hereditary erythrocyte defects (Table 270-1) have been described in dogs and cats.[19] The mode of inheritance is autosomal recessive for all described erythrocyte defects, with the exception of feline porphyria,

in which at least one defect is inherited as a dominant trait. This is a large heterogeneous group of disorders, and most occur rarely. Through inbreeding practices (popular sire, line breeding), some erythrocyte defects have become common in certain breeds. Unless the affected breeds are closely related, a particular disease is probably caused by different mutations of the same gene. Erythrocyte-induced defects vary from mild compensated hemolytic to life-threatening anemia. Accurate laboratory tests are now available for many erythrocyte defects to detect affected and carrier animals.

Some defects represent hematologic curiosities without clinical signs (such as in Akitas and miniature poodles with inconsequential microcytosis and macrocytosis, respectively). Hereditary erythrocyte disorders have been classified into three groups: (1) heme defects and hemoglobinopathies, (2) membrane abnormalities, and (3) erythroenzymopathies.[28] Hereditary production and maturation defects of erythrocytes and other hematopoietic cells are discussed in Chapter 271.

270.3.2 Hemoglobin and Related Disorders

Dogs and cats apparently have embryonic but no fetal hemoglobin.[2] With the exception of some Japanese dog breeds, only one adult hemoglobin has been found in dogs. Historically, two major adult hemoglobins were described in cats with a large variation of the hemoglobin A/hemoglobin B ratios. Later studies, however, revealed only one alpha globin, but six different beta globins were found.[29] With each cat having one to four different beta globins, at least 17 hemoglobin patterns were recognized. In contrast to the common occurrence of thalassemia and sickle cell anemia in humans, no hemoglobinopathies have been documented in anemic dogs and cats.

Physiologically or pathologically generated methemoglobin contains heme in the ferric form (Fe^{3+}) and therefore cannot carry oxygen. It is reduced to the ferrous form (Fe^{2+}) by the methemoglobin or cytochrome b_5 reductase system. Isolated cases of methemoglobinemia associated with methemoglobin reductase deficiency were found among dogs of various breeds and several domestic shorthair cats (DSH).[3,30–32] Affected animals have cyanotic mucous membranes but generally do not exhibit any other clinical signs of hypoxemia unless vigorously exercised. The blood remains dark after air exposure because of the presence of 13% to 52% methemoglobin. In contrast to those with other erythrocyte defects, these animals are not anemic but rather develop a mild erythrocytosis and can have a normal life expectancy. Reducing agents such as methylene blue could be used but are generally not needed.

Defects of heme synthesis known as *porphyrias* have been reported in anemic Siamese cats and nonanemic DSH cats with pigmented and pink-fluorescent teeth and bones.

270.3.3 Erythrocyte Membrane–Related Abnormalities

The erythrocyte membrane consists of a bilayer affixed to a membrane skeleton, which determines cell shape and deformability. Owing to proteolysis, canine and feline erythrocytes lose their Na^+, K^+-adenosine triphosphatase (Na^+,K^+-ATPase) during late maturation in the bone marrow and reticulocytes.[33] Therefore erythrocytes have high-sodium and low-potassium concentrations similar to those of serum electrolyte values. Consequently, hyperkalemia generally does not occur after intravascular hemolysis unless stress reticulocytes are lysed. Erythrocytes from Sheba, Inus, Akitas, and some mongrel dogs in Korea and Japan represent an exception, because they keep their erythrocytic Na^+,K^+-ATPases and therefore have high-potassium and low-sodium concentrations in erythrocytes. Because Akitas' erythrocytes are leaky *in vitro*,

pseudohyperkalemia may occur if the plasma and serum are not readily separated from erythrocytes and its clot.[34]

Elliptocytosis and microcytosis related to cytoskeleton protein band 4.1 deficiency has been described in an inbred, nonanemic mongrel dog.[35,36] Other erythrocyte membrane defects are far less well defined but are generally characterized by increased osmotic fragility (Figure 270-5). Stomatocytes are overhydrated, cup-shaped macrocytes that are recognized by a slitlike pallor on a blood film. In the Alaskan malamute, stomatocytosis is associated with a chondrodysplastic dwarfism.[37] Miniature and middle schnauzers with stomatocytosis had no skeletal abnormalities, and both breeds had only mild regenerative anemia on the basis of hemoglobin measurements with high MCV and low MCHC indices[38,39] (Figure 270-6). Furthermore, stomatocytosis and hypertrophic gastritis have been reported in the Drentse partrijshond dog breed (Dutch breed) and a lipid disorder is suspected on the basis of abnormal erythrocyte membrane and plasma phospholipids.[40] A hereditary spherocytosis has been described in some golden retrievers.[41] A marked osmotic fragility of erythrocytes associated with recurrent anemia, severe splenomegaly, weight loss, lymphocytosis, and hyperglobulinemia but a negative Coombs' test has been observed mostly in Abyssinian and Somali cats.[42] Their erythrocytes are so fragile that the lysis is clearly evident once the ethylenediaminetetraacetic acid (EDTA) tube is left in the refrigerator overnight. Although the cause has not been identified, affected cats with marked splenomegaly may benefit from prednisone treatment and splenectomy. This may reduce the degree of *in vivo* phagocytosis of damaged erythrocytes; however, the *in vitro* osmotic fragility of erythrocytes does not appear to improve after treatment. This osmotic fragility has also been seen in Siamese and DSH cats.

270.3.4 Erythroenzymopathies

Devoid of a nucleus and mitochondria, erythrocytes generate energy almost exclusively through anaerobic glycolysis, also known as the *Embden-Meyerhof* pathway. Phosphofructokinase (PFK) and PK are two key regulatory enzymes of this pathway, but their deficiency results in two distinctly different forms of anemia in dogs. The Embden-Meyerhof pathway also plays an important role in an ancillary pathway. The *Rapoport-Luebering* pathway is responsible for the synthesis of DPG, which influences the oxygen affinity of canine but not feline hemoglobin. Erythrocyte DPG concentrations are low in cats.[3,43]

Table • 270-1 Inherited Erythrocyte Defects

DEFECTS	BREEDS	INHERITANCE	PACKED CELL VOLUME (PCV) (%) RANGE	RETICULOCYTE (%) (CORRECTED)	ERYTHROCYTE HALF-LIFE (DAYS)	ERYTHROCYTE MORPHOLOGY	SPECIFIC TESTS	CLINICAL FEATURES
Erythroenzymopathies								
Pyruvate kinase (PK) deficiency	Basenji*, beagle*, West Highland white* and cairn terrier, miniature poodle, dachshund*, toy Eskimo*, pug	AR	11–29	5–95	4–9	Polychromasia, ecchinocytes	DNA test, abnormal M-PK, PK kinetic, stability, and glycolytic intermediates	Hemolytic anemia, myelofibrosis, osteosclerosis
	Abyssinian*, Somali*, DSH cats*	AR	10–33	1–33	U	Polychromasia	DNA test PK activity <20%	Intermittent hemolytic anemia
Phosphofructokinase (PFK) deficiency	English springer spaniel*, cocker spaniel*, mixed breed dog*	AR	11–48	5–23	4	Polychromasia	DNA test PFK activity, 8%–22%	Inducible hemolytic crises, mild myopathy, pigmenturia
Hemoglobin Synthesis Defects								
Hemoglobinopathies	None							
Cytochrome-b_5 reductase (Cb_5R) deficiency	Many isolated cases in dogs and DSH cats	U	High	N	U	Unremarkable	Cb_5R activity, 10%–30%; methemoglobin >10%	Cyanosis, no anemia, but polycythemia, exercise intolerance
Porphyria	Siamese	AD	10–25		U	Unremarkable	Porphyrins in urine and erythrocytes	Anemia, discolored teeth
	DSH	AD	N	N to 5	U	Unremarkable	Porphobilinogen deaminase deficiency (?)	Discolored teeth, ± anemia
Membrane and Other Abnormalities								
Elliptocytosis (band 4.1 deficiency)	Mixed breed dog*	AR	34	2	16–23	Elliptocytes	Membrane protein electrophoresis	None
Stomatocytosis	Alaskan malamute, miniature & middle schnauzer	AR	N	3–7	6–18	Stomatocytes, macrocytes, polychromasia	Stomatocytes, increased osmotic fragility	Chondrodysplasia in malamutes, none in schnauzers
Increased osmotic fragility	English springer spaniel, mixed breed dogs	U	N	2–5	U	Polychromasia, poikilocytosis	Increased osmotic fragility, unknown	Exercise-induced hyperthermia
Increased osmotic fragility	Abyssinian, Somali	U	8–35	1–4	U	Macrocytosis	Increased osmotic fragility	Intermittent anemia, splenomegaly
High-potassium erythrocytes	Akita, Japanese mongrels	U	N	N	U	Unremarkable	Increased erythrocyte and serum potassium	None, pseudo-hyperkalemia
Nonspherocytic hemolytic disorders	Beagle	AR	29–12	8–23	7–15	Polychromasia	Calcium ATPase pump (?)	None, mild anemia

Poikilocytosis	DSH cats	U	7–12	10–30	U	Severe poikilocytosis	Poikilocytosis	Severe anemia
Familial microcytosis	Akita	U	N	N	U	Microcytosis	Erythrocyte indices	None
Familial macrocytosis and dyshematopoiesis	Poodle (miniature and toy)	U	N	N	U	Macrocytes, hypersegmented neutrophils	Macrocytosis, normal osmotic fragility	None, gingivitis

Data collected from references and author's unpublished observations.
N, Normal; *U*, unknown; *AR*, autosomal recessive; *AD*, autosomal dominant; *DSH*, domestic shorthair.

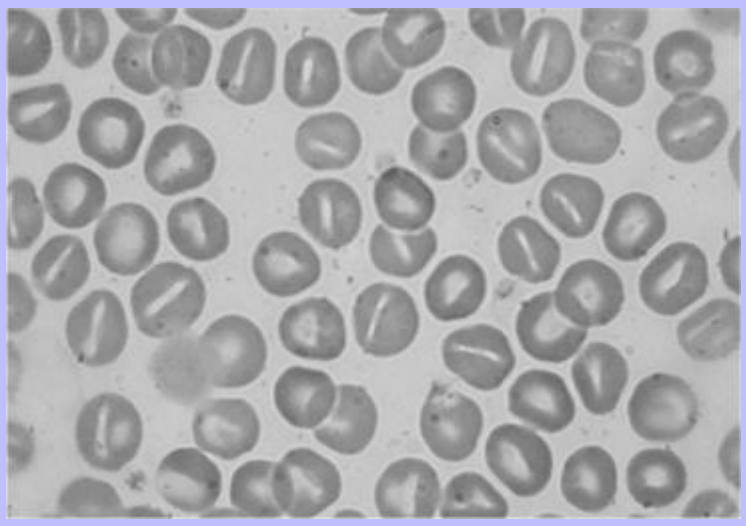
270.3.4.1 Phosphofructokinase Deficiency (PFK)

PFK deficiency is characterized by a chronic hemolytic disorder accentuated by hemolytic crises and an exertional myopathy.[44–47] After episodes of excessive panting and barking, extensive exercise, and high temperatures, affected dogs develop dark brown-red urine because of hemoglobinuria and hyperbilirubinuria. These sporadic events are associated with hyperventilation and elevated body

temperature, and the ensuing slight alkalemia results in intravascular lysis of PFK-deficient erythrocytes because these cells are more alkaline fragile than normal canine erythrocytes. During these crises, affected dogs may become severely anemic, icteric, lethargic, anorexic, and develop a fever that usually resolves within days with supportive care. If situations that trigger hemolytic crises are avoided, PFK-deficient dogs may not have problems and can reach a normal life expectancy. However, they have persistent hyperbilirubinuria and reticulocytosis despite a normal hematocrit because of ongoing hemolysis and a high hemoglobin-oxygen affinity because PFK-deficient erythrocytes contain low DPG levels and therefore lead to a relative tissue hypoxia. Furthermore, because affected dogs totally lack PFK activity in muscle, they have a metabolic myopathy characterized by exercise intolerance, occasional muscle cramps, and mildly increased serum creatine kinase activity; thus they perform poorly as field trial dogs.[44]

Figure 270-6 Stomatocytosis in a miniature schnauzer without anemia.



This glycolytic enzyme deficiency is common in field trial English springer spaniels in the United States, Great Britain, and Denmark, but has also been reported in bench English springer spaniels, as well as a cocker spaniel and a mixed breed dog.[43,48] Although the true prevalence remains unknown, a 1% to 4% prevalence among championed breeding bench and field English springer spaniels has been documented in a randomized survey in the United States.[49] PFK deficiency is caused by a missense mutation of the muscle-type PFK gene that results in truncation and instability of the enzyme, thereby leading to a complete muscle-type PFK deficiency.[50] A simple polymerase chain reaction (PCR)-based DNA test accurately diagnoses PFK-deficient and carrier dogs. A small blood sample, buccal swab, or semen is an appropriate source for DNA testing and requires no special handling or shipping. English springer spaniels (and cocker spaniels) with suspicious clinical signs or before field training and breeding should be DNA tested for PFK deficiency. In other breeds with suspicious signs, an enzymatic PFK test could be performed.

270.3.4.2 Pyruvate Kinase Deficiency (PK)

The classic erythrocytic PK deficiency initially reported in Basenjis is now seen in several other breeds including beagles, West Highland white and cairn terriers, miniature poodles, toy Eskimos, pugs, and

dachshunds.[43,44,51–54] Despite a persistent hemolytic anemia, the clinical signs, except for pallor, are often mild. The anemia ranges from about 10% to 32% and is highly regenerative with numerous circulating metarubricytes and reticulocyte counts that can be as high as sometimes approaching 95%. An unexplained progressive myelofibrosis and osteosclerosis of the bone marrow develops at about 1 year of age, although some West Highland white terriers may not show evidence until several years of life. Furthermore, it appears likely that previously described nonspherocytic hemolytic anemia and osteosclerosis in miniature poodles were caused by a PK deficiency.[55] PK-deficient dogs usually die because of anemias and generalized hemosiderosis with associated hepatic failure before 8 years of age. Splenectomy and prednisone treatment appear unhelpful in dogs. Erythrocytes completely lack the adult erythrocyte isozyme form of PK known as *R-PK*. Instead, they express a fetal or leukocyte M-PK form that is dysfunctional in erythrocytes *in vivo*. Molecular genetic screening tests are available for the identification of the PK mutation of affected and carrier Basenjis, beagles, dachshunds, toy Eskimos, and West Highland white and cairn terriers, but not yet for others.[56–58] A cumbersome PK enzyme activity test with isozyme characterization is required to define PK deficiency in other breeds. Carriers do not express the M-PK form and have approximately half-normal PK activity; however, differentiation between carriers and homozygous normal dogs based on enzyme activity may not be accurate.

1895

1896

Feline erythrocytic PK deficiency has also been described in the Abyssinian and Somali breeds and few DSH cats.[59] Affected cats have chronic intermittent hemolytic anemia and mild splenomegaly but no osteosclerosis. The anemia is moderately regenerative and no poikilocytosis is seen. Erythrocyte PK activity is severely reduced, and no M-type PK expression occurs. A deletion caused by a splicing mutation in the R-PK gene has been identified, and a molecular screening test has been made available. Intermittent prednisone therapy and splenectomy appear to ameliorate the clinical signs of intermittent anemia. The oldest living cat reached 13 years of age.

270.3.5 Immune-Mediated Hemolytic Anemia (IMHA)

IMHA arises when an immune response targets erythrocytes directly or indirectly and hemolytic anemia ensues. Until the antierythrocytic antibodies are identified and the pathogenesis is better understood, the nomenclature and classification of IMHA remain imprecise and sometimes confusing.[46,60,61] In primary IMHA no inciting cause can be identified, hence the synonyms *idiopathic IMHA* and *autoimmune hemolytic anemia*. In contrast, secondary IMHA is associated with an underlying condition. "*Alloimmune*" hemolytic anemias such as neonatal isoerythrolysis (NI) and hemolytic transfusion reactions are caused by antierythrocytic alloantibodies.

270.3.5.1 Immune Mechanisms

Regardless of the underlying cause, IMHA results from a breakdown in immune self-tolerance. The process of clonal deletion for central tolerance is not capable of completely eliminating all potential self-reacting B cell clones *in utero*. Clonal anergy, another central control mechanism, is not totally efficient in the inactivation of B cells designed to respond to self-antigens. Therefore an immune response against erythrocytes may occur.[62] Because some erythrocyte antigens are hidden or cryptic, the appropriate B cell may encounter the antigen only after membrane damage exposes the antigen. An inflammatory or infectious process can also release new antigens into the circulation that cross-react with erythrocyte antigens or attach to the erythrocyte membrane. Furthermore, the appropriate T cell must find the matching B cell and bind via receptor-ligand pairs to activate the respective cell. However, during infection and

inflammation, nonspecific activation of lymphocytes can occur, so self-reacting antibodies may be nonspecifically induced. Finally, impairment of the down-regulation mechanisms such as activated B-cell death by apoptosis through a Fas ligand signal from T cells may allow an active autoimmune response to develop.[63–65]

The binding of immunoglobulin G (IgG) or IgM antibodies and complement to the surface of erythrocytes initiates immune destruction of the erythrocytes. Under most clinical circumstances, immune destruction is an extravascular process that depends on recognition of erythrocytes opsonized with IgG, complement, or both by specific receptors on reticuloendothelial cells.

IgG-coated erythrocytes can be destroyed without complement activation because tissue macrophages express receptors that recognize the Fc portion of the IgG molecule. IgG binding by Fc receptors on macrophages can mediate complete phagocytosis, particularly in the red pulp of the spleen. Macrophages with engulfed erythrocytes may be noted by cytologic examination of tissue aspirates. Alternatively, phagocytes remove only a portion of the membrane, leaving erythrocytes with a reduced surface area/volume ratio and thereby forming spherocytes. Because the deformability of spherocytes is impaired, these rigid cells are trapped in the spleen and are subsequently destroyed. Erythrocyte-bound IgG1 and IgG3 antibodies have a strong affinity for Fc receptors. Erythrocytes that become heavily coated with IgG can also bind complement. In as much as macrophages also have receptors for complement components C3b and iC3b, the attachment of complement component C3b, iC3b, or both via CR1 and CR3 receptors together with IgG enhances the phagocytic process, particularly of hepatic macrophages (Kupffer's cells). In addition, erythrocytes heavily coated with IgG may activate so much complement that intravascular cytolysis occurs.[60,66]

In contrast, macrophages do not have receptors for the Fc portion of IgM, and thus the destruction of IgM-coated erythrocytes is mediated by complement. The pentameric structure of IgM is readily able to induce binding and activation of complement on erythrocytes. High IgM antibody titers can generate the cytolytic complex via the classical complement system and, thereby, intravascular hemolysis ensues. However, the IgM antierythrocyte antibodies are more commonly present in sublytic concentrations, and inhibitory regulatory proteins prevent full complement activation. Nevertheless, some C3b and iC3b are bound to the cell surface, resulting in extravascular destruction of complement-sensitized erythrocytes. Alternatively, erythrocyte-bound complement may be inactivated to C3dg, which no longer impairs erythrocyte survival. Antierythrocytic antibodies inducing hemolysis are generally reactive at body temperature. Only in exceptional cases do cold-acting antibodies (at 4° to 37°C thermoamplitude) contribute to *in vivo* hemolysis and erythrocyte agglutination in cooler, peripheral vasculature.

270.3.5.2 Underlying Conditions and Predispositions

Historically, in most dogs with IMHA, no underlying condition was ever identified, and thus it was considered to be primary or idiopathic IMHA.[67] However, in later studies of autoimmune hemolytic anemia, probably reflecting more intense clinical investigations, an underlying disease process or trigger could be identified, including drug exposures, emerging infections, bee stings, neoplastic processes, and other immune disorders (Box 270-1).[68–70] Best exemplified in babesiosis and hemobartonellosis, hemolysis is severely exaggerated by immune processes. Many chronic infections including abscesses, discospondylitis, pyometra, and pyelonephritis can induce secondary immune disorders including IMHA. A temporal association between vaccination and onset of IMHA has also been suggested. In a limited retrospective study, one quarter of all dogs with IMHA of unknown cause were vaccinated within 1 month

of onset of clinical signs.[71] As this correlation was associated with modified and killed vaccines against common infectious diseases from different manufacturers, it appears likely that vaccines may trigger or enhance a smoldering immune process rather than be the underlying cause. Although a number of anecdotal reports support a temporal relationship between vaccination and IMHA, no significant association was found in a large-scale retrospective survey of animal health insurance records from Britain.[72] The higher rate of IMHA during the warmer months from May through August reported in some studies, but not in others, may also suggest an infectious cause including tick-borne disorders and allergen exposure during the warmer months.[73] The seasonality may vary geographically. The association of IMHA with other immune disorders, including hypothyroidism and immune-mediated thrombocytopenia (ITP), lends support to the hypothesis of a general immune disturbance. IMHA and ITP occurring concurrently are known as *Evans' syndrome*.[52,74] In contrast to humans, IMHA in dogs is often associated with inflammation and necrosis, suggesting again an underlying mechanism to trigger an immune response.

Genetic Predisposition

American cocker spaniel (one third of all cases)

English springer spaniel

Old English sheepdog

Irish setter

Poodle

Dachshund

FeLV, Feline leukemia virus; *FIV,* feline immunodeficiency virus; *SLE,* systemic lupus erythematosus.

IMHA is the most common reason for hemolytic anemias in dogs. A genetic predisposition is evident in some dogs by the breed predilection and familial occurrence. Thus they should no longer be grouped with the idiopathic form.[67,73] American cocker spaniels may represent one third of all dogs with IMHA. In other canine breeds predisposition is less well documented and may vary geographically. Certain histocompatibility leukocyte antigens have been associated with the occurrence of IMHA in humans. The previously reviewed hereditary erythrocyte defects, particularly the common occurrence of PK and PFK deficiency and osmotic fragility problems, should also be considered as an important differential diagnosis whenever IMHA is suspected in breeds documented to have these erythrocytic defects. As with other immune disorders, female dogs appear slightly predisposed, even when spayed. Primary IMHA is relatively rarely documented in cats, but IMHA may be secondary to FeLV or *Haemobartonella* infections, inflammation, or antithyroidal medication[75,76] No breed, gender, or other association has been found in cats.

270.3.5.3

Clinical Signs of Immune-Mediated Hemolytic Anemia

IMHA may present at any age but is most commonly encountered in young adult to middle-aged dogs. The clinical history is generally brief and vague. An underlying condition may be identified. A brief episode of vomiting or diarrhea may precede the typical signs of anemia (lethargy, weakness, exercise intolerance, pallor) and hemolysis (pigmenturia, icterus).[59–73] Some animals may be febrile, presumably because of erythrocyte lysis or an underlying infectious or inflammatory disease process. Others develop dyspnea, indicating pulmonary problems either as cause of the underlying disease or as a thromboembolic complication of IMHA.[77] Physical examination may also reveal mild splenomegaly and, less commonly, mild hepatomegaly and lymphadenopathy, which again suggest a secondary cause of IMHA. A

normal-sized spleen does not rule out a massive hemolytic process. Furthermore, signs attributable to their underlying disease may predominate, whereas chronic or recurrent signs of IMHA suggest a primary form.

In the rare case of cold-reacting antierythrocytic antibodies, peripheral skin lesions characterized by acrocyanosis and gangrenous necrosis of ear, nose, tail tip, and nail beds may be the obvious problem without any evidence of hemolysis.

270.3.5.4 Routine Laboratory Test Results

IMHA can be a mild to life threatening condition. The hematocrit may drop precipitously at any time because of active hemolysis. Although a regenerative, macrocytic-hypochromic anemia would be expected, as many as one third of all pets with IMHA have a nonregenerative anemia when first examined.[73,78,79] The disease course may have been peracute, not yet allowing time to mount a regenerative response. Alternatively, antibodies may be directed against erythroid precursors, thereby removing metarubricytes and reticulocytes, or the IMHA disease process may change the microenvironment of the bone marrow and thereby impair erythropoiesis. Evidence of ineffective erythropoiesis and erythrophagocytosis may be found on cytologic examination of a bone marrow aspirate.[80] Autoagglutination of erythrocytes and spherocytosis are typical findings on blood smears (Figures 270-7 to 270-9).

Besides erythroid abnormalities, a leukocytosis is often present and can exceed 100,000/μL, mostly because of a mature neutrophilia, but degenerative left shifts have also been observed. The degree of leukocytosis and toxic neutrophil changes has been correlated with the amount of necroses at necropsy.[81] Because high WBC counts are not generally encountered with other forms of anemia, this probably reflects a unique cytokine-mediated response to inflammation and necroses specific for IMHA, but concomitant infection and steroid-induced leukocytosis should also be considered. Thus concurrent hyperplasia of erythroid and myeloid cells may be present in the bone marrow. Furthermore, thrombocytopenia related to a concomitant ITP (Evans' syndrome) or other consumptive processes, such as with disseminated intravascular coagulation (DIC), may occur.[73] Dogs with IMHA often have coagulation test abnormalities with increased plasma fibrinogen and D dimer and FSP concentrations suggesting a DIC like syndrome.[82]

Figure 270-7 Spherocytosis with polychromasia and anisocytosis.

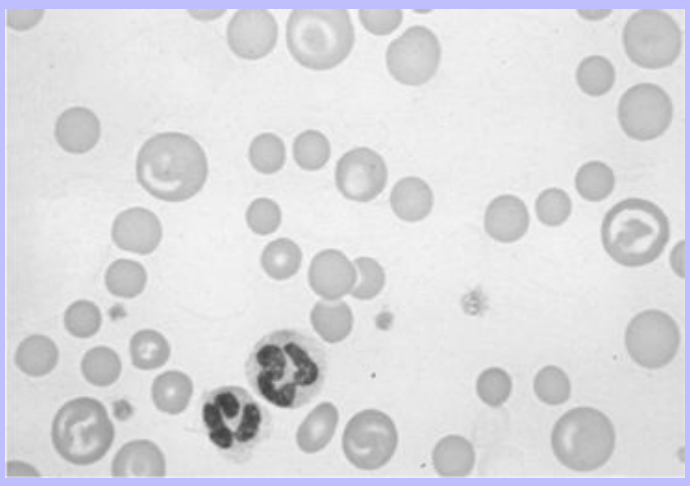

Figure 270-8 Macroscopic agglutination on slide **(A).** Agglutination of regular and washed blood. Reader should note macroscopic agglutination disappeared **(B)**.

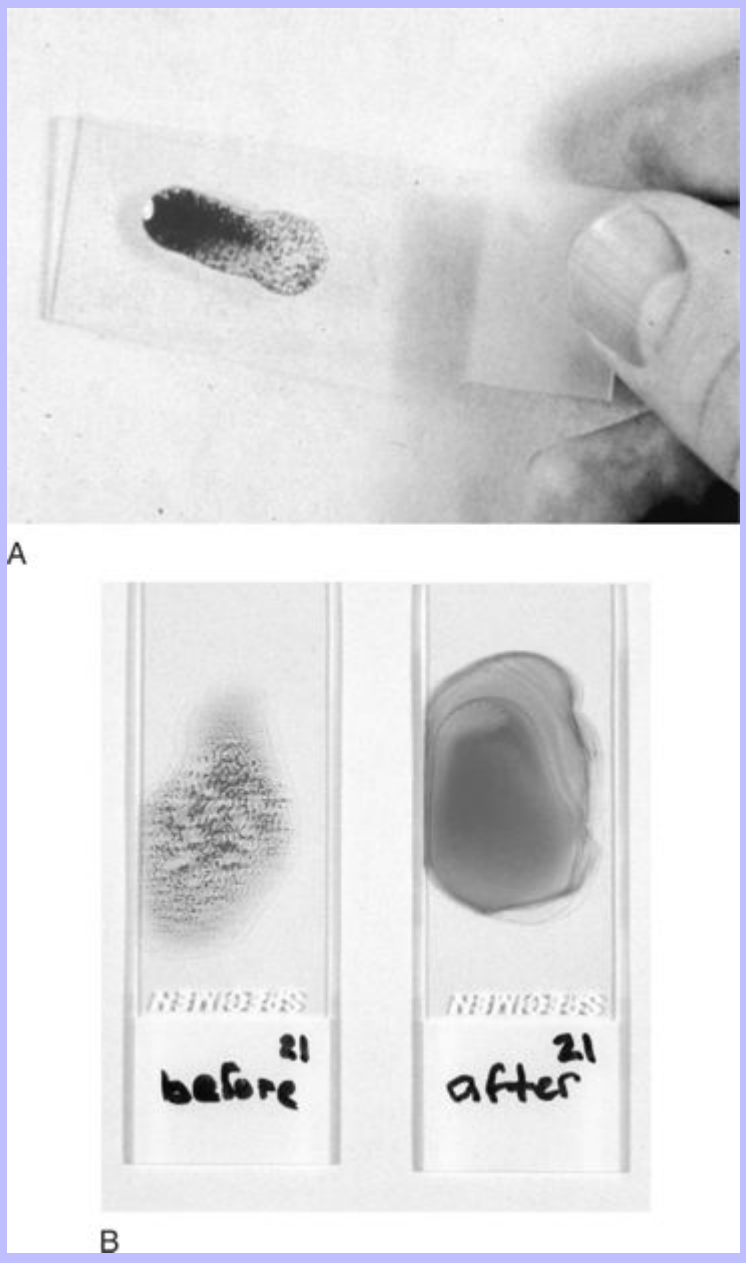


Serum analysis may reveal a hyperbilirubinemia, and a serum bilirubin concentration above 10 mg/dL has been associated with a grave prognosis.[73] However, serum bilirubin values may be only slightly increased

in chronic cases, presumably because of highly efficient and accelerated bilirubin metabolism. Thus increased serum bilirubin concentrations could also indicate a concomitant hepatopathy. Dogs with IMHA often have increased serum liver enzyme activities even before steroid therapy. Pathologic examination has revealed major hepatic and other tissue necroses and inflammation in dogs with severe forms of IMHA.[81] The degree of hemoglobinemia (a sign of intravascular hemolysis) can vary drastically and rapidly and is associated with hemoglobinuria. Hyperbilirubinuria is expected as with any other hemolytic anemia; in cats, any degree of bilirubinuria is considered important, whereas larger amounts of bilirubin are generally present in urine of dogs with IMHA. There may also be evidence of a bacterial cystitis, which may indicate an underlying infectious disease or may occur secondarily because of immunoderegulation or immunosuppressive therapy.

Various imaging studies may be indicated to reveal underlying disease processes, such as neoplasia, and complications of IMHA. Evidence of thromboemboli may be detected on chest radiographs and abdominal ultrasonography, as well as at the site of catheters.[77,82]

270.3.5.5 Diagnostic Laboratory Test Results

A diagnosis of IMHA requires demonstration of accelerated immune destruction of erythrocytes. Thus besides documenting a hemolytic anemia, a search for antibodies or complement or both directed against erythrocytes is required; that is, one or more of the following three hallmarks has to be present to reach a definitive diagnosis of IMHA:

1. Marked spherocytosis
2. True autoagglutination
3. Positive direct Coombs' test

270.3.5.5.1 Spherocytosis

Spherocytes (Figure 270-3 and 270-7) are spherical erythrocytes that appear microcytic with no central pallor. They result from either partial phagocytosis or lysis. Such cells are rigid and extremely fragile in the erythrocyte osmotic fragility test. Because spherocytes have lost some membrane, they do not have any reserves to expand in hypotonic solution. Large numbers of spherocytes are highly suggestive of IMHA and are present in approximately two thirds of dogs with IMHA, but small numbers may be seen with hypophosphatemia, zinc intoxication, and microangiopathic hemolysis. Hereditary spherocytosis related to various membrane defects in humans has only been reported in one dog. In cats, spherocytes are difficult, if not impossible, to identify owing to the small size and lack of central pallor of normal feline erythrocytes.

270.3.5.5.2 Autoagglutination

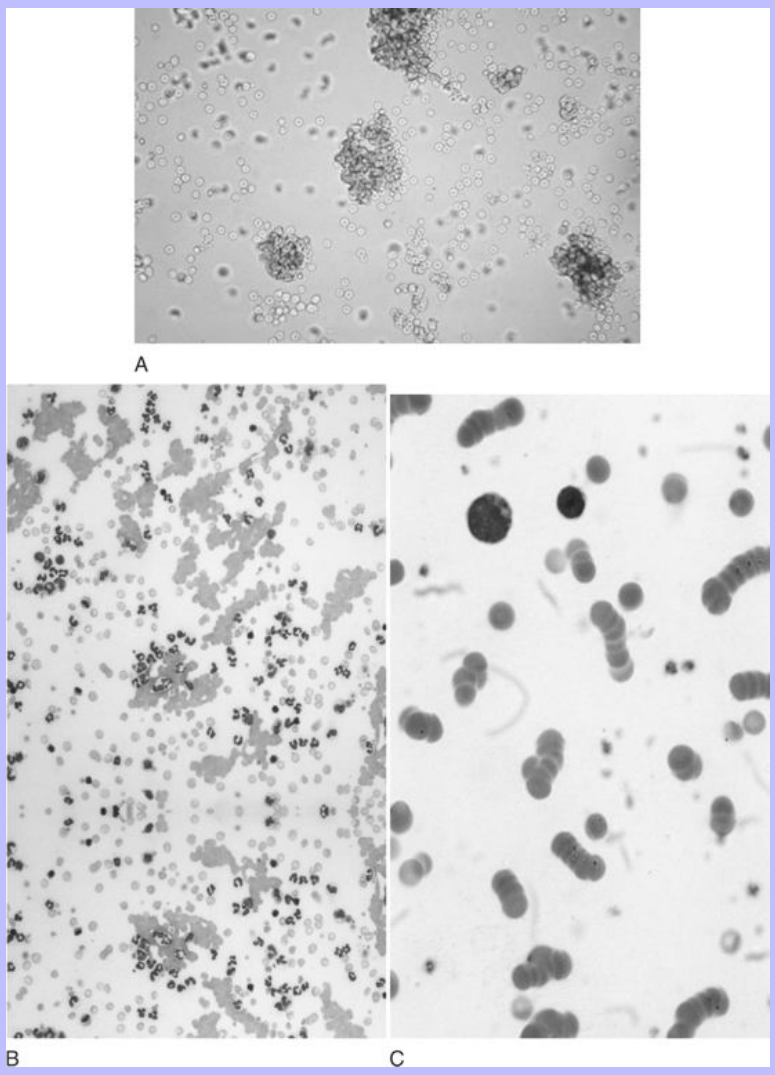
Antierythrocytic IgM and, in large quantities, IgG antibodies may cause direct autoagglutination (Figure 270-8). Agglutination may be visible to the naked eye when blood (at low hematocrit) is in an EDTA tube or placed on a glass slide (macroscopic agglutination) (Figure 270-9), or it may become apparent as small clumps of erythrocytes on a stained blood smear or in a saline wet mount (microscopic agglutination). Autoagglutination has to be distinguished from rouleaux formation (Figure 270-9C), in which erythrocytes stack up on top of each other. For unexplained reasons, canine erythrocytes have a

tendency to agglutinate unspecifically in the presence of plasma, particularly at lower temperatures in EDTA. Mixing one drop of blood with one drop of saline may not break up this unspecific form of agglutination. It is therefore important to determine whether the agglutination persists after "saline washing," which has been termed *true autoagglutination*. This is accomplished by adding three times physiologic saline solution to blood (in a ratio of 3:1 to 5:1) after repeated centrifugation and removal of supernatant including the plasma. It should be noted that autoagglutination can interfere with the direct Coombs', crossmatch, and blood typing tests. Thus the simultaneous use of the so-called autocontrols is imperative.

1898

1899

Figure 270-9 Microscopic agglutination wet mount **(A)** and Wright-Giemsa stain **(B)**. Reader should also note leukocytosis. Autoagglutination should not be confused with rouleaux formation **(C)**.



270.3.5.5.3

Direct Coombs test

The direct Coombs' test, also known as the *direct antiglobulin test (DAT)*, is used to detect antibodies, complement on a dog or cat's erythrocyte surface, or both, when the antierythrocyte antibody strength or concentration is too low (subagglutinating titer) to cause spontaneous autoagglutination.[83–85] The so-called incomplete antibodies on erythrocytes, together with species-specific antiglobulins against IgG, IgM, and C3b (Coombs' reagents), allow antibody bridging and thereby agglutination or lysis of coated erythrocytes (or both). Separate IgG, IgM, and C3b, as well as polyvalent Coombs' reagents, are available for dogs and cats. They are added at varied concentrations after washing the patient's erythrocytes free of plasma. The mixture is generally incubated at 37°C, then centrifuged, and supernatant and pellet are analyzed for hemolysis and agglutination, respectively. Performance of the direct Coombs' test at lower temperatures (4° and 20°C) is rarely indicated, because cold agglutinins and hemolysins are rarely strong enough and rarely active at near-normal body temperatures (30°C) to cause hemolysis. Cold agglutinins and hemolysins of clinical importance are generally IgM antibodies at high titer with a thermal amplitude that reaches 30°C. Because the same erythrocyte washing procedure is used in the direct Coombs' test as in the true autoagglutination test and the end point of the Coombs' reaction is agglutination and lysis of erythrocytes, true autoagglutination precludes the performance of a direct Coombs' test.

Positive direct Coombs' test results are reported as +1 to +4 or in the form of dilutions of the Coombs' reagent that cause in vitro agglutination, lysis, or both; the strength of the Coombs' reaction does not necessarily predict the severity of hemolysis seen clinically. Most dogs are IgG positive, some are IgG and IgM positive, and a few are only IgM positive.[86] To reach a definitive diagnosis of IMHA, the direct Coombs' test should be positive, but this does not discriminate between primary and secondary IMHA. Dogs with negative Coombs' test results should be re-evaluated for other causes of hemolytic anemia. However, a small proportion of dogs may have IMHA despite a negative Coombs' test result. False-negative Coombs' test results may occur because of insufficient quantities of bound antibodies on erythrocytes and for many technical reasons (inappropriate reagents or dilutions). Various techniques have been used to enhance the sensitivity of the direct Coombs' test, but none of them have gained wide acceptance in human and veterinary medicine. Furthermore, the test result may be negative in the absence of an inciting agent (e.g., drug). Negative results are also obtained for animals in which the disease is in remission; however, a few days of immunosuppressive therapy are not likely to reverse test results (i.e., in the presence of anemia and hemolysis the Coombs' test should be positive in a dog or cat with IMHA). Some treated animals have positive Coombs' test results long after the hemolytic anemia resolves. False-positive Coombs' test results occur only rarely, for example, early after an incompatible transfusion or because of technical problems. Furthermore, some animals may have a positive Coombs' test result without evidence of hemolysis and anemia; this has also been observed in healthy human blood donors.

1899

1900

Little is known about the usefulness of the indirect Coombs' or antiglobin test in which the presence of antierythrocyte antibodies in the patient's serum is evaluated with random erythrocytes. Clearly, the indirect Coombs' test would remain negative if the antibody is directed against a cryptic or new (drug, parasite) antigen on the erythrocyte surface. Alternatively, a false-positive test result may occur in a dog that has previously been transfused and developed certain alloantibodies.

270.3.5.6 Therapy of Immune-Mediated Hemolytic Anemia

Because the severity of IMHA ranges from an indolent to a life-threatening disease, therapy has to be tailored for each pet and depends, in part, on whether the IMHA is primary or secondary. Removal of the triggering agent or treatment of the underlying condition can bring the IMHA under control. Thus if the IMHA is thought to be secondary to an infection, treatment with antiprotozoals, antirickettsials, or antibiotics should be instituted. Because of the potential for underlying occult infection and the predisposition to infection related to the immunoderegulation associated with IMHA and immunosuppressive therapy, antibiotic therapy is generally indicated. In addition, surgical correction of abscesses or other infections may be considered. Nonessential drugs, particularly those that might cause an immune reaction, should immediately be withdrawn. Despite these interventions, transfusion and immunosuppressive therapy are probably still required in the initial control of secondary IMHA.

Rehydration of the severely ill animal is pivotal to improve organ perfusion even when it lowers the hematocrit. If hypoxia due to severe anemia and a rapidly dropping hematocrit to critical levels ensues, packed RBC transfusions are beneficial. The increased oxygen-carrying capacity provided by transfused cells may be sufficient to maintain the animal for the few days required for other treatment modalities to become effective. The notion that transfusions are especially hazardous in animals with IMHA has been overemphasized and is not supported by retrospective studies in dogs and humans. Because the antierythrocytic antibody in IMHA is not an alloantibody, the destruction of transfused cells is no higher than that of autologous erythrocytes. However, autoagglutination may hamper accurate dog erythrocyte antigen (DEA) 1.1 blood typing and cross-matching tests even after RBC washing; hence, only DEA 1.1-negative blood should be transfused in autoagglutinating, untyped dogs. If compatible blood is not available, the ultrapurified bovine hemoglobin solution recently approved by the Food and Drug Administration can be administered and provides increased oxygen-carrying capacity and plasma expansion. In the original randomized study for Food and Drug Administration approval, this hemoglobin solution reduced the need for blood transfusions in the initial management of dogs with severe IMHA.[10] Some retrospective studies, however, suggested that this therapy was not beneficial if it was used as a last effort. With adequate transfusion support, animals with IMHA rarely die because of anemia, but they die because of overwhelming hemolysis and secondary complications such as thromboemboli and infections. Oxygen inhalation therapy is of little benefit unless the animal is suffering from pulmonary disease such as pulmonary thromboemboli.

The main goal in the treatment of IMHA is to control the immune response by reducing phagocytosis, complement activation, and antierythrocytic antibody production.[87] Glucocorticosteroids are the initial treatment of choice for IMHA. They interfere with both the expression and function of macrophage Fc receptors and thereby immediately impair the clearance of antibody-coated erythrocytes by the macrophage system. In addition, glucocorticosteroids may reduce the degree of antibody binding and complement activation on erythrocytes and, after weeks, diminish the production of autoantibodies. Oral prednisone or prednisolone at a dose of 0.5 to 1 mg/lb twice daily is the mainstay treatment. Alternatively, oral or parenteral dexamethasone at an equipotent dose of 0.3 mg/lb daily can be used but is probably not more beneficial. A response reflected by a stabilized or even rising hematocrit, appropriate reticulocytosis, and less autoagglutination and spherocytes can be expected within days. As glucocorticosteroid therapy is associated with well-known side effects, the initial dose is then tapered by reducing the amount by one quarter to one third every 7 to 14 days. Generally the faster the response to treatment the more rapidly the tapering is done. Within weeks to months, a low-dose alternate-day therapy may be reached with minimal steroid side effects. In secondary IMHA with appropriate control of the underlying disease, the tapering can

be accomplished more rapidly. Because of the potential for GI ulceration by steroids, treatment with sucralfate or other similar GI drugs may be considered, although none have been documented to be effective.

Despite apparent recovery as judged by reaching a normal hematocrit, animals, particularly those with primary IMHA, may continue to have a positive Coombs' test for weeks to months and could obviously have relapses. Such relapses may be controlled by the same treatment as initially used, but a more gradual tapering regimen may be used in which the animal receives prednisone (preferably every other day) or other immunosuppressive therapy for months.

Other immunosuppressive therapy is warranted when prednisone fails, controls the disease only at persistently high doses, or causes unacceptable side effects. Cytotoxic drugs are usually given with prednisone but may eventually be used independently. These cytotoxic drugs inhibit lymphocytes and thereby suppress the antierythrocyte antibody production only after weeks. They are therefore probably not effective in the acute management of IMHA but may have a place in the long-term control of refractory and relapsing cases. Cyclophosphamide, an alkylating and potent myelosuppressive agent, has been advocated in cases of fulminant IMHA. However, a randomized limited prospective clinical trial comparing prednisone with a combination of prednisone and cyclophosphamide did not find any beneficial effects of cyclophosphamide in the acute management of IMHA.[88] Retrospective studies with cyclophosphamide, azathioprine (an antimetabolite), or both were similarly disappointing, but overall assessment of these and other immunosuppressive agents is difficult based on retrospective and small case studies.[89–92] In addition to the strong myelosuppressive effects of these cytotoxic drugs, leading to reticulocytopenia, neutropenia, and thrombocytopenia, cyclophosphamide can induce a sterile hemorrhagic cystitis and secondary neoplasia. A potential regimen for the long-term management of dogs with IMHA might include azathioprine at 1 mg/lb once a day or every other day, but dogs need to be carefully monitored for cytopenias.[90] Hence, the risk/benefit ratio should be carefully considered when using these drugs.

1900

1901

Several other immunosuppressive agents have been used on a limited basis in conjunction with prednisone, and anecdotal success has been reported in dogs and rarely in humans. Because some of these agents interfere with antibody action and macrophage function, they can elicit more immediate effects. Cyclosporine, an expensive but potent immunosuppressive agent most commonly used in preventing graft rejection and graft-versus-host disease in transplant patients, may be beneficial in controlling the immune response in dogs with IMHA. A dose regimen of 5 mg/lb once a day may be used initially, but blood concentrations should be monitored periodically to achieve an effective but safe level. Leflunomide and mycophenolate are in a class of agents similar to that of cyclosporine and have been used in a few cases with anecdotal success. Danazol, an androgen derivative, at a dose of 5 mg/lb once a day, may inhibit binding of antibodies and phagocytosis. However, a retrospective study in dogs with IMHA was disappointing; furthermore, danazol is expensive and may be hepatotoxic.[93] Intravenous human immunoglobulin (IVIG) may be helpful in the short-term treatment of dogs with IMHA, although its mode of action remains unresolved.[94–96] IVIG can block Fc receptors on macrophages (thereby reducing Fc-mediated phagocytosis of IgG-coated erythrocytes), interfere with complement action, and suppress antibody production. Human IVIG binds to canine lymphocytes and monocytes and inhibits erythrocyte phagocytosis.[96] A single IVIG dose of 0.25 to 1 g/lb has been beneficial in some refractory cases as indicated by a rising PCV and reticulocytosis within days, but the response has often been only temporary. More recently two 0.5 g/lb doses of IVIG 1 day apart has resulted in good responses. Anecdotally, plasmapheresis has also been used as an adjuvant therapy, but is currently not available for companion animals.[97]

Splenectomy may be considered in IMHA dogs and cats that do not respond to prednisone and other immunosuppressive therapy, that require long-term high-dose therapy to remain in remission, or that have intractable drug-induced side effects. The spleen is a major site of autoantibody production, as well as sequestration and destruction of erythrocytes coated with IgG, but probably does not directly affect the clearance of IgM-coated cells. In addition, histologic examination of the spleen may provide evidence of an underlying disease. The response to splenectomy has recently been described in a few dogs with IMHA, but an objective assessment based on a randomized trial has not been completed.[98] A risk exists of developing overwhelming infections after splenectomy. Splenectomy should not be considered in pets receiving immunosuppressive therapy aside from prednisone.

Thromboemboli and DIC-like syndromes are serious complications of IMHA that greatly contribute to morbidity and mortality. Although the pathogenesis remains unknown, venipuncture, catheters, and glucocorticosteroid therapy represent potential predisposing conditions. No study has documented any successful prevention or management protocol for these life-threatening problems, which represent rare complications in humans with IMHA. Predisposing factors should, whenever possible, be limited. Adequate perfusion and oxygenation of tissue should be provided with fluids and transfusions. Generally, anticoagulant therapy is instituted only after some evidence or suspicion of thromboembolism exists. Heparin at a dose of 5 to 250 IU/lb subcutaneously every 6 hours or by continuous infusion is the most commonly used drug, and other antithrombotic agents are being evaluated.[99] However, none of them have been documented to be effective and safe in dogs or other species in the control of thrombotic complications. Fresh frozen plasma (5 mL/lb every 12 hours) may be administered to replenish dangerously low plasma antithrombin III concentrations, but its efficacy has not been demonstrated.[100] Other complications may also be related to drug therapy.

Despite appropriate implementation of these therapeutic strategies, the mortality rate remains high. An impression exists that the fulminate form of IMHA is more frequently encountered today. Depending on the type of practice (primary to tertiary), mortality rates from 20% to 75% have been reported. Negative prognostic indicators are a rapid drop in PCV, highly increased serum bilirubin concentrations, nonregenerative anemia, intravascular hemolysis, persistent autoagglutination, and thromboembolic complications.[101]

270.3.6 Alloimmune Hemolytic Anemias—Neonatal Isoerythrolysis and Hemolytic Transfusion Reactions

Erythrocyte alloantibodies, also known as *isoantibodies*, are specific antibodies directed against erythrocyte antigens (blood types) from the same species but not from the individual producing the antibody.[2] Depending on the species and blood group system, these alloantibodies occur naturally (cats) or are produced only after sensitization with a mismatched blood transfusion (dog) and are responsible for NI (cats) and acute or delayed hemolytic transfusion reactions (dogs and cats). Additional information can be found in Chapter 127 on transfusion medicine.

In cats, only the AB blood group system has been recognized; it consists of three blood types: type A, type B, and type AB.[2] The inheritance pattern of these blood types is unique and of considerable importance to breeders. The A allele is dominant over the B allele. Thus only homozygous b/b cats express the type B antigen on their erythrocytes. Type A cats are either homozygous (a/a) or heterozygous (a/b).[102] The rare AB blood type, seen in certain families, is inherited separately as a third allele that is recessive to A and

codominant with B.[103] Simple in-practice blood typing cards are available, and other methods are being developed. Because a reaction in both test wells could be caused by autoagglutination, type AB test results should be confirmed after saline washing and in a reference laboratory using another method.[104] The prevalence of feline blood types varies geographically and among breeds.[102] Whereas purebred Siamese cats have all type A blood, Turkish Van and Angoras have equal numbers of type A and type B cats. All type B cats develop strong naturally occurring anti-A antibodies with high hemolysin and agglutinin titers (>1:32) after a few weeks of age, whereas type A cats generally develop only weak anti-B antibodies. Type AB cats have no alloantibodies. Thus acute life-threatening hemolytic transfusion reactions occur during the first mismatched transfusion (as little as 1 mL of blood), and NI is seen in type A and AB kittens born to primiparous type B queens.

1901

1902

Feline NI is caused by maternal anti-A alloantibodies that gain access to the circulation and destroy type A and type AB erythrocytes.[2,105–107] Thus type A and type AB kittens from matings between a type B queen and a type A or AB tom are at risk. The proportion of kittens at risk for NI varies from zero to 25%, depending on the frequency of type B cats, and therefore represents a major and now preventable cause of the neonatal kitten complex in purebred cats.[102] The low-titer anti-B alloantibodies of type A queens have not been associated with NI. Cats (and dogs) have an endotheliochorial placenta that is impermeable to immunoglobulins from the mother's serum. However, feline colostrum and milk contains high maternal concentrations of immunoglobulins that pass the GI tract and are absorbed intact only during the first 16 hours of life.

Thus type A or type AB kittens produced by type B queens are born healthy. Upon ingestion of colostrum or milk containing anti-A antibodies, the kittens at risk can develop clinical signs during the first few days of life. They may die suddenly without obvious clinical signs during the first few hours of life. They can develop severe pigmenturia, which is readily visible when stimulating the neonates to urinate with a moist cotton ball. These kittens fail to thrive, are reluctant to nurse, become anemic and icteric, and rarely survive the first week of life. Some kittens at risk may have a subclinical course or slough their tail tip at 1 to 2 weeks of age, presumably because of an agglutinin-induced occlusion. The severity of clinical signs depends on the amount of colostral antibodies ingested before the kitten's ability to digest proteins and closure of the gut to the absorption of intact proteins, which varies from kitten to kitten, between queens and litters, and even within a litter. NI can be confirmed by typing the queen and kitten or the tom if the kitten died with suspicious signs.

Because of the acute disease course, treatment of NI is rarely successful. Foster nursing by a type A queen, who delivered recently, or with milk replacer, transfusion, and supportive care may be attempted. During the first day, when anti-A alloantibodies could still be absorbed, washed type B blood may be preferred, but thereafter type A blood is appropriate and may be best administered by the intraosseous route. However, NI can be readily prevented by (1) blood typing queen and tom and mating type B queens only to type B toms or (2) foster nursing type A and AB kittens born to type B queens for the first 24 hours. This can be accomplished by placing the kittens at risk with a type A queen (exchanged only if the type A queen's kittens are older than 1 day) or feeding a commercial milk replacer at least four times a day. Either all kittens of a litter at risk should be removed from the type B queen, or umbilical cord blood or blood from the jugular vein of the kittens (0.5 mL) can be typed with the typing card or cross-matched with anti-A plasma from the queen, thereby providing an opportunity to leave the type B kittens with the type B queen. Although maternal passive immunity does not appear to be essential in most cattery situations, 1 to 3 mL of serum from a type A cat (which lacks harmful anti-A antibodies) may be given orally during the first few hours of life or intraperitoneally or subcutaneously to kittens receiving a milk replacer.

More than a dozen blood group systems have been described in dogs and are referred to as *DEA* followed by a number.[2,104,108] For all blood groups other than the DEA 1 system, erythrocytes from a dog can be either positive or negative (e.g., DEA 4 positive or negative). The DEA 1 system, however, has at least two subtypes: DEA 1.1 (also known as A_1) and DEA 2 (A_2). Thus the dog's erythrocytes can be DEA 1.1 positive or negative, and DEA 1.1-negative erythrocytes can be DEA 1.2 positive or negative. The most antigenic and therefore most important blood type is DEA 1.1, for which simple blood typing cards are available. Typing of both blood recipient and donor for DEA 1.1 is recommended. An autoagglutination test card has been added, because autoagglutinating samples appear like DEA 1.1 positive.[104] True autoagglutination precludes typing. Typing for DEA 1.2, 3, 4, 5, and 7 is provided only by Midwestern Blood Services, but this extended blood typing has not be proven helpful in preventing blood type incompatibility reactions. In contrast to cats, dogs do not have clinically important naturally occurring alloantibodies but can develop them after mismatched transfusions, particularly anti-DEA 1.1 antibodies in DEA 1.1-negative dogs. Thus NI is not a clinical problem in dogs unless the bitch has previously received blood products. Similarly, acute hemolytic transfusion reactions are encountered only when a dog receives a blood transfusion 4 or more days after the first transfusion.[108–109] Careful history should indicate prior transfusions. These reactions can be prevented by cross-matching all dogs that have been previously transfused even when using the same donor. Furthermore, delayed hemolytic transfusion reactions characterized by a more rapid than anticipated drop of the hematocrit may be observed 1 to 2 weeks after a (first) transfusion because of the development of new antibodies. Because most reactions are directed against the DEA 1.1 antigen, DEA 1.1-negative (as well as untyped) dogs should never receive any blood products from DEA 1.1-positive donors. The only other acute hemolytic transfusion reactions were documented against a missing common antigen and DEA 4 in a DEA 4-negative dog, thus questioning the term *universal donor* for DEA 4-positive but otherwise negative dogs. However, a matched DEA 1.1 transfusion with crossmatching for a subsequent transfusion is practical and safe. Furthermore, some acute hemolytic reactions may be caused by use of expired, inappropriately stored, and contaminated blood. In case of acute hemolytic transfusion reactions, the transfusion should be stopped immediately and supportive therapy provided. Glucocorticosteroid administration has not been proven to be effective in preventing or treating hemolytic transfusion reactions.

270.3.7 Infection-Associated Hemolysis

Hemolytic anemia may develop after exposure to several parasitic, bacterial, and viral agents because of the direct action of the infectious agent or its products on erythrocytes. Few rickettsial and protozoal organisms are capable of infecting erythrocytes directly and causing severe hemolytic anemia (Table 270-2). Other infectious agents may induce a hemolytic component indirectly along with other major clinical signs. Thus any infection may trigger the production of humoral antibodies against host erythrocytes and together with an activated complement and phagocytic system, the rate of erythrocyte destruction may be markedly accelerated. Cats in particular have an inflammation-associated shortened survival of erythrocytes caused by an abscess, surgery, or trauma.[110] Furthermore, during bacterial (e.g., *Leptospira, Clostridium, Streptococcus, Staphylococcus*) septicemia, specific hemolysins can be produced. For instance, alpha toxin released during clostridial sepsis is a lecithinase that can attack erythrocyte membrane lipids, leading to erythrocyte fragmentation. Additional information on these infectious diseases can be found in Section VIII.

270.3.7.1 Hemobartonellosis

Hemobartonellosis in cats, also known as *feline infectious anemia*, is caused by an epicellular rickettsial organism of erythrocytes.[111,112] *H. felis* is classified in the family Anaplasmataceae, is distinctly different

from *Bartonella*, but is genetically similar to *Mycoplasma*. Hence *H. felis* has been renamed as *Mycoplasma haemofelis*, the large and more pathogenic form, and *M. haemominutum*, the small form. The natural transmission of these mycoplasmas still remains unclear, although bloodsucking ectoparasites are considered to be major vectors. Iatrogenic infection can occur via blood transfusion from carrier cats. In addition, they may be transmitted by oral ingestion of infected blood or from queens to their newborns. Finally, because cat bite abscesses often precede hemobartonellosis by a few weeks, particularly in male cats that roam outdoors, this may represent another form of transmission.

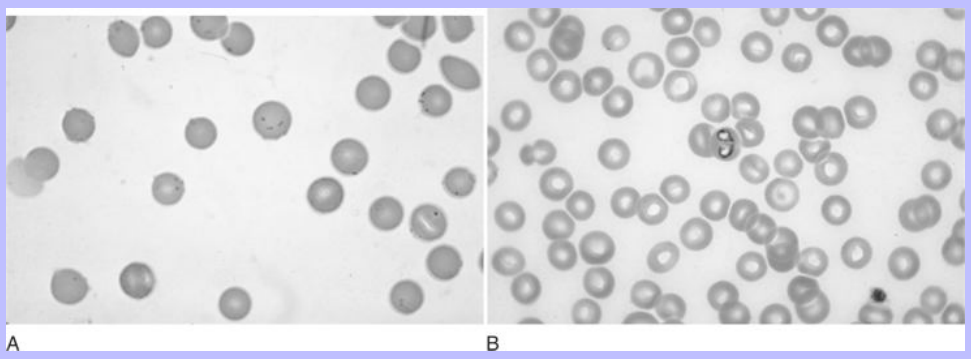
It is considered an opportunistic organism that causes illness only under predisposing conditions. Approximately half of the cats with hemobartonellosis were FeLV positive and infection with both agents exaggerates the severity of the anemia, whereas concurrent infection with feline immunodeficiency virus (FIV) does not appear to worsen the anemia. Although viral infections, abscesses, systemic illnesses, and trauma (including surgery) are apparent predisposing factors, such conditions are not always identifiable.[113,114]

The pathogenesis of hemobartonellosis can be divided into parasitic incubation, acute parasitemia, and recovery or carrier stage.[115] One week to months after infection, cats, when stressed, develop an acute parasitemic phase that results in mild to severe anemia. This stage is characterized by cyclic parasitemia and often lasts for weeks to months unless death caused by massive parasitemia and anemia ensues earlier. Parasitized erythrocytes lose their deformability and elicit an immune response and are therefore rapidly sequestered and phagocytized in spleen and other tissues. However, sequestered erythrocytes may shed the parasites and re-enter the blood circulation. Although cats may recover by mounting an immune response against the parasites, they cannot completely clear the infection and thus they remain carriers indefinitely by harboring organisms in macrophages.

Feline hemobartonellosis is associated with a gradual to precipitous drop in hematocrit that results in clinical signs of anemia. Cats are lethargic, weak, and inappetent, and cyclic fevers occur during the transient periods of parasitemia. Icterus is rare, but pale mucous membranes are common. Splenomegaly and weight loss may develop gradually.

No serologic tests are presently available, but PCR-based tests to detect the mycoplasma-DNA have greatly aided in the detection of these infections.[116] However, not every cat positive for *M. haemominutum* is anemic or experiences hemolysis. These organisms may be incidentally discovered in carrier cats with other diseases. A diagnosis of feline hemobartonellosis can also be made by recognizing the organisms on erythrocytes in a blood smear (Figure 270-10A). Blood needs to be collected before treatment and sometimes repeatedly. Blood smears should be prepared shortly after collection because organisms may detach. Any Romanowsky-type blood stain (e.g., Wright's-Giemsa, Diff-Quik) may be used. Organisms appear as blue-staining ring, rod, or coccoid forms on the surface of erythrocytes. They need to be differentiated from Howell-Jolly bodies, other parasites, basophilic stippling, and staining artifacts. New methylene blue and reticulocyte stains are inappropriate, because organisms may be confused with punctate reticulocytes and Heinz bodies; fluorescent stains provide no advantages. Parasitized erythrocytes become spherical. Erythrophagocytosis by monocytes and tissue macrophages (e.g., bone marrow, splenic aspirates), as well as autoagglutination of parasitized erythrocytes may be observed, and the direct Coombs' test at 37°C is often positive, supporting the major role of immune destruction. Because of the cyclic nature of the parasitemia, absence of organisms does not rule out an infection.

Figure 270-10 Hemobartonellosis in a cat **(A)** and babesiosis in a dog **(B)**.



Infected cats should be treated with tetracycline products for 3 weeks.[111] Doxycycline at a dose of 2.5 mg/lb twice a day is the preferred product because it needs to be administered only twice daily and appears to cause fewer side effects such as fever, anorexia, and hepatopathy. Enrofloxacin at a dose of 2.5 mg/lb once a day, orally, alone is a good alternative. Use of the two drugs in combination may be helpful in refractory cats. Parasitemia typically resolves quickly, and a clinical response is seen within days. None of the tetracyclines clear the infection completely; thus treated cats remain carriers, although relapses appear uncommon and have not been documented experimentally. Severely anemic cats may also benefit from blood transfusion from a blood type-compatible donor. Furthermore, because of the immune-mediated mechanism involved, treatment with prednisone at 0.5 to 1.0 mg/lb twice a day is indicated, particularly to inhibit the erythrophagocytosis.

In contrast to cats, dogs rarely have hemobartonellosis. It is caused by *Haemobartonella canis*, which can be transmitted by the brown dog tick (which also serves as a reservoir) and infected blood.[117] Unless dogs are splenectomized or have other serious illness and splenic dysfunction, infected dogs do not develop clinical signs of anemia. On stained blood smears *H. canis* differs from *H. felis* in that *H. canis* often forms chains across the surface of erythrocytes. Infected dogs with anemia are treated as described for cats and probably also remain latently infected.

1903

1904

270.3.7.2 Cytauxzoonosis

Cytauxzoonosis has been sporadically reported in cats in south central and southeastern states of the United States and in Africa.[118,119] It is caused by *Cytauxzoon felis*, a piroplasm of the family Theileriidae. In *C. felis's* life cycle schizonts develop to merozoites in mononuclear phagocytes, whereas the erythrocytic piroplasms are the terminal chronically infected stage. Wildcats, particularly the bobcat *(Lynx rufus)*, appear to be the natural reservoir for *C. felis* in North America, and ticks probably serve as vectors. Thus cats with access to tick-infected wooded areas during the summer months are mostly at risk.

After an incubation period of days to weeks, the course of illness is rapidly progressive and leads to death in less than 1 week. Affected cats develop fever, anemia, icterus, pigmenturia, and dyspnea. The rapid multiplication of the protozoa in tissue and destruction of parasitized erythrocytes result in organ dysfunction, particularly of lungs, and hemolytic anemia, respectively, leading to hypoperfusion, hypoxia, and DIC. Only extremely rarely does a cat recover from the acute illness. A diagnosis is reached by

documenting the protozoa in erythrocytes on a Wright's-Giemsa-stained blood smear. They appear classically as signet ring–shaped blue forms, although other oval, tetrad, and dot forms may also be observed. Up to 5% of the erythrocytes may be parasitized, each with one piroplasm. Serologic and direct fluorescent antibody tissue tests have been developed but are not commercially available. Supportive fluid therapy and administration of the compound diminazene or imidocarb may be attempted, but cytauxzoonosis remains a disorder with a high degree of mortality.

270.3.7.3 Babesiosis

Whereas *Haemobartonella* and *Cytauxzoon* are important infectious agents in cats, babesiosis (see Chapter 168) is a major cause of acute hemolytic anemia in dogs.[120] *Babesia canis* and *B. gibsoni* are the only two hematozoan species that infect dogs, but strains of *B. canis* have been proposed on the basis of geographic range and pathogenesis. In the United States, canine babesiosis occurs most commonly in the southern states, but endemic areas have also been found farther north.[121–123] *B. gibsoni* has also been documented in California. Babesia infection is endemic in greyhounds and pit bulls. Puppies younger than 8 months of age and greyhounds appear to be more susceptible to *Babesia* infection; depending on the degree of tick control, few to all of the greyhounds in a kennel may be seropositive. Feline babesiosis has not been reported in the United States.

Ticks such as *Haemophilalis bispinosa* and *H. longicornus,* as well as *Rhipicephalus sangineus,* likely serve as major vectors, although transplacental transmission and transfer via blood transfusion have also been documented.[124] Ticks must feed a minimum of 2 days to pass sporozoites via saliva into the circulation of the host. *Babesia spp*. are engulfed by erythrocytes, in which they multiply into merozoites that infect other erythrocytes. A host immune response is elicited that may clear the infection. Most infected dogs in the United States do not become ill but remain carriers.

After a 10-to 12-day incubation period, infected dogs may develop severe hemolytic anemia, hypotensive shock, and a multiple organ dysfunction syndrome.[121–127] Although direct parasite damage contributes to the anemia, a oxidative damage and secondary IMHA appears more important. Autoagglutination and a positive direct Coombs' test result are commonly encountered.[128,129] Furthermore, infected dogs often have thrombocytopenia and leukocytosis. Besides the typical signs of anemia, fever, vomiting, lymphadenopathy, and splenomegaly may be noted. Although the hemolysis is mostly extravascular, signs of intravascular hemolysis may also be observed. The erythrocytic osmotic fragility is increased *in vitro*. Finally, a variety of other atypical signs, DIC, and death may occur because of multiple organ failure.

Babesiosis is diagnosed by DNA testing, blood smear examination, or immunodiagnostics (Figure 270-10B).[120] Single or pairs of large piriform organisms in erythrocytes are characteristic of *B. canis*, whereas singular intracellular organisms are probably *B. gibsoni*. Because only few erythrocytes are generally parasitized, examination of erythrocytes in or below the buffy coat or of blood collected from an ear prick may improve the chances of finding the organism. The indirect fluorescent antibody test and enzyme-linked immunosorbent assay (ELISA) are most helpful in the screening for babesiosis, although dogs seen early in the disease course are serologically negative, and a few dogs may even remain serologically negative. Because of some serologic cross-reactivity, *B. canis* and *B. gibsoni* may be differentiated only by DNA testing and examination of parasites. Finally, dogs infected with *B. gibsoni* may have false-seropositive reactions for *Toxoplasma, Neospora*, and *B. canis*.

Imidocarb dipropionate as a single intramuscular injection of 3.5 mg/lb clears *B. canis* and probably *B. gibsoni* infection.[120] In addition, it has prophylactic activity for 6 weeks, eliminates the infectivity of ticks for up to 4 weeks, and is effective against *Ehrlichia canis*, a common dual infection. The few side effects are thought to be related to the anticholinergic effects of the drug and include hypersalivation, GI signs, and dyspnea. In addition, supportive care to correct dehydration, anemia, and acidosis is important.[130] Treatment with immunosuppressive doses of prednisone is also indicated for 2 to 3 weeks to control the immune-mediated hemolytic component. Tick control is important in preventing spread in a kennel. A vaccine against *B. canis* is available in Europe.[131] All prospective blood donors should be tested for *Babesia* by serology and blood smear examination. Splenectomy of blood donors to increase the likelihood of finding parasites is not generally recommended.

270.3.8 Chemical-Induced Hemolytic Anemia

Many compounds including chemical agents, drugs, and food components and additives can induce oxidative damage to erythrocytes leading to a hemolytic anemia.[132] Many of these agents are derivatives of aromatic organic compounds (Box 270-2). In some cases the chemical itself acts as an oxidative agent, but more often the compound or its metabolite interacts with oxygen to form free radicals and peroxides (see Chapter 168). Extracellularly produced oxidants injure the membrane, whereas oxidants generated intracellularly attack hemoglobin and membrane structures. Thus a single agent may inflict erythrocyte injury (and thereby hemolysis) and reduced oxygen delivery to tissue by one or all three of the following mechanisms:

1. Oxidation of heme iron resulting in methemoglobin production
2. Oxidative denaturation of hemoglobin leading to Heinz body formation
3. Membrane damage causing impaired deformability and ion transport

270.3.9 Methemoglobinemia

Methemoglobin is the form of hemoglobin in which the heme iron has been oxidized from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state and is therefore unable to bind and transport oxygen.[3] Normally, approximately 3% of hemoglobin is daily oxidized by spontaneous oxidation of oxyhemoglobin to methemoglobin and oxidant generation in regular metabolic pathways. This is a reversible process, because methemoglobin is being continuously reduced by the reduced nicotinamide adenine dinucleotide (NADH) cytochrome-b_5 reductase enzyme in erythrocytes, thereby keeping the blood methemoglobin concentration below 1%. Methemoglobin can accumulate because of a hereditary deficiency of the cytochrome b_5 reductase enzyme, as described earlier in this chapter, or because of exposure to oxidative agents. Dogs and cats with a genetic predisposition to methemoglobinemia generally have relatively high hematocrits and are at extreme risk of developing a life-threatening methemoglobinemia-associated anemic crises.

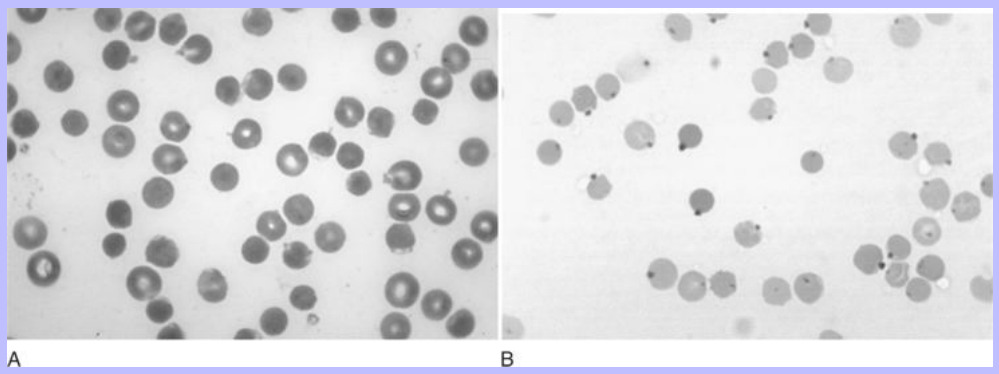
Hyperthyroidism

Lymphoma and other neoplasms

Figure 270-11 Heinz bodies and eccentrocytes on Wright's stain, canine **(A)**. Large Heinz bodies NMB stain feline **(B)**.



Although many compounds are capable of inducing methemoglobin formation, benzocaine-containing skin products and laryngeal or nasopharyngeal sprays, phenazopyridine (a urinary tract analgesic), and acetaminophen produce severe methemoglobinemia in cats within minutes to hours of exposure.

For several reasons, cats appear more susceptible to oxidative agents. Feline hemoglobin contains eight to 10 reactive sulfhydryl groups that are easy targets for oxidation, whereas other species' hemoglobins have a maximum of four sulfhydryl groups. Furthermore, the drug-metabolizing steps are restricted in cats. They cannot conjugate drugs with glucuronides and their sulfate conjugation and glutathione pathways are rapidly saturated and depleted. Thus instead of excreting acetaminophen as a glucuronide conjugate, cats produce reactive metabolites through mixed function oxidase activities that damage erythrocytes, leading to methemoglobinemia and Heinz body anemia.[133] As little as one small acetaminophen tablet (65 mg) may be lethal to a debilitated cat, whereas tenfold higher doses are required to induce toxicity characterized by hepatic failure in other species.

Although methemoglobin is quantified in EDTA-anticoagulated blood spectrophotometrically in commercial laboratories, simple spot tests can indicate the presence of clinically important methemoglobinemia. If a tube of blood or drop of blood on a filter paper remains brown after exposure to air (oxygen), whereas the control venous sample turns red, the patient's blood methemoglobin concentration exceeds 10% of the total hemoglobin. At this level the mucous membranes appear cyanotic, but serious clinical signs are not appreciated until the methemoglobin level reaches 40%. Exercise intolerance, lethargy, dyspnea, ataxia, and coma develop and death ensues when the methemoglobin concentration exceeds 60% to 70%. Besides the clinical signs related to hypoxia, cats intoxicated with acetaminophen may develop facial edema, vomiting, and hypersalivation.

270.3.9.2 Heinz Body Anemia

Heinz bodies represent irreversibly denatured and precipitated hemoglobin in erythrocytes. Eccentrocytes may be noted instead and are characterized by shifting of hemoglobin to one side of the cell, leaving a clear moon-shaped zone outlined by membrane (Figure 270-11).[134] The conformational changes of the globin chains caused by oxidation of the hemoglobin sulfhydryl groups and oxidative membrane damage result in binding and clustering of precipitated hemoglobin on the erythrocyte membrane. Heinz bodies containing

erythrocytes are rigid, have decreased deformability, and therefore may lyse or be removed from the circulation by macrophages. When passing through the spleen, Heinz body–containing erythrocytes are retained in the meshwork and phagocytized as a whole (culled), or only the Heinz bodies are removed (pitting). However, because of large openings in the venous sinus walls, the feline spleen has poor pitting function. Heinz body hemolytic anemia has been associated with a variety of conditions, many of which also cause methemoglobinemia and membrane injury. Ingestion of dietary onions (raw, cooked, or dehydrated [onion powder]), as well as garlic, usually fed by owners as part of table scraps, can result in up to 90% Heinz body formation within 1 day, followed by hemolysis leading to severe anemia by 5 days.[135–137] Several thiosulfates in onion extracts have been implicated in producing Heinz bodies but only minimal amounts of methemoglobin. Onion and garlic toxicity occurs more commonly in dogs than cats, and the susceptibility appears to vary among individual animals. Administration of various drugs, including methylene blue, DL-methionine, phenacetin, and vitamin K_3 (above 2.5 mg/lb/day) can also lead to Heinz body hemolytic anemia.

Acetaminophen, benzocaine-containing products, and phenazopyridine can induce severe methemoglobinemia and also cause Heinz body formation. Furthermore, increased numbers of Heinz bodies have been associated with various organ disorders in cats. These disorders include hyperthyroidism, lymphoma, other cancers, and diabetes mellitus, particularly in the presence of ketoacidosis.[138]

270.3.9.3 Membrane Injury

Many oxidative agents directly cause membrane lipid peroxidation, cross-linking and clustering of cytoskeleton proteins, and impaired ion transport function. These membrane injuries result in severe intra-and extravascular hemolysis, sometimes without much Heinz body and methemoglobin formation. For instance, naphthalene, the active ingredient in old-fashioned mothballs or crystals and in toilet bowl deodorizers, is an important poison in small animals, causing intravascular hemolysis, vomiting, seizures, and hepatopathy.[139] Hemolytic anemia has also been associated with acute zinc toxicity in dogs that swallowed zinc-containing objects such as zinc nuts and bolts from animal carriers, U.S. pennies minted since 1983 (98% zinc by weight), and zinc oxide dermatologic ointments (Fig. 270-12).[140,142] Because these objects may be retained in the stomach, the gastric acid liberates zinc, which allows absorption. The mechanism by which zinc causes life-threatening intravascular hemolysis remains uncertain, but few Heinz bodies and spherocytes have been found. Besides identifying the metal object by radiographs, the diagnosis can be confirmed by documenting increased serum zinc concentrations (above 5 parts per million; samples must be submitted in plastic tubes for analysis). Similarly, acute copper toxicosis may result in severe intravascular hemolysis and some methemoglobinemia. It has been associated with fulminant hepatic failure caused by copper storage in Bedlington terriers (see Chapter 227). In contrast, lead toxicity is generally not associated with hemolysis, but large numbers of nucleated RBCs and GI and neurologic signs are observed.

Figure 270-12 Zinc-containing coins eroded in stomach of a dog with hemolytic anemia.

Treatment of oxidative hemolytic anemias includes immediate removal of the oxidative agent, use of antioxidants, transfusion, and supportive care. Vomiting is induced only if the substance has just been ingested and activated charcoal may be administered. Metallic objects such as pennies and nuts are best removed by gastroscopy or gastrotomy. In case of severe anemia, methemoglobinemia, or both, transfusion with packed RBCs is indicated, whereas oxygen therapy hardly improves tissue oxygenation. The anemia nadir is often not reached for several days, but with the commonly observed strong regenerative response, recovery from anemia is swift. Severe methemoglobinemia can be corrected with one slow intravenous injection of methylene blue (0.4 mg/lb). Methylene blue acts as an electron donor for an alternative, otherwise nonfunctional methemoglobin reductase. In cats with acetaminophen intoxication, either oral or intravenous *N*-acetylcysteine (Mucomyst) at an initial dose of 64 mg/lb followed by seven treatments of 32 mg/lb every 8 hours should be administered. As the drug of choice, *N*-acetylcysteine, increases the sulfate availability for conjugation of acetaminophen and provides cysteine for glutathione regeneration and metabolism of toxic metabolites of acetaminophen. Treatments with other agents such as sodium sulfate to add sulfide, cimetidine to inhibit cytochrome P-450, and ascorbic acid as weak antioxidants have been proposed, but they have not been shown to provide additional benefit. Because of the effect of oxidative substances on other organ systems including GI tract, liver, and central nervous system (CNS), animals may continue to show clinical signs after correction of the anemia and methemoglobinemia and require additional supportive care. Furthermore, care should be taken to avoid any re-exposure to these and other toxins.

270.3.9.4 Hypophosphatemia-Induced Hemolysis

Severe hypophosphatemia causing hemolysis in dogs and cats has been associated with diabetes mellitus, hepatic lipidosis, enteral and parenteral hyperalimentation (starvation-refeeding syndrome), and oral administration of phosphate-binding antacids.[143–145] During insulin, fluid, and bicarbonate treatment of (ketoacidotic) diabetic animals, serum phosphate concentrations may decrease precipitously. Hypophosphatemia occurs because of intracellular phosphate shifts, enhanced renal loss, and reduced

intestinal absorption of phosphate. In addition to myopathy, cardiac dysfunction, neurologic dysfunction, and acute hemolytic anemia (characterized by a rapid drop in PCV and mild intravascular lysis and Heinz body formation) may be observed in animals with hypophosphatemia. Based on experimental data, serum phosphorus concentrations would need to be less than 1 mg/dL (normal 2.9 to 7 mg/dL) to cause hemolysis, but in clinical practice hemolysis occurs with phosphate values less than 2.5 mg/dL. Serum phosphate measurements may underestimate the phosphate depletion in these disease states and can erroneously be higher because of hemoglobinemia and hyperbilirubinemia. The pathogenesis of the hypophosphatemia-induced anemia is probably related to depletion of erythrocytic ATP, DPG (in dogs), and reduced glutathione, which leads to decreased deformability, increased osmotic fragility, and susceptibility to oxidative injury. As discussed in relation to canine erythrocyte PFK deficiency, DPG-depleted erythrocytes are extremely alkaline fragile and have a high hemoglobin oxygen affinity, thereby contributing to intravascular hemolysis and tissue hypoxia in dogs but not in cats. Furthermore, thrombocytopenia and platelet and leukocyte dysfunction have been documented experimentally in dogs.

1906

1907

Hypophosphatemic animals need to receive oral or parenteral phosphate supplementation. Aggressive intravenous phosphate therapy is often needed in severely hypophosphatemic and anorexic or vomiting animals. An initial sodium or potassium phosphate dose of 0.005 to 0.015 mmol/lb/hr (maximum, 0.03) appears safe and effective, but serum phosphorus and calcium concentrations should be measured every 6 hours and the dose adjusted and route switched to oral when appropriate. Potential complications of intravenous phosphate supplementation include hypocalcemia, acute renal failure, and dystrophic soft tissue calcification and should be immediately corrected by stopping the phosphate infusion and initiating infusion of a calcium gluconate. Oral supplementation with a normal balanced diet, skim milk, or commercial phosphate products is preferred in cases of mild hypophosphatemia, and prophylactic phosphorus supplementation should always be considered when treating severe diabetes mellitus or hepatic lipidosis. This can be easily accomplished by supplementing potassium using both chloride and phosphate solutions.

270.3.10 Microangiopathic Hemolytic Anemia

A large variety of conditions may cause physical damage to erythrocytes that leads to cell fragmentation and intra-and extravascular hemolysis.[146] In case of water intoxication associated with near drowning in fresh water, erythrocytes undergo hypotonic lysis similar to the swelling and lysis of erythrocytes in the *in vitro* osmotic fragility test. Heat stroke and severe burns can inflict thermal injury to erythrocytes. Heart valve disease, cardiovascular implants, and intravenous catheters can induce mechanical damage to erythrocytes as much as dirofilariasis, particularly in the form of the caval syndrome (see Chapter 206). In addition, other endothelial damage caused by vasculitis, hemangiosarcoma and other tumors, various splenic diseases or torsion, and liver disease can injure erythrocytes (Figure 270-13). A hemolytic-uremic syndrome characterized by acute renal failure, platelet activation leading to thrombocytopenia and thrombosis, and microangiopathic hemolytic anemia has been described in dogs. Similarly, DIC is associated with a fragmentation hemolysis (see Chapter 274).

Figure 270-13 Acanthocytes dog with liver disease.

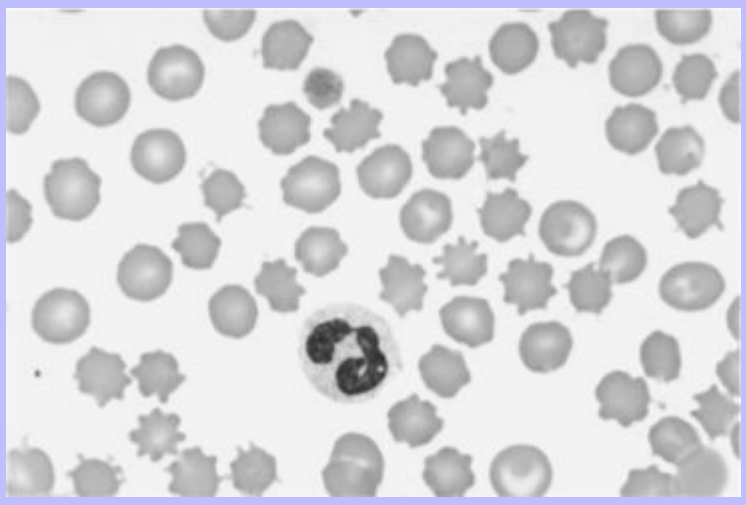


Figure 270-14 Schistocytes, canine.

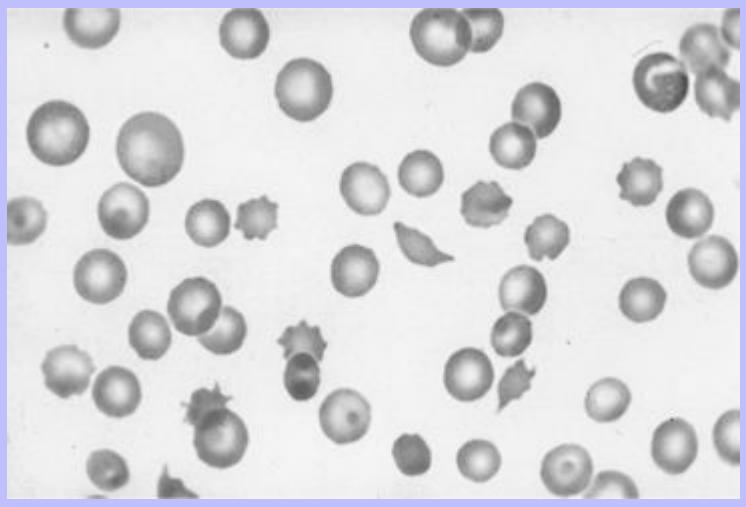

A diagnosis of microangiopathic hemolysis that is often subclinical and rarely causes overt intravascular hemolytic anemia is made by identifying the triggering condition and characterizing schistocytes (schizocytes) (Figure 270-14). These are erythrocyte fragments that appear on blood smears as small, misshapen, often triangular or helmet-shaped structures. Schistocytes are important even in small numbers and can unlikely be fabricated by poor blood smear preparation. On the other hand, schistocytes are observed with a variety of other anemias including chronic iron deficiency states and zinc intoxication. Concomitantly, thrombocytopenia and coagulopathy are often present. Besides supportive care, therapy is directed at the underlying disease and control of DIC. Blood component therapy should be considered. The prognosis is guarded to poor if the underlying disease cannot be corrected.

271 CHAPTER • 271 Nonregenerative Anemia

Bernard F. Feldman[†]

Anemia is a common clinical and laboratory finding that in and of itself does not constitute a diagnosis. In other words, anemia is a sign of disease, not a disease per se. The mere coexistence of anemia with another illness does not necessarily pinpoint the etiology. The clinical goal is to determine the pathogenesis in order to deliver the most appropriate therapy and to instigate steps to ameliorate this condition. The cause of anemia may be evident from the signalment, history, vaccination status, travel history, life style, duration of signs, drug or toxin exposure, prior or current illnesses, illnesses in housemates or relatives, or physical examination (Box 271-1). When a dog or cat is actively bleeding, the presence of anemia can be anticipated. If the bleeding is chronic, iron deficiency can be anticipated. Signs of inflammation or systemic illness can explain moderate anemia.[1–5]

271.1 IS THE ANEMIA NONREGENERATIVE OR REGENERATIVE?

There are seven general causes of anemia. Five of these remain nonregenerative unless the underlying etiology is successfully ameliorated. Two causes, hemolysis and hemorrhage, are nonregenerative in the acute stages but most often become regenerative 3 to 7 days after the onset of the problem. The seven general causes are:

1. Lack of iron
2. Anemia associated with inflammatory disease
3. Bone marrow disorders
4. Erythropoietin-related anemias
5. Maturation abnormalities (rarely encountered)
6. Hemolysis
7. Hemorrhage

The initial approach to treatment of the anemic pet is an attempt to discern whether the anemia is nonregenerative or regenerative. This determination is critical, because a dog or cat with regenerative change has either a hemolytic or hemorrhagic process and requires specific additional diagnostics and forms of therapy. Beyond the minimum database of a complete hemogram, urinalysis, and biochemical profile, diagnostics and therapeutics often are significantly different for the numerous nonregenerative anemias.

The decision as to whether the animal is responding appropriately to anemia treatment requires examination of reticulocyte numbers (from a vital stain) or polychromatophil numbers (from a Romanovsky-based stain). The reticulocyte count is the only index of *effective* erythropoiesis. Proper use of this value requires (1) conversion to an absolute quantity, (2) adjustment for the reduced red cell mass, and (3) correction for the effect of erythropoietin on marrow reticulocyte release. These adjustments result in the determination of reticulocyte numbers adjusted for the pet's red cell mass.[6]

The first step is to convert the reticulocyte percentage into an absolute quantity of reticulocytes. In a canine example, if the mean red cell count is 7 million and 1% reticulocytes is the mean number for that red cell mass,

1% reticulocytes in absolute terms is 70,000 reticulocytes. The reference interval for a normal adult dog is approximately 35,000 to 105,000 reticulocytes per microliter (0.5% to 1.5% reticulocytes).

The second step is to correct for the reduced red cell mass using red cell numbers *or* the hemoglobin *or* the hematocrit. Using the hematocrit as an example, the absolute reticulocyte number is multiplied by the dog's hematocrit, and the product is divided by the mean species hematocrit.

The third step is to correct for the effect of erythropoietin (EPO) on bone marrow reticulocyte release; EPO is inversely correlated with the red cell count (or hemoglobin or hematocrit). Continuing with the hematocrit example, the lower the hematocrit, the higher the concentration of EPO (with some exceptions, such as renal failure). EPO has four clinically significant effects: (1) it causes uncommitted stem cells to differentiate to the erythroid line; (2) it decreases the bone marrow maturation time for red cell development; (3) it increases individual red cell hemoglobin synthesis; and (4) it causes premature release of reticulocytes from bone marrow to blood.

The approximate average time for reticulocytes to mature in the dog or cat is 4.5 days: 3.5 days in the marrow and 1 day (24 hours) in peripheral blood if the hematocrit is appropriate (Table 271-1).

To correct for the effect of EPO on bone marrow reticulocyte release, the examiner converts the reticulocyte percentage to absolute values and adjusts for the reduced hematocrit, then divides the final figure by the number of days the average reticulocyte lives as a reticulocyte in peripheral blood based on the dog's or cat's hematocrit (see Table 271-1). Determine red cell production over basal or anticipated numbers (basal numbers are anticipated to be 35,000 to 105,000 absolute reticulocytes per microliter in a normal adult dog with a reticulocyte reference interval of 0.5% to 1.5%).

If a dog's hematocrit is 23% (mean canine normal is 46%) and its reticulocyte percentage is 5%, the question is, is there an appropriate response to the reduced hematocrit? To determine the corrected absolute reticulocyte count in this dog, the following calculations are made:

1. If the reticulocyte count is 5% of a red cell count of 3.5 million/mL (the approximate number of red cells per microliter with a hematocrit of 23%), the absolute reticulocyte number is approximately 175,000/mL. Thus:

$$175{,}000 \times 23\% \text{ (Dog's hematocrit)} \div 46\% \text{ (Mean canine hematocrit)} = 87{,}500/\text{mL}$$

2. The number of reticulocytes per milliliter (87,500) is divided by 2 (the average length of time [2 days] a reticulocyte circulates in peripheral blood at a hematocrit of 23%) to determine the corrected absolute reticulocyte number:

$$87{,}500 \div 2 = 43{,}750/\text{mL}$$

1908

The corrected absolute reticulocyte value in this example (43,750/mL) is well within the reference interval observed for dogs with appropriate hematocrits. In fact, in this example, even without correction for the effect of EPO (without correction, the reticulocyte count would have been 87,500/mL), this anemia must be considered nonregenerative. A corrected absolute reticulocyte count of less than 105,000/mL must be considered nonregenerative. Patients with hemolysis and hemorrhage that are responding appropriately often have adjusted absolute reticulocyte counts in excess of 150,000/mL.

271.2 CLINICAL MANIFESTATIONS OF ANEMIA

The clinical manifestations of anemia are also common manifestations of processes or diseases that primarily affect other organ systems. Weakness, fatigue, and pallor are often manifestations of anemia of recent onset, such as that caused by recent blood loss or acute hemolysis. Anemia that develops gradually, particularly in inactive cats or dogs, may cause only fatigue or may go unnoticed. Pallor of the conjunctiva or mucous membranes may be caused by both anemia and hypovolemia. Icterus may obscure pallor. Pain may also result from increased bone marrow activity; this may simply be manifested by fatigue, unwillingness to move or, in stoic small animals, concern with movement or difficulty walking. Lymphadenopathy and splenomegaly are common with infectious, inflammatory, and hematologic diseases, particularly lymphomas and the leukemias. Bleeding occurs as a consequence of vascular, platelet, or coagulation factor abnormalities. Thrombosis can be either venous or arterial and often results in significant thrombocytopenia. Venous thrombosis is often caused by blood flow or obstructive processes or by imbalances in coagulation factors. Immune-mediated hemolytic anemia can be an example of such a process. Arterial thrombosis is most often caused by vascular problems, including vascular trauma thrombocytopenia, thrombocytosis or thrombocytopathia, and processes associated with infection or neoplasia.[4]

271.3 LABORATORY EVALUATION

Laboratory assistance usually is required to determine the cause of anemia. The routine but complete hemogram and blood smear document the presence, severity, and morphologic nature of the anemia (Box 271-2). A complete evaluation includes study of marrow production and red blood cell destruction and is usually required for accurate classification of the anemia into one of the two major categories, regenerative (responsive) or nonregenerative (nonresponsive). In the absence of specific clues, anemia initially may be broadly classified as regenerative or nonregenerative on the basis of reticulocyte (or polychromatophil) numbers (Box 271-3).

Most anemias are nonregenerative (Box 271-3). This type of anemia may be due to (1) an abnormality of the stem cell population and bone marrow environment, (2) an abnormality in the early modulators of stem cell activity, or (3) a deficiency in the late-stage regulators of erythroid proliferation, including EPO, cytokines, and iron.[5]

Disorders of marrow stroma and stem cells are relatively uncommon, but when they do occur, they often result in severe anemia and may represent myelodysplastic syndromes, including those variously lumped together as the "preleukemic syndromes." Nonregenerative anemia associated with iron depletion caused by inflammation is the most common mild anemia in dogs and cats. Anemias that occur secondary to a decrease in EPO are also often mild, at least in the early stages of the process, because the anemia reflects a physiologic readjustment of red cell production to fit reduced metabolic need. This can even be true in early renal disease. Red blood cell morphology and production indices (reticulocyte numbers and the mean cell volume, mean cell hemoglobin, and mean cell hemoglobin concentration) may be similar for the various types of nonregenerative anemia. However, findings on marrow morphology (and perhaps iron studies) usually allow categorization of the specific abnormality as one of the three types listed previously.[6]

271.4 HYPOPROLIFERATIVE ANEMIA

271.4.1 Erythropoietin-Related Causes

271.4.1.1 Renal Insufficiency

Renal insufficiency, especially chronic and severe renal disease, invariably affects the hemopoietic system adversely. To provide effective treatment, the clinician must have a clear understanding of the factors that induce anemia and intensify the failure of erythropoiesis. The bone marrow provides important clues to the pathogenesis of the anemia of renal failure. Given the variety of possible complicating factors, it is not surprising that a wide spectrum of abnormalities have been reported. Marrow cellularity has been reported to be normal, decreased, and increased. However, most dogs and cats with uncomplicated anemia secondary to renal insufficiency have appropriate marrow cellularity, with appropriate myeloid to erythroid ratios and appropriate erythroid development, despite the severe anemia. The argument may be made that an appropriate myeloid to erythroid ratio may not in fact be appropriate in the anemia of renal insufficiency. Iron distribution tends to be normal unless some element of anemia of inflammation is present, in which case iron may be redistributed to the monocyte-macrophage cells. Ferrokinetics are nearly normal in most small animals with anemia of renal disease. When these individuals are stressed by hypoxia or worsening anemia as a result of hemorrhage, the bone marrow erythron is able to respond in the appropriate direction but does so with a suboptimal recovery phase.[7]

From examination of the marrow alone it can be determined that (1) the defect in anemia of renal disease is not primarily related to defects in iron, which distinguishes this disorder from anemia of inflammation, and (2) the primary defect is not the result of an absolute absence of EPO. If it were, the myeloid to erythroid ratio would show a marked increase, approaching infinity, as the effect of EPO on the erythroid marrow decreases.

Two primary mechanisms have been advanced to explain most cases of normocytic, normochromic anemia with normal iron distribution and normal absolute reticulocyte counts associated with renal insufficiency. One mechanism is a deficiency of EPO, which causes the anemia. The other mechanism is an accumulation of toxins that suppress hemopoiesis. The latter mechanism probably accounts for much of the anemia, especially in dogs. Of course, if underlying inflammatory renal disease is present, anemia of inflammation may be a component.

EPO is a vital hemopoietic growth factor that not only enhances red cell production but also has been shown to increase platelet counts in rats and humans with end-stage renal failure.[8] EPO plays an important role in the pathogenesis of anemia in the dog and to a lesser degree in the cat. A significant increase in the plasma EPO concentration was observed in 22 cats and 32 dogs with anemia without renal insufficiency or chronic renal failure; however, 37 dogs and 35 cats with chronic renal failure had a normal or only modestly reduced EPO concentration. Cats showed almost no overlap between the groups, whereas dogs showed significant overlap.[9] This suggests that measurement of the plasma EPO concentration is more useful for characterization of anemia in cats than in dogs, either with or without chronic renal disease.[10] It also suggests that successful use of EPO may be a target molecule and/or a threshold response, perhaps to “kick start” erythropoiesis. The effects of EPO in these circumstances occur only with even more EPO, an argument for using exogenous EPO clinically.

As a general rule, the use of commercially available human recombinant growth factors for several consecutive weeks in dogs and cats results in the development of antibodies. Fortunately, it appears that short-term use of these products (less than several weeks) does not result in significant antibody effect.[11] The use of any human recombinant hemopoietic growth factor, including EPO, is strictly extralabel, because these products are not approved for use in the dog or cat. Only dogs and cats that have clinical signs related to anemia and that are profoundly affected (i.e., a hematocrit below 25% in the dog and 20% in the cat) should be considered for EPO therapy because of the potential for the development of antibodies.[9] Animals that are hypotensive or that have iron deficiency should not be treated until these problems have been corrected. The blood pressure and the serum iron concentration should be checked before and during EPO therapy.

The current recommended dosage of recombinant human EPO is 100 U per kilogram of body weight given subcutaneously three times weekly. Once the target hematocrit has been reached, the frequency should be reduced to twice weekly. The lowest possible maintenance dosage should be used. It is also recommended that iron be given to any dog or cat undergoing EPO therapy. If refractory anemia is noted despite therapy, EPO administration should be suspended and the pet evaluated further, at least with a complete hemogram and bone marrow examination. If erythrocytic hypoplasia exists, the development of antibodies may be the cause, and the pet must be supported with blood products and other adjunctive therapies.[11]

Older studies have provided convincing evidence that implicates uremic toxins (as yet many are implicated but none specified) in the genesis of anemia of renal insufficiency.[12] These investigators reasoned that because several studies in humans with anemia of renal insufficiency had indicated that the plasma EPO concentrations were within the reference interval or modestly above or below it, all are inappropriate for the degree of anemia. However, it seemed unlikely that anemia of renal insufficiency could be explained *in toto* by EPO deficiency, therefore it must be due to retention of some materials that inhibit EPO or its effects. When continuous peritoneal dialysis was used in human patients with end-stage renal disease, half the patients showed full correction of the anemia. The researchers concluded that anemia of renal insufficiency can be corrected by dialysis alone in patients in whom sufficient renal endocrine function remains to mount a modest EPO response. Another conclusion was that, because EPO plays a pivotal role in erythropoiesis, if the endocrine function of the kidney has been destroyed by the same disease that impairs excretory function, the clearance of uremic toxins by dialysis will not reverse the suppression of the erythron.[12,13]

Certainly other factors, if investigated, can help the clinician define etiologies and develop appropriate therapeutic strategies. These factors, which have been suggested to contribute to anemia of renal insufficiency, include reduced half-life of red cells due to uremic toxins, hemorrhagic loss from gastrointestinal ulcers, increased hemorrhagic tendency due to reduced platelet function, suppression of erythropoiesis by high concentrations of parathyroid hormone, reduced nutrient intake due to inappetence, and injury of red cells due to glomerular pathology and renal fibrosis.[2]

271.4.1.2 Anemia Secondary to Endocrine or Metabolic Disorders

Endocrine disorders involving the thyroid and the pituitary-adrenal axis can cause hypoproliferative anemias. Hypothyroidism impairs erythrocyte production in humans and dogs. The anemia is usually mild and may be either normocytic or slightly macrocytic. Other clinical signs are related to the underlying thyroid disorder, and the anemia remits when the thyroid status is corrected. This is an interesting anemia in physiologic terms, because in a sense it is not an anemia at all. It represents an inappropriate response on the part of the kidney (i.e., EPO production) and bone marrow to decreased tissue oxygen consumption in the hypothyroid patient. The anemia is slow to develop and slow to remit; 3 to 4 months may be required from the onset of replacement therapy before the red cell mass returns toward or to normal. Other deficiencies of necessary nutrient materials (e.g., cobalamin or folic acid deficiency) may result from immune-mediated thyroid disease,[14,15] although this has not been addressed specifically in veterinary medicine. Prealbumin, an alpha$_2$-globulin produced in the liver and a transport protein for thyroxine, has been measured in dogs with hypothyroidism. In horses, the prealbumin concentration negatively correlates with albumin. Prealbumin increases with infectious, immune, and neoplastic etiologies, which suggests that the mild anemia associated with canine hypothyroidism may have a component of anemia of inflammation.[16–18]

1911

1912

Other endocrine disorders that might be associated with mild anemia are hypopituitarism, hypoadrenocorticism, and decreased growth hormone.[18] A mild anemia recognized in late pregnancy is the result of an increase in the plasma volume. The red cell mass remains appropriate.

271.4.2 Causes Related to Lack of Iron

271.4.2.1 Anemia Due to Iron Abnormalities

Iron-deficient erythropoiesis occurs secondary to body iron depletion or inflammation. In young, nursing animals suffering from any type of blood loss (including parasitism or repeated phlebotomy), iron depletion occurs rapidly, because iron stores are insignificant and the mother's milk does not contain adequate iron. In

older animals with iron-deficient erythropoiesis, gastrointestinal or urinary tract hemorrhage, often occult and chronic, should be suspected. Among the clinical considerations would be ulceration, parasitism, neoplasia, and hemostatic disorders.

Most natural iron exists in a largely unavailable (to biologic systems), oxidized, insoluble, ferric (Fe^{3+}) form. Free iron can catalyze the formation of free radicals that damage cell membranes and deoxyribonucleic acid (DNA). Intracellular iron, therefore, is bound to various proteins to reduce its toxicity. These proteins are responsible for the absorption, transport, storage, and biologic activity of iron.

Any clinical study of iron metabolism must, of necessity, study the physiologic compounds associated with it. Iron exists in the following compartments: hemoglobin; storage, in the form of hemosiderin and ferritin; myoglobin; labile iron; tissue iron; and transport.[7] These compartments are defined by anatomic distribution, chemical characteristics, and function.[19]

Most iron in animals exists in red cells as hemoglobin iron. Each hemoglobin molecule contains four iron atoms, and each milliliter of red cells contains 1.1 mg of iron. The exact amount of total body iron depends on the red cell mass, blood volume, and body weight.[20] Storage iron exists as either a soluble, mobile fraction (ferritin) or as an insoluble, aggregated form (hemosiderin). As iron storage increases, more iron is stored as hemosiderin. Hemosiderin is mostly formed by lysosomal action on ferritin. In tissues it is readily recognized by the Prussian blue reaction. Ferritin consists of protein (apoferritin) and iron. Once iron is in the apoferritin shell, it must be oxidized to the ferric form, hydrolyzed, and polymerized to the ferric oxyhydroxide polymer. Reversal of the process allows iron to exit ferritin. The molecular shape and therefore the immunogenicity of ferritin is both species and tissue specific.[21,22]

Myoglobin iron is found mostly in muscle, where it can temporarily provide oxygen during anaerobic conditions. The labile iron pool may be an intermediate between plasma, storage, and hemoglobin. The tissue iron compartment consists of heme-containing compounds similar to hemoglobin (e.g., myoglobin and the cytochromes), non-heme-containing enzymes (e.g., iron sulfur compounds and metalloflavoproteins), enzymes that require iron or heme as a cofactor, and enzymes that contain iron in an unknown form (e.g., ribonucleotide reductase).

The transport compartment consists of plasma transferrin. The transfer of iron to erythroid cells requires internalization of the iron-laden transferrin molecule. The amount of iron delivered depends on the plasma iron concentration, the percentage iron saturation, and the number of membrane receptors.[7,23] Copper also plays an important part in the transportation of iron across cell membranes. Most circulating copper is found attached to the serum glycoprotein ceruloplasmin, which provides ferroxidase activity and may be needed to deliver iron into the circulation. When pigs are copper deficient, they have hypoceruloplasminemia and show signs of functional iron deficiency, presumably as the result of an inability to mobilize iron from the mononuclear phagocytic system and the gastrointestinal tract.[7,24]

Examination of the complete hemogram may be useful for evaluating iron adequacy. In severe iron deficiency, hemoglobin production is slowed and nucleated red cells continue to divide, resulting in the release into the circulation of late-stage nucleated red cells and adult red cells with marked central pallor. The red cell indices, the mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and mean corpuscular hemoglobin (MCH), are variably lowered in late-stage iron deficiency, with lowering of the MCH often preceding the other indices. It should be noted that deficiency of copper and pyridoxine, which also are needed for hemoglobin synthesis, can lower these indices.

The concentrations of serum iron and transferrin (the total iron binding capacity [TIBC] when the transferrin molecule is saturated) are useful analytes in the determination of iron adequacy. Use of non-iron-containing anticoagulants (ethylenediamine tetra-acetic acid [EDTA] is satisfactory), disposable plastic pipettes, test tubes, and test tube stoppers prevents contamination of patient blood with iron or zinc. Serum iron declines with iron deficiency, acute-phase inflammatory reactions, hypoproteinemia, hypothyroidism, renal disease, and chronic inflammatory states. The serum iron concentration should not be used as a predictor of iron stores. The transferrin concentration is stable or may increase with primary nutritional iron deficiency and remains stable or decreases with inflammatory processes. The unbound iron binding capacity (UIBC) estimates the saturation of transferrin, and its determination is of little clinical use.

Determination of the bone marrow iron concentration with Prussian blue stain occasionally is useful. Under appropriate circumstances, stainable iron is evident, whereas with iron-deficient processes, it is not evident.[7,19] Analysis of serum ferritin using species-specific, antibody-driven reactions has proven useful for determining nonheme iron stores in domestic animals, as well as increases after iron therapy. Ferritin, an acute-phase inflammatory protein, can increase during inflammatory reactions when interleukin-1 (IL-1) is produced. Serum ferritin can also be increased in hepatic disease, hemolysis, and some neoplastic disorders.[22,24] Body iron stores can be measured directly by measurement of the iron concentration in various organs.[25]

271.4.2.2 Anemia of Inflammatory Disease

Anemia of inflammatory disease (AID) is a mild, normocytic, normochromic, nonregenerative anemia associated with acute or chronic inflammatory processes, including trauma, infection, immune processes, and focal or disseminated neoplastic disease. It is the most common anemia found in small animals and is probably the most common anemia in veterinary medicine. This anemia appears within several days to a week. Clinically, it is an iron-deficient process; however, although the cause is multifactorial, iron sequestration in the mononuclear phagocytic system is the physiologic basis.[26–30]

The pathogenesis is mediated by cytokines produced during inflammation and results from iron sequestration (relative unavailability), a decline in red cell survival, and decreased erythropoietic response.[28,29] Reduced iron availability appears to be a physiologic metabolic response, an attempt to deprive infectious organisms of iron essential to metabolism. Apolactoferrin (iron-free lactoferrin), found in milk, mucosal secretions, and polymorphonuclear leukocytes (neutrophils), chelates and binds large amounts of iron, especially at the low pH concentrations associated with inflammation. Both the synthesis and release of apolactoferrin are increased primarily by IL-1 and tumor necrosis factor alpha. Macrophages express increased lactoferrin receptors on their surfaces; this allows them to internalize lactoferrin-bound iron, which is transferred to ferritin. Neutrophils release apolactoferrin at sites of infection, which helps in iron chelation. Lactoferrin is also intrinsically bacteriocidal.[30] This results in diversion of iron from fast-release (ferritin storage) to slow-release (hemosiderin storage) pathways. Intestinal epithelial cells and hepatocytes are also affected and contribute to the relative iron deficiency. Iron absorption from the gastrointestinal tract is reduced as a result of decreased transferrin synthesis during the acute-phase reaction.[31]

1912 1913

Experimental studies in cats suggest that red cell survival may be a predominant factor in the early stage of AID. Macrophages activated by the inflammatory process are more efficient in clearing senescent red cells

and those coated with immunoglobulins.[29,32] Although not all AID patients are febrile, fever per se has been implicated in decreased red cell survival.[27]

The defects in erythropoiesis in AID have been enumerated: inappropriately low EPO production, diminished marrow response, and iron-limited erythropoiesis. The appropriate inverse relationship between the EPO concentration and the degree of anemia is lost in AID.[33] IL-1-alpha, IL-1-beta, and tumor necrosis factor all inhibited hypoxia-induced EPO secretion *in vitro,* suggesting an important role for cytokines in the pathogenesis of AID.[34] EPO concentrations in cats with experimentally induced AID were found to be slightly increased but somewhat low for the degree of anemia, which also suggests that EPO production may be a contributor to this process.[27] Tumor necrosis factor has been demonstrated to suppress erythropoiesis in laboratory animals and to prohibit the development of erythroid precursors. In contrast, a heat-stable serum factor that could not be neutralized by antibody to tumor necrosis factor or gamma interferon has been shown to render normal T cells suppressive to autologous colony-forming units–erythroid (CFU-E).[34]

AID is an anticipated complication of all focal or systemic inflammatory processes, contributing to the development of anemia due to the underlying process. Certainly the overall well being of an animal has to be influenced by the development and consequences of anemia. Numerous disease states can result in human AID. Although many of the diseases have not been specifically studied in veterinary medicine, one disease, lymphoma, has been studied in dogs.[35] Dogs with lymphoma had appropriate concentrations of iron, transferrin, and EPO, findings contrary to those associated with AID.[36]

Table • 271-2 Differentiation of Iron Deficiency, Anemia of Inflammation, and Hemolysis

ANALYTE	IRON DEFICIENCY	ANEMIA OF INFLAMMATION	HEMOLYSIS
Red cell indices	Microcytic, hypochromic	Normocytic, normochromic	Normocytic, normochromic
Serum iron	Reduced	Normal to reduced	Increased
Transferrin (TIBC)*	Increased	Normal to reduced	Decreased
Marrow iron stores	Reduced	Normal to increased	Normal to increased
Ferritin	Decreased	Normal to increased	Normal to increased
Platelet count	Increased	Normal	Variable

Modified from Waner T et al: Anemia of inflammatory disease. *In* Feldman BF, Zinkl JG, Jain NC (eds): Schalm's Veterinary Hematology, 5th ed. Baltimore, Lippincott Williams & Wilkins, 2000, p 205.

* *TIBC,* Total iron binding capacity; for clinical purposes, this is the transferrin concentration.

Parameters that differentiate anemia of inflammation from iron deficiency and hemolysis are presented in Table 271-2. Therapy of this mild anemia involves amelioration of the underlying disorder, given the realization that AID contributes to and potentially complicates any anemic process accompanied by inflammation. Administration of iron is of no value. Administration of EPO may increase the red cell mass, but the overall response may be inappropriate or inadequate.[30]

271.5 NONPROLIFERATIVE ANEMIA

271.5.1 Anemia Associated with Marrow Disorders

Bone marrow suppression and/or toxicity is a widely recognized negative side effect of antineoplastic agents. This effect is often predictable, dose related, generally reversible, and observed with a high incidence because these drugs are given at or near maximum tolerated dosages.[37] Most antineoplastic drug groups, including alkylating agents (now rarely used), antimetabolites, antineoplastic antibiotics, and naturally occurring compounds (e.g., vincristine, vinblastine), as well as other drugs, including cisplatin, carboplatin, dacarbazine, procarbazine, and hydroxyurea, have been known to cause bone marrow toxicity,[38] as can radiotherapy.

271.5.1.1 Pure Red Cell Aplasia

Pure red cell aplasia (PRCA) usually is an acquired disorder. The anemia is often severe, resulting in hematocrits in dogs and cats of less than 20%, with absolute reticulocytopenia and virtually absent marrow precursors. Marrow myeloid and megakaryocytic elements appear to be preserved, and the peripheral white cell and platelet counts are appropriate. This condition can be caused by feline leukemia virus (FeLV) or by direct suppression of the stem cells identified as burst-forming units–erythroid (BFU-E), or it may be immune mediated in dogs. In dogs, antibodies may be specifically directed at epitopes on the immature erythroid cells. In dogs and occasionally in cats, spherocytes and stomatocytes may be observed in peripheral blood, and the direct or indirect antiglobulin (Coombs') test result may be positive.[2,39]

271.5.1.2 Aplasia Anemia (Aplastic Pancytopenia)

Aplastic pancytopenia in several species can occur secondary to increased endogenous blood estrogen concentrations. The effects appear to be most severe in ferrets and dogs. Bone marrow panhypoplasia and pancytopenia are often preceded by myeloid hyperplasia and leukocytosis for several weeks. Multiple mechanisms have been incriminated, including reduction of hemopoietic stem cell numbers, inhibition of stem cell differentiation, and decreased response to EPO.[37,40] Another mechanism is iatrogenic overdose of exogenous estrogenic compounds, especially estradiol cyclopentylproprionate, intended to prevent pregnancy or to treat prostatic hyperplasia. All types of testicular neoplasia in male dogs and granulosa cell tumors in female dogs can be associated with hyperestrogenism and pancytopenia. At least 10% of male dogs with testicular neoplasia, predominantly those with Sertoli cell neoplasia, have pancytopenia, and approximately 90% of those do not recover.[3,40]

1913 1914

Azidothymidine (AZT), a dideoxynucleoside derivative reverse transcriptase inhibitor used in the treatment of feline immunodeficiency viremia (FIV) or FeLV, causes transient or progressive anemia after several weeks of therapy; this anemia is thought to be the result of bone marrow suppression and/or Heinz body–induced hemolysis.[41] The immunosuppressive agent cyclophosphamide is known to cause bone marrow suppression in dogs. Azathioprine, a thioguanine-derivative immunosuppressive agent, has been associated with induced anemia and hypocellular bone marrow in dogs, with recovery after drug withdrawal. Possible incorporation of the drug into bone marrow progenitor cells is thought to cause bone marrow failure.[38] Other drugs, including meclofenamic acid, phenylbutazone, quinidine, trimethoprim-sulfadiazine, and

fenbendazole, have been incriminated in bone marrow aplasia in dogs. Chloramphenicol appears to cause mild, reversible, nonregenerative anemia in dogs.[38,40]

Infectious agents other than retroviruses can cause aplastic pancytopenia (see Anemia Associated with Infectious Etiologies, below). Among these are parvovirus, *Ehrlichia* sp. and bacterial endotoxins. Aflatoxin B toxicity has been reported to cause aplastic pancytopenia in the dog (among many other species). Idiopathic aplasia has also been reported in many species, including dogs and cats. Cell-mediated cytotoxicity, marrow stromal defects, overproduction of inhibitory hemopoietic cytokines, deficiency in stem cell factor, and genetic mutation all have been proposed as causes of the human form of this process.

271.5.1.3 Myelophthistic Disease

The term *myelophthisis* denotes a situation in which bone marrow has been replaced by nonmarrow elements. Common invaders of the bone marrow are leukemic or other tumor cells, infectious granulomas, fibrous tissue, and lipid storage cells. Although conceptually it is thought that the anemia resulting from this process is due to simple mechanical replacement of the bone marrow, the pathophysiology probably is more complex. For example, the anemia may result from competition between hemopoietic cells and invading cells for essential nutrients. Some evidence suggests that metastatic tumor lesions may secrete substances (i.e., cytokines) that block or inhibit hemopoietic cytokines, affecting the surrounding cells. In this regard, it is interesting to note that some of the same peripheral blood alterations observed in animals with metastatic bone marrow disease are observed in animals with metastatic neoplasia without bone marrow involvement.

Typical clinical features of myelophthisis include (1) normocytic, normochromic anemia with reticulocytopenia; (2) leukoerythroblastic reaction, in which the white cell count is increased and many immature white cells are present, as are many nucleated red cells; (3) marked anisocytosis and poikilocytosis of red cells, including dacrocytes or teardrop-shaped red cells; and (4) a low-normal or increased platelet count with the presence of immature and sometimes bizarre megathrombocytes. The ultimate diagnosis depends on demonstration of inappropriate invading cells in a bone marrow core biopsy.[39]

271.5.1.4 Myelofibrosis

Myelofibrosis may accompany or precede neoplastic diseases or may occur subsequent to chronically stimulated erythropoiesis in pets with severe hemolytic anemia (e.g., congenital red cell pyruvate kinase deficiency). Aspiration of marrow in these instances is difficult or impossible, and the diagnosis is based on bone marrow biopsy evaluation.[39,42–45] Idiopathic myelofibrosis (IM) (i.e., agnogenic myeloid metaplasia with myelofibrosis) is a clonal hemopoietic stem cell disorder that predominantly affects the megakaryocyte lineage in the bone marrow. It is characterized by splenomegaly, extramedullary hemopoiesis, and bone marrow fibrosis. The fibrosis is caused by deposition of abnormal collagen by polyclonal fibroblasts, which in turn are stimulated by growth factors (e.g., transforming growth factor beta) secreted by adjacent megakaryocytes. IM often is difficult to recognize as a distinct clinical entity, because many conditions can cause marrow fibrosis, and myeloproliferative disorders can terminate in a fibrotic phase. The term *myeloid metaplasia* often refers to an earlier phase of IM in which fibrosis is less prominent and extramedullary hemopoiesis in the spleen and liver is evident.[46] Various histiocytic neoplastic processes must also be considered. Many of these processes may be best distinguished by immunophenotyping.

Most patients with IM have significant anemia, and some have thrombocytosis. Signs associated with anemia are most common. The extramedullary hemopoiesis in the liver and spleen often causes notable organomegaly. Peripheral blood left shifts in the erythroid, myeloid, and megakaryocytic (megathrombocyte) lines (i.e., leukoerythroblastosis) are typical features of the complete hemogram. Bone marrow aspiration often is difficult, and biopsy demonstrates extensive fibrosis and osteosclerosis.[45,46] No effective therapy exists for this process except bone marrow transplantation.[46]

271.5.1.5 Myelodysplasia

Myelodysplasia (myelodysplastic syndromes [MDSs]) is a heterogeneous group of hemopoietic stem cell disorders characterized by cytologic dysplasia in the blood and bone marrow and by various combinations of anemia, neutropenia, and thrombocytopenia. MDS may be associated with refractory anemia (RA) or with refractory anemia with an excess number of blast cells (RAEB) either in the peripheral blood or, primarily, in the bone marrow. A variety of terms besides myelodysplasia, including *preleukemia, smoldering* or *subacute leukemia, dysmyelopoietic syndrome,* and *dyserythropoiesis* have been used to describe MDS. These disorders are best considered a form of chronic or smoldering leukemia; they have a monoclonal population of hemopoietic cells, usually involving multiple lineages, and generally are accompanied by suppression of appropriate bone marrow hemopoiesis. Unfortunately, diagnostic capabilities and nomenclature are not yet adequate to discriminate consistently among clinically distinct subsets. Increased use of cytogenetic analysis and the development of clonality techniques may be useful for diagnosis and for providing insight into disease pathogenesis, patterns of responsiveness to growth factors, and the possibility of differentiation-inducing agents.[47]

In dogs, the conditions may be primary, resulting from genetic transformation in a multipotential stem cell, or secondary and associated with administration of a drug. The primary conditions are unlikely to respond satisfactorily to hemopoietic cytokines acting as maturation factors.[2,48]

271.5.1.6 Hemopoietic Neoplasia

Neoplasia of hemopoietic tissue is characterized by replacement of normal tissue with an abnormal clonal proliferation of cells. Often, but not always, a concomitant increase in neoplastic cells in peripheral blood is seen. The neoplastic cells also commonly infiltrate other hemopoietic and lymphoid tissues, such as the liver, spleen, and lymph nodes.[2] Recent advances in the application of newer techniques have improved the accuracy of classification. These advances include immunophenotyping for clusters of differentiation (CD) antigens and cytogenetics. Immunophenotyping uses specific monoclonal antibodies to differentiate antigens. Flow cytometry has provided a powerful tool for analysis of immunophenotyped cells and is becoming an essential component in the study of leukemias. It complements morphologic studies and cytochemical staining.[48] A fundamental feature of leukemic cells is their monoclonality, which implies derivation from a single stem cell that has become neoplastic. Clonal marker systems are used to investigate not only the presence of clonality, but also the stage of hemopoietic cell development at which the neoplastic cells originate.[2,49–52]

1914 1915

It is important to understand the multistep progression from normal cells to neoplastic cells.[52] Now that the molecular mechanisms that regulate normal cell growth are becoming clear, it has also become clear that failure of one or more of these fundamental steps leads to malignant transformation. Cell proliferation and

differentiation are regulated by proteins encoded by proto-oncogenes (growth promoting) and tumor suppressor genes (growth suppressing). It is now recognized that oncogenesis involves specific molecular events that result in genetic alterations in these two gene classes, with subsequent dysregulation of cell growth. A number of mechanisms can cause genetic abnormalities. Although the exact origin of these abnormalities is unknown, several environmental inciting factors have been recognized, including irradiation, chemical agents, and retroviral infection.[52]

In dogs and cats, acute and chronic myeloproliferative disorders (MPDs) are less frequently reported than lymphoproliferative disorders (LPDs). No breed or sex predilection has been identified for animals with nonlymphoid leukemia. The origin of MPDs in dogs is unknown, although environmental, viral, and genetic causes have been postulated. In contrast, MPDs in cats have been associated with FeLV and FIV infection.[53]

The diagnostic approach should be systematic and should be completed before initiation of any chemotherapy. The history may provide clues to help differentiate between acute and chronic hemopoietic neoplasia. General clinical signs of hemopoietic neoplasia include nonspecific bone pain, fever, lethargy, inappetence, vomiting, and diarrhea. The physical examination often reveals organomegaly involving the liver, spleen, or lymph nodes, and lung and central nervous system involvement can occur. Specific signs of hemopoietic neoplasia are often associated with involvement of particular cells, such as hypoxia with red cell involvement, sepsis with neutrophil involvement, and petechial, purpuric, and ecchymotic bleeding with platelet involvement.[54]

Chemotherapy in veterinary medicine can offer prolongation of life and improvement in the quality of life, but it is often palliative and rarely curative. Many myelosuppressive agents may cause profound cytopenias, with neutropenia and thrombocytopenia being common. Supportive care includes nursing care for comfort, administration of fluids and electrolytes to maintain adequate hydration and electrolyte balance, broad-spectrum antimicrobial therapy, and administration of blood products to meet specific needs. Nutritional care is essential and should be definitively addressed.[53,54]

271.5.2 Anemia Associated with Infectious Etiologies

Infectious agents, their products, or the response to the agent may cause anemia by damaging red cells and causing hemolysis; by causing developmental erythroid hypoplasia through direct damage to the erythroid precursors or the marrow microenvironment; or by damaging hemopoietic or supportive bone marrow stromal cells. Most bacterial or viral infections are indirect causes of mild anemia; AID is often the anemic etiology.[55]

FeLV may cause anemia by direct or indirect methods. By predisposing cats to other opportunistic diseases, FeLV infection may induce AID. Pure red cell aplasia or aplastic pancytopenia can be produced with experimental FeLV infection. The anemia of FeLV can be hemolytic through infectious organisms such as *Mycoplasma hemofelis,* other forms of immune-mediated hemolytic anemia, MPDs, or myelofibrosis. In FeLV-positive cats that have macrocytic, normochromic anemia, megaloblastoid rubricytes are seen, perhaps as a result of myelodysplasia related to folate or vitamin B_{12} deficiency.[55,56] FeLV frequently produces severe selective suppression of erythropoiesis (nonregenerative anemia) and thrombocytopoiesis but may cause aplastic pancytopenia.[57–59]

Cats infected with FIV may develop chronic debilitating disorders ranging from opportunistic infections to neoplasia. Approximately 18% to 36% of FIV-positive cats have anemia and may also have neutropenia,

lymphopenia or lymphocytosis, monocytosis, and thrombocytopenia. The exact pathogenesis of the FIV anemia is not known. In contrast to FeLV, FIV infects megakaryocytes and bone marrow accessory cells but not erythroid and myeloid precursors.[57]

Infectious etiologies for aplastic pancytopenia, other than FeLV and FIV, have been associated with parvoviral infection, ehrlichiosis, babesiosis, *M. hemofelis* infection, and endotoxemia. Parvoviral infection in both dogs and cats causes acute aplastic pancytopenia as a result of viral proliferation in progenitor and proliferative cells in the bone marrow, although marrow injury secondary to endotoxemia or septicemia cannot be ruled out. The bone marrow is characterized by severe degenerative changes in the developing hemopoietic cells, necrosis, and an increased number of phagocytic macrophages. Hematologic recovery usually is rapid if the pet survives the acute stages of the disease.[60] Ehrlichiosis (caused by *Ehrlichia canis, Ehrlichia ewingii,* or *Ehrlichia equi*) may cause a hypercellular bone marrow initially, but in the chronic phase, the bone marrow is characterized by pancytopenia and hypoplasia, except with plasmacytosis. Occasionally *Babesia* spp. can cause nonregenerative anemia. *M. hemofelis* infection is also sometimes associated with nonregenerative anemia, which attests to the possibility that some of these cats may be immunosuppressed or debilitiated.[60]

Cytopenias occur in the blood of dogs and cats with acute and chronic ehrlichiosis. In the acute form, the bone marrow is hypercellular, which suggests that the peripheral cytopenias are the result of cell destruction. In the chronic form, the marrow is acellular and is consistent with a diagnosis of aplastic pancytopenia.[61]

Diagnosis of aplasia includes a complete history, with questions pertaining to drug exposure, chemicals, and infectious agents; a complete hemogram with blood smear evaluation, bone marrow aspiration, and consideration of bone marrow core biopsy. The core biopsy may be most helpful for assessing cellularity and architecture. Particular attention should be paid to potential drug or chemical exposure 2 to 3 weeks prior to examination. Anemia is initially mild but becomes progressive over time. Leukopenia (neutropenia) and thrombocytopenia may accompany the anemia, with clinical signs of fever and sepsis (neutropenia) and hemorrhage in the form of petechiae, purpura, and ecchymoses (thrombocytopenia). Some residual production may be seen with the neutropenia and thrombocytopenia, and this appears to be sufficient to permit development of anemia over weeks or months.[3,60]

Treatment with prophylactic antimicrobial drugs is the only therapy that addresses the severe neutropenia with sepsis, which is most often evident when the neutrophil cell count is below 500/mL. It is difficult to address thrombocytopenia clinically without sufficient units of platelet-rich plasma. Developing anemia is treated with packed red cells, preferably, or with whole blood if packed red cells are not available. Immunosuppressive therapy and anabolic steroids are probably not indicated or useful. The use of recombinant hemopoietic growth factor and bone marrow transplantation should be considered.[62]

1915 1916

271.6 INEFFECTIVE ERYTHROPOIESIS

271.6.1 Macrocytosis and Macrocytic, Normochromic Anemia

An MCV above the reference interval is considered macrocytosis. Macrocytosis can be present without anemia. Examination of peripheral blood reveals prominent macrocytes and poikilocytes. Hypersegemented neutrophils with more than five lobes are often observed, and modest decreases in both the leukocyte and platelet counts may be seen. Sometimes the morphologic changes in peripheral blood are sufficiently characteristic to make marrow examination unnecessary in the initial diagnostic workup.

With the erythroid-regenerative response in the dog and cat (i.e., sufficient reticulocytosis), the size and number of reticulocytes are usually proportional to the degree of erythropoietic stimulation. Macroreticulocytes are produced under conditions of intense erythropoietic stimulation and become macrocytic red cells as the cells mature.

Greyhounds have higher reference values for the hematocrit, hemoglobin concentration, red cell concentration, and MCV. Greyhound red cells have a shorter life span (53.6 ± 6.5 days) compared with other dog breeds (104.3 ± 2.2 days), which could account for the macrocytosis.[63,64] Macrocytosis is a familial condition in some poodles, especially the small and toy breeds. The MCV is markedly increased over reference values, and there is notable nuclear-cytoplasmic asynchrony. Megaloblastic changes and nuclear fragmentation are noted among red cell precursors, and some of the nuclear fragments are retained in the adult cells. Hypersegmentation is seen in adult neutrophils. Although these morphologic changes are also described in vitamin B_{12} deficiency, the exact nature of the defect is unknown, but it is not related to nutritional deficiency. These dogs are not anemic or, if so, the anemia is almost undetectable.[65]

271.6.1.1 Vitamin B_{12} and Folic Acid Deficiencies

Vitamin B_{12} deficiency is associated with macrocytic anemia in humans, but there does not appear to be a counterpart in nonhuman primates, dogs, or cats. The megaloblastic changes noted in feline erythroid cells have also been described in feline folic acid–depleted bone marrow, but the morphologic changes are not dramatic. Dogs and cats treated with phenobarbital or primidone occasionally develop megaloblastic changes in the bone marrow, but the changes are not accompanied by peripheral blood macrocytosis.[63] Vitamin B_{12} and folic acid deficiencies are most often related to gastric malabsorption. Gastric mucosa produces an “intrinsic factor” necessary for absorption of vitamin B_{12} in the terminal ileum. Lack of intrinsic factor in small animals may be associated with partial or total gastrectomy. Bacterial colonization of the small intestine by vitamin B_{12}–consuming micro-organisms may, theoretically, lead to vitamin B_{12} deficiency. Drugs such as colchicine and neomycin may also lead to minor malabsorption syndromes.[63]

Folic acid deficiency has been associated with gluten-sensitive enteropathy due to malabsorption and with increased requirements during pregnancy. It also is seen in neonates and in myelofibrosis and chronic inflammatory diseases. These do not appear to be clinically significant findings in small animals.[63]

Clinical assessment requires a simple dietary history and inquiries about gastrointestinal disease or surgery, any prior hematologic disease, and the animal's drug history. Laboratory assessment involves determination of the serum vitamin B_{12} and folic acid concentrations. Radioimmunoassay (RIA) yields the fewest false-positive or false-negative effects. An increased concentration of vitamin B_{12} with RIA may be seen with marked leukocytosis and active but nonspecific hepatic disease. Examination of the gastrointestinal tract by ultrasonography and with endoscopic biopsy is recommended.[63,64]

271.6.1.2 Anemia Associated with Feline Leukemia Virus Infection

Most cats that have anemia and FeLV infection have macrocytosis and resultant anisocytosis. Some FeLV-positive cats have an appropriate MCV but increased anisocytosis, perhaps reflecting a minor subpopulation of macrocytic red cells. The macrocytosis does not correlate with reticulocytosis or other

evidence of red cell regenerative response. Macrocytosis is most prominent in cats that have anemia, including both regenerative and nonregenerative anemia. However, more than 50% of nonanemic cats infected with FeLV have some macrocytosis. It has been suggested that macrocytosis could reflect a period of intense erythropoiesis before conversion to hypoproliferative anemia, but the cause is as yet unknown. In a study of cats with experimental FeLV–induced anemia, the macrocytic changes were not as significant as noted in the naturally occurring disease, and no period of reticulocytosis was detected over the course of the disease.[63] Macrocytosis has been reported in erythroid aplasia in cats and in myelodysplasia in dogs. No response to vitamin B_{12} therapy was detected.[63–67]

271.6.1.3 Normochromic, Normocytic Anemia

Normochromic, normocytic anemia is defined as a low red cell count, hematocrit, or hemoglobin concentration with appropriate MCV, MCHC, and MCH values. Almost all nonregenerative anemia is presented as normocytic and normochromic. AID has already been discussed and is associated with underlying inflammation, infection, immune-mediated processes, or neoplasia. Most often these animals have clinical signs associated with the underlying process rather than the mild anemia. General signs include weight loss, icterus, and lymphadenopathy. Abdominal signs include diarrhea or constipation, nausea and vomiting, or pain. Other signs are often associated with specific organ systems, such as cardiac murmurs or dyspnea, cough, polyuria, dysuria, bone or joint pain, or the drug history. Management requires correction of the underlying cause and the use of specific blood products as needed. Treatment with iron is contraindicated.

271.6.1.4 Hypochromic, Microcytic Anemia

A low red cell count, low hemoglobin concentration, and low hematocrit with low MCV, MCHC, and MCH values are associated with hypochromic and microcytic red cells on examination of the peripheral blood smear. It is important to know that some canine breeds are normally microcytic (Akita and Shiba). When hemoglobin concentrations reach a certain level in developing erythroid cells, cell division appears to stop. Because chronic iron deficiency is the most common cause of hypochromia and microcytosis, and as cell division is unimpeded, extra red cell division occurs until the intraerythroid hemoglobin concentration is at a level to signal cessation of division. Potential causes of this type of anemia include AID, portosystemic shunts in dogs and cats, pyridoxine deficiency, copper deficiency, hereditary elliptocytosis in dogs, dyserythropoiesis, and drug or chemical toxicities. Iron deficiency has already been discussed (see above).[68,69]

1916

Congenital portosystemic shunts are most often caused by a single blood vessel that fails to regress *in utero* and that diverts portal blood around the liver. Acquired shunts are often multiple and are associated with chronic hepatobiliary disease.[69,70] The cause of the microcytosis is not fully understood, but the condition is associated with abnormal iron metabolism, at least in dogs. Clinically the most common signs are encephalopathy in patients who are thin and have poor haircoats. Young dogs with congenital shunts are often small for their age. The liver is difficult to palpate as a result of microhepatica. Approximately two thirds of dogs with shunts have mild microcytosis with MCV and red cell masses at the low end or slightly below the reference interval. The MCHC is also slightly low, and the red cell distribution width (RDW) is slightly increased in most cases. About one third of cats with shunts have decreased MCV.[69–72] Target cells (codocytes), keratocytes, and elliptocytes are the poikilocytes most frequently seen. The abnormalities in the clinical biochemistry profiles of dogs include decreases in urea nitrogen, creatinine, glucose, albumin, total protein, and cholesterol. Increases are observed in serum alkaline phosphatase, bile acids, serum

1917

alanine aminotransferase (ALT), and bilirubin.[71,72] Fasting ammonia concentrations are elevated. The urinalysis may reveal ammonium urate crystals. Similar abnormalities are seen in cats with shunts, but hypocholesterolemia and hyperbilirubinemia are not reported. Storage iron, measured indirectly by species-specific serum ferritin assay, is appropriate or increased. The serum iron and transferrin concentrations are modestly decreased, because the physiology is similar to that of AID (see Table 271-2).[69]

Other potential causes of microcytic anemia include pyridoxine (vitamin B_6) and copper deficiency, drug and chemical toxicity, dyserythropoiesis, and hereditary elliptocytosis. Pyridoxine deficiency has been produced only experimentally in dogs and cats. These animals have microcytosis, increased serum iron, and siderotic (iron) inclusions in adult red cells. Prolonged copper deficiency in dogs and cats may cause microcytosis due to functional iron deficiency, in turn caused by inability to access storage iron as the copper transport enzyme ceruloplasmin is decreased. This protein has ferroxidase activity that is important for changing ferrous storage iron (Fe^{2+}) to ferric iron (Fe^{3+}), a change necessary for iron binding to transferrin (the iron transporting protein). Chloramphenicol is one of numerous drugs or chemicals that block heme synthesis, resulting in microcytosis and red cell siderotic inclusions.[69] Dyserythropoiesis in English springer spaniels causes nonregenerative microcytic anemia with increased circulating nucleated red cells. These dogs also have cardiac disease and polymyopathy.[73,74] Hereditary elliptocytosis has been described in a mixed-breed dog that had a red cell membrane deficiency (lack of membrane band 4.1).[75]

271.7 SUMMATION OF NONREGENERATIVE ANEMIA

Anemia is a common clinical presentation of an underlying disease. Nonregenerative anemias are the most common anemias observed by veterinary clinicians (Box 271-4). Lack of iron, anemia of inflammation, bone marrow disorders, anemias related to erythropoietin, maturation abnormalities, and the early stages of hemolysis and hemorrhage—the main anemia causation groups—present as nonregenerative anemias; that is, a relative or absolute reticulocytopenia. Examination of a minimum database (i.e., complete hemogram, urinalysis, and biochemical profile) often reveals sufficient information to diagnose the underlying disorder. Examination of the complete hemogram includes comments on platelet, red cell, and white cell morphology. Specific factors to be considered include the total protein concentration, the red cell indices, and the adjusted reticulocyte count. Once an etiology has been suggested, ancillary specific tests often bring understanding to these interesting but elusive disorders.

271.7.1 Box • 271-4 Approach to Diagnosis of Nonregenerative Anemia

271.7.1.1 Nonregenerative anemia without other cytopenias

Examine bone marrow

- Severe erythroid hypoplasia—consider pure red cell aplasia
- Normal or mild erythroid hypoplasia—consider:
  - Inflammatory disease

Renal disease

Neoplasia

Hepatic disease

Hypothyroidism

Hypoadrenocorticism

Hypercellular marrow

Less than 30% blast forms—consider myelodysplastic syndrome

Greater than 30% blast forms—consider hemopoietic neoplasia

271.7.1.2 Nonregenerative anemia with leukopenia and/or thrombocytopenia

Examine bone marrow

Panhypoplasia—aplastic pancytopenia (aplastic anemia)

Pathology determined by core biopsy

Myelonecrosis

Myelofibrosis

Hypercellular bone marrow

Less than 30% blast forms—consider myelodysplastic syndrome

Greater than 30% blast forms—consider hematopoietic neoplasia

272 CHAPTER • 272 Platelet Disorders and von Willebrand Disease

Marjory B. Brooks

James L. Catalfamo

272.1 PRIMARY HEMOSTASIS

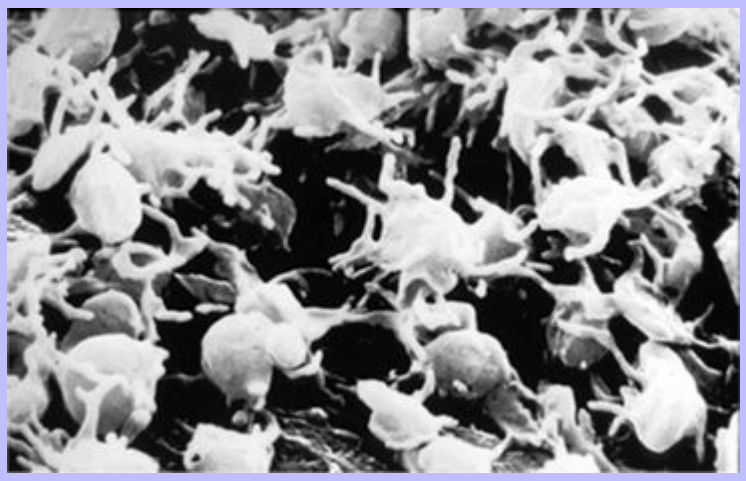
Platelets play a critical role in the initiation, regulation, and localization of hemostasis. The term *primary hemostasis* refers to the interactions among platelets, von Willebrand factor (vWF), and the vessel wall that culminate in the formation of a platelet plug (Figure 272-1). These reactions begin with platelet contact with the damaged vessel and vWF-mediated adhesion; proceed through platelet activation, degranulation, and aggregation; and conclude with the development of platelet-dependent procoagulant activity and clot retraction.

272.1.1 Platelet Physiology

Megakaryocytic precursor cells in the bone marrow are programmed, through the action of transcription factors and thrombopoietin, to form platelet-specific organelles and to express platelet cell surface proteins. In the final stages of megakaryocyte maturation, a network of demarcation membranes generates long processes that fragment into large numbers of anucleate platelets. Platelets are released from the marrow and circulate in the vascular compartment as quiescent, nonadhesive, smooth disks. Approximately 100 billion platelets are released each day to maintain a peripheral platelet count of 200 million to 500 million cells per milliliter of blood.

Injury to the vessel wall triggers platelet activation within nanoseconds. In the initial step of activation, platelets rapidly transform into adhesive, spiny spheres capable of recognizing and binding to exposed matrix components of the subendothelium. Surface binding initiates cell signaling pathways, which then mediate granule secretion. Granule contents include adenine nucleotides, calcium, serotonin, and adhesive proteins, such as fibrinogen, vWF, fibronectin, and P-selectin. Secreted compounds accumulate locally, interact with their respective surface receptors, and recruit additional platelets to the site of injury. Large-order platelet aggregates then accumulate and bridge the zone of vascular damage to form a hemostatic plug. Thrombin cleavage of fibrinogen strengthens the platelet plug as a fibrin-platelet meshwork develops.[1]

Figure 272-1 Scanning electron micrograph of platelet thrombus. Activated platelets have undergone shape change, are adherent to the underlying matrix, and have formed intraplatelet bonds in the process of aggregation. (Courtesy Bristol-Myers Squibb, New York, NY.)



Late-stage platelet activation includes exposure of platelet membrane phosphatidylserine (PS) and the release of PS-rich microparticles, which act as scaffolding for the assembly of coagulation factor complexes. The expression of platelet procoagulant activity greatly amplifies local thrombin and fibrin generation. Contraction of platelet cytoskeletal proteins linked to platelet integrin receptors for fibrin and fibrinogen results in consolidation and subsequent retraction of the growing clot.

Platelet activation requires simultaneous engagement of the platelet membrane surface receptors (Figure 272-2). Species differences in response to platelet stimuli may reflect differences in receptor subclasses for specific ligands. The endoperoxides prostacyclin (prostaglandin I_2 [PGI_2]), prostaglandin E_2 (PGE_2), and prostaglandin D_2 (PGD_2), which are synthesized by endothelial cells and released into the vascular space, serve as antagonist ligands that react with their respective platelet receptors to dampen platelet reactivity.[2]

Platelet integrins and nonintegrin glycoprotein receptors play a critical role in adhesion (platelet–subendothelial matrix interactions) and aggregation (platelet-platelet association). The αIIbβ3 complex ($GPII_bIII_a$) is the most abundant platelet integrin and functions as the activation-dependent receptor for fibrinogen, fibronectin, and vWF. Binding of fibrinogen to this receptor is essential for aggregation and clot retraction. Platelet adhesion to collagen and collagen-induced signaling are supported by collagen's interaction with the integrin receptor α2β1 (GPI_aII_a).

Surface receptors, coupled to G proteins, span the platelet membrane and transmit signals induced by agonist binding. In platelets, Gq serves as this link for most agonists. Gq is coupled to phospholipase C, which in turn generates diacylglycerol (DAG) and inositol triphosphate, leading to calcium release from the endoplasmic reticulum; protein kinase C and myosin light chain kinase activation; and phosphorylation of platelet signaling

proteins. During activation, phospholipase A_2 releases arachidonic acid from membrane phospholipids. Cyclo-oxygenase and thromboxane synthetase convert arachidonic acid to the potent agonist thromboxane A_2 (see Figure 272-2).

272.1.2 Platelet–von Willebrand Factor Interaction

Subendothelial collagen fibrils and bound vWF are exposed when the vascular endothelium is injured. The affinity and strength of the vWF-collagen bond is proportional to vWF multimer size. Collagen-bound vWF displays a conformational change that allows it to interact with the platelet GPIb/V/IX complex. As platelet GPIb contacts and engages with vWF, platelets slowly roll and become activated by interaction with collagen fibrils. vWF then binds to $GPII_b/III_a$ receptors exposed on the surface of activated platelets. Adhesion and aggregation at high shear rates depend on this vWF binding to activate platelet $GPII_b/III_a$.

272.2 DIAGNOSIS OF PLATELET DISORDERS

272.2.1 Clinical Signs of Primary Hemostatic Defects

Primary hemostatic defects typically cause signs of petechiae (pinpoint hemorrhage), ecchymoses (bruising), and mucosal hemorrhage, such as epistaxis, hematuria, gingival and intestinal hemorrhage, and prolonged bleeding after injury. These signs are suggestive of capillary and small vessel hemorrhage, but none are pathognomonic for a specific disease. For example, ecchymoses (Figure 272-3) are often seen in association with thrombocytopenia but also may be signs of inflammatory vasculitis.

272.2.2 Screening Tests

The initial assessment of any patient with signs of bleeding should aim to distinguish between hemorrhage from injured or diseased blood vessels and hemostatic failure. If the source or cause of hemorrhage cannot be readily identified, platelet count and coagulation screening tests should be performed early in the diagnostic workup. These tests can help both to detect a hemostatic defect and to guide the selection of appropriate ancillary diagnostic tests (Figure 272-4).

The platelet count (per μL) can be estimated by counting the number of platelets in 10 oil immersion fields and multiplying the average number per field by 15,000 to 20,000 (Figure 272-5).[3] Either the activated clotting time (ACT) or point-of-care coagulation assays can be performed in-house to rule out clinically severe coagulation factor deficiencies.

272.2.2.1 Testing for Quantitative Platelet Defects

Quantitative platelet defects are common hematologic abnormalities.[4–6] Normal platelet numbers for dogs and cats range from approximately 200,000/μL to 500,000/μL. Each testing laboratory should provide species-specific reference ranges for their method (Table 272-1). High or low platelet counts are found in many patients having systemic inflammatory and neoplastic diseases. Specific diagnostic tests (Table 272-2) are indicated for patients with moderate to severe thrombocytopenia or thrombocytosis, with associated clinical signs.

Figure 272-3 Petechiae and ecchymoses in the inguinal region of a mixed-breed dog with thrombocytopenia (platelet count, 5000/μL).

272.2.2.1.1

Thrombocytopenia

Platelets are highly reactive; spurious low platelet counts are common laboratory artifacts and should be confirmed by examination of a blood smear to rule out platelet clumping.[7] Collection artifacts are minimized by the use of citrate anticoagulant, atraumatic venipuncture with collection directly into anticoagulant, assay within hours of blood draw, and avoidance of cold temperature. Thrombocytopenia rarely causes signs of abnormal hemostasis unless the platelet count falls below 50,000/μL, with petechiation and spontaneous hemorrhage most likely at counts below 20,000/μL. Clinical signs may appear at higher platelet counts, however, if the patient has a concurrent disease that further impairs hemostasis.

Three general mechanisms cause thrombocytopenia: impaired platelet production, increased peripheral consumption or sequestration, and immune-mediated destruction. In many disease syndromes, more than one mechanism is involved.[8]

Production defects are likely in patients with thrombocytopenia combined with leukopenia and/or anemia.[9] Immature platelets have a relatively high mean platelet volume (MPV) and ribonucleic acid (RNA) content, detected as “reticulated” platelets by thiazole orange staining. The presence of reticulated platelets indicates ongoing platelet production, but their absence does not confirm megakaryocyte hypoplasia. Bone marrow examination, therefore, is the most accurate and direct means of evaluating megakaryopoiesis. Normal to high megakaryocyte numbers are typical of peripheral platelet consumption or destruction. Megakaryocyte hypoplasia confirms a platelet production defect and may reveal an infectious agent or abnormal cellular or stromal proliferation. In most cases, the combination of bone marrow examination, drug and travel history, and serology or polymerase chain reaction (PCR) testing to detect infectious agents leads to definitive diagnosis of production defects.

Splenic enlargement, for any reason, causes increased platelet sequestration and may result in thrombocytopenia with a shortened platelet life span.[10] Increased peripheral platelet consumption accompanies systemic vasculitic disorders and disseminated intravascular coagulation (DIC). The primary means of diagnosing sequestration disorders include splenic and lymph node aspiration cytology, serology and biopsy to detect infectious agents and inflammatory disorders, and coagulation tests to define a DIC process.

Immune-mediated platelet destruction is common. *Primary immune-mediated thrombocytopenia* (*IMT*) implies an autoimmune disorder with production of antibodies directed against normal platelet antigens.[11] *Secondary IMT* occurs in association with infection, drug therapy, neoplasia, or polyimmune syndromes or as a complication of platelet transfusion.[12] In these patients, platelet-bound antibody may represent immune complexes, antibodies directed against neoantigens or foreign platelet antigens, or nonspecific binding.[13] The presence of antibodies on the surface of platelets (platelet-bound antibody) or antibodies in patient sera capable of binding normal platelets (platelet-bindable antibodies) can be detected with flow cytometry or enzyme-linked immunosorbent assay (ELISA). Flow cytometric assays configured to detect platelet-bound canine IgG have been developed for clinical use.[14,15] The tests are generally sensitive, but they are nonspecific. Detection of platelet-bound IgG does not differentiate patients with primary IMT from those with secondary IMT, and nonspecific antibody binding may complicate interpretation of test results. Microthrombocytosis (MPV less than 5.5 fL) has been described as a feature of primary and secondary IMT and is seen early in the disease course.[1] In a case review,

severe thrombocytopenia (less than 20,000/μL) and microthrombocytosis were found almost exclusively in dogs with IMT; however only half of the IMT patients had these abnormalities.[16] Accurate MPV determination is affected by the anticoagulant used; platelets stored in ethylenediamine tetra-acetic acid (EDTA) rather than citrate may have artifactual increases in MPV.

Figure 272-4 Diagnostic algorithm for primary hemostatic defects. *BMBT*, Buccal mucosa bleeding time; *PFA*, platelet function analyzer; *vWF:Ag*, von Willebrand factor antigen.

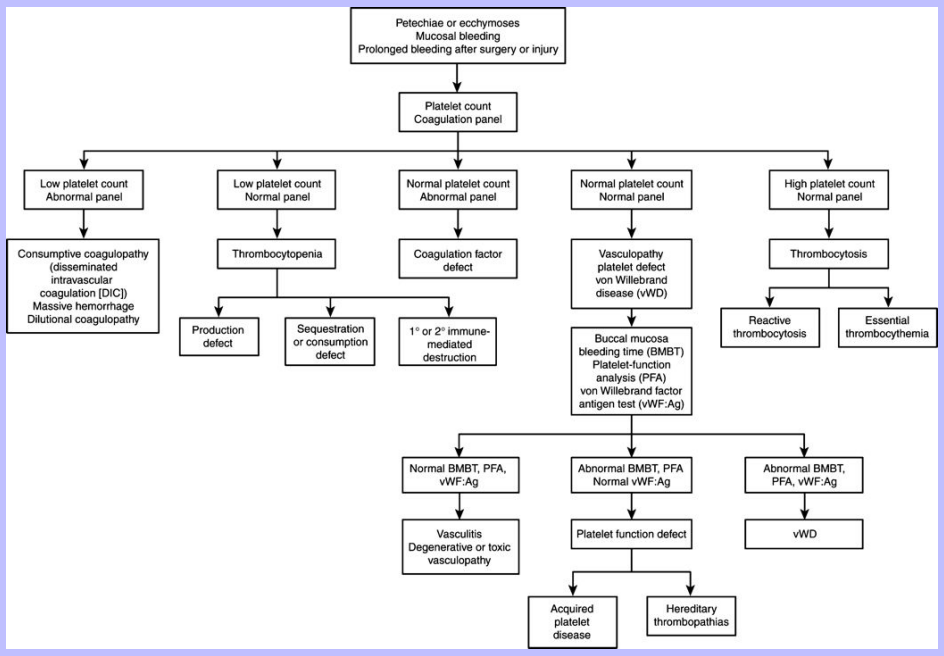

Figure 272-5 Wright-stained blood smear from a healthy cat emonstrating normal feline platelet morphology (.400). Courtesy Dr. Tracy Stokol, Cornell University, Ithaca, New York.)

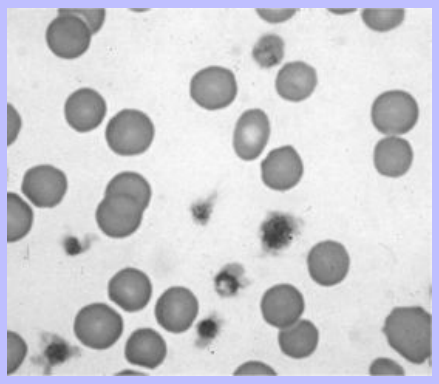

272.2.2.1.2 Thrombocytosis

Mild to moderate increases in the platelet count ("reactive" thrombocytosis, are seen in association with chronic blood loss, neoplasia, systemic inflammatory disease, and hypercortisolism.[17] High platelet counts may occur after splenectomy. A persistent and markedly high platelet count (greater than 900,000/μL) is suggestive of primary bone marrow disease (e.g., myelodysplasia, essential thrombocythemia) and is an indication for bone marrow examination. The clinical features of essential thrombocythemia in human beings and dogs include splenomegaly and hemorrhage caused by platelet dysfunction.[18]

Table • 272-1 Reference Values* for Canine and Feline Platelet Count and Mean Platelet Volume

VALUE	DOG	CAT
Platelet count ($\times 10^3$/uL)	179 to 483	201 to 523
Mean platelet volume (fL)	8.4 to 13.2	10.8 to 19.8

Values current 2003, Clinical Pathology, Cornell University, Ithaca, New York.

* Advia Hematology Analyzer (Bayer, Tarrytown, New York).

Table • 272-2 Diagnostic Tests for Quantitative Platelet Defects

TESTS	SPECIFIC ASSESSMENTS
CBC	Review to detect: Infectious agents, neoplastic cells, spherocytes, schistocytes Assess: Platelet count and morphology, MPV, percentage of reticulated platelets
Bone marrow examination	Review to detect: Megakaryocyte number and morphology, infectious agents, lymphoproliferative or myeloproliferative neoplasia, myelofibrosis, myelodysplasia Special stains or labels: Immunophenotyping, histochemistry, iron stains, antimegakaryocyte antibody
Spleen/lymph node examination	Review to detect: Infectious agents, neoplastic cells
Serology	Review to detect: Infectious agents, antinuclear antibody
Polymerase chain reaction	Review to detect: Infectious agents
Platelet-bound antibody	Configured to detect: Antibody specificity (i.e., IgG, IgM, IgA) or epitope specificity (i.e., anti-$GPII_bIII_a$ antibody)
Coagulation tests	Review: Coagulation panel (aPTT, PT, TCT), fibrinogen, antithrombin activity, FDP or D-dimer concentration

CBC, Complete blood count: *MPV*, mean platelet volume; *aPTT*, activated partial thromboplastin time; *PT*, prothrombin time; *TCT*, thrombin clotting time; *FDP*, fibrin and fibrinogen degradation products.

272.2.3 Platelet Function Tests

The buccal mucosa bleeding time (BMBT) is an *in vivo* screening test of primary hemostasis (Figure 272-6). If thrombocytopenia has been ruled out, a long BMBT is compatible with either platelet dysfunction or vWF deficiency.[19] Platelet dysfunction is definitively diagnosed using more comprehensive tests of platelet structure and activation response (Table 272-3).

To ensure platelet viability, functional assays are best performed within 2 to 3 hours of sample collection. The PFA 100 (Dade Behring, Newark, DE) is a new analyzer that can be used to measure platelet adhesion and aggregation with small volumes of whole blood (less than 2 mL) under conditions that simulate blood flow.[20,21] More specific assessment of platelet function is performed by monitoring agonist-induced responses of shape change, aggregation, and release of dense granule contents (Figure 272-7).[22]

Flow cytometry is used to assess platelet function by means of detection of membrane glycoproteins (required for adhesion and aggregation) and activation markers, such as P-selectin, fibrinogen, and surface PS.[23] These markers are evidence of effective alpha granule release and procoagulant activity (Figure 272-8). Detailed evaluations of platelet function, physiology, and ultrastructure are usually reserved for characterization of hereditary thrombopathias.

1922

1923

Figure 272-6 Buccal mucosal bleeding time. **A,** Template device (Simplate II; Organon Teknika, Durham, North Carolina) with spring-loaded blades that make incisions of uniform depth and length when the device is triggered. **B,** Incised buccal bleeding time wounds in a Shetland sheepdog affected with type 3 vWD. After incision, shed blood is collected by gently blotting below the wounds with gauze or filter paper. The time from incision to cessation of blood flow is the buccal bleeding time.

B

272.3 SPECIFIC PLATELET DISORDERS

272.3.1 Thrombocytopenia

Thrombocytopenia is the most common acquired hemostatic defect of dogs and cats.[10] Many different pathogens cause thrombocytopenia (Table 272-4), often through combined marrow suppression and an increased rate of peripheral loss. Arthropod-borne agents are increasingly identified as the cause of cytopenias in dogs and cats.[8,24] Infectious agents usually cause systemic signs, producing physical examination findings and complete blood count (CBC) abnormalities beyond those of thrombocytopenia alone. Although dogs and cats with infectious thrombocytopenias may initially respond to steroid administration, sustained platelet response and disease resolution require specific treatment. It therefore is important to rule out infectious thrombocytopenia (through serology, cytology, or PCR) before an immunosuppressive steroid regimen is begun.

Mild to moderate thrombocytopenia is seen in association with many tumor types, with more severe depression likely in hematopoietic neoplasia such as multiple myeloma, lymphoma, and leukemia.[5] DIC is a common cause of thrombocytopenia in hemangiosarcoma, and tests to define a DIC process (see Table 272-2) should be performed in any cancer patient with a falling or low platelet count. In addition to tumor-mediated thrombocytopenia, cancer patients are at risk of developing thrombocytopenia arising from cytotoxic drug therapy.

Table • 272-3 Platelet Function Assays

TESTS	SPECIFIC ASSESSMENTS
Dilute whole blood clot retraction	$GPII_bIII_a$-mediated clot retraction
Platelet aggregation studies	Aggregation response to specific agonists: adenosine diphosphate (ADP), collagen, arachidonate, epinephrine, platelet-activating factor
Platelet secretion studies	Secretion of dense granule contents: ADP, adenosine triphosphate (ATP), serotonin
Flow cytometry	Detection of constitutive membrane antigens: $GPII_bIII_a$ (CD61 =GPIIIa); GPIb (CD42b =GP1bα) Detection of activation markers: P-selectin (CD62p), phosphatidylserine (annexin-V), fibrinogen binding site (CAP1), platelet-bound fibrinogen (antifibrinogen antibody) Platelet calcium entry and release: Fluo-3
Spectrofluorimetry	Platelet calcium entry and release: Fura-2AM
Electron microscopy	Platelet ultrastructure: Shape change, cytoskeleton, intracellular organelles (granules, dense bodies, lysosomes), dense tubular system

A thorough drug history is indicated for any patient with thrombocytopenia, because numerous drugs have been reported to impair platelet production, induce secondary immune destruction, and/or cause platelet dysfunction (Table 272-5).[25] Establishing the causality of drug-induced thrombocytopenia is difficult, but ancillary diagnostics can help define possible underlying mechanisms. The findings of pancytopenia and

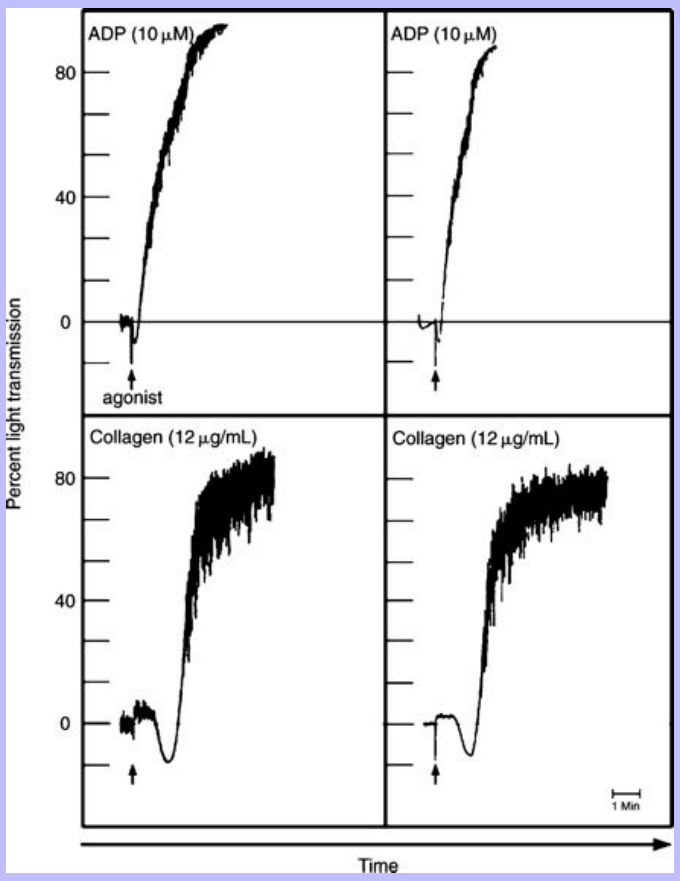
megakaryocytic hypoplasia indicate bone marrow suppression, and the presence of platelet-bound antibody is compatible with an immune-mediated process.

Idiopathic, or primary, IMT is an autoimmune disease, usually mediated by IgG directed against platelet membrane $G_pII_bIII_a$. The disease is uncommon in cats, but in case reviews of canine thrombocytopenia, primary IMT accounts for approximately 5% to 15% of patients, with over-representation of females and certain breeds (cocker spaniels, poodles, and Old English sheepdogs).[4,11] The diagnosis of primary IMT is generally based on combined clinical and laboratory criteria: exclusion of other underlying disease processes, the presence of severe thrombocytopenia (less than 50,000/μL), normal to increased megakaryopoiesis, microthrombocytosis, platelet-bound antibodies, and response to immunosuppressive therapy.

1923

1924

Figure 272-7 Platelet aggregation profiles of platelet-rich plasma obtained from two healthy dogs. Platelet activation was initiated by the addition *(arrow)* of adenosine diphosphate (ADP) *(top panels)* or collagen *(bottom panels)*. Aggregate formation is evidenced by an increase in light transmission. ADP induces a rapid aggregation response. In contrast, collagen stimulation is followed by a lag phase before aggregation ensues.



Breed-specific, clinically asymptomatic thrombocytopenias occur in dogs. Healthy greyhounds have a platelet count somewhat lower than that of other breeds, with a mean platelet count of approximately 150,000/μL.[26] Cavalier King Charles spaniels have a hereditary macrothrombocytopenia, with affected dogs having platelet counts ranging from 25,000/μL to 100,000/μL.[27]

272.3.1.1 Acquired Platelet Dysfunction

Many common drugs and disease syndromes impair platelet function, but the clinical significance is highly variable.[28] A mild to moderate bleeding tendency may complicate management of disease syndromes such as anemia, liver failure, uremia, DIC, and paraproteinemia. The pathogenesis of platelet dysfunction in these disorders is complex and multifactorial and includes intrinsic alterations in platelet metabolism and extrinsic changes in blood viscosity. Many drugs demonstrate *in vitro* platelet inhibition (see Table 272-5), by a variety of different mechanisms. The antiplatelet effects of aspirin are caused by a well-characterized, irreversible inactivation of intraplatelet cyclo-oxygenase (COX).[29] Other nonsteroidal anti-inflammatory drugs (NSAIDs) cause transient COX inhibition, and newer NSAIDs that selectively inhibit the COX-2 isoform are predicted to have fewer antiplatelet effects. Although drugs with potential antiplatelet effects may not cause spontaneous or severe bleeding, they should be given cautiously, if at all, to thrombocytopenic patients, patients undergoing surgery, or patients with signs of abnormal hemostasis.

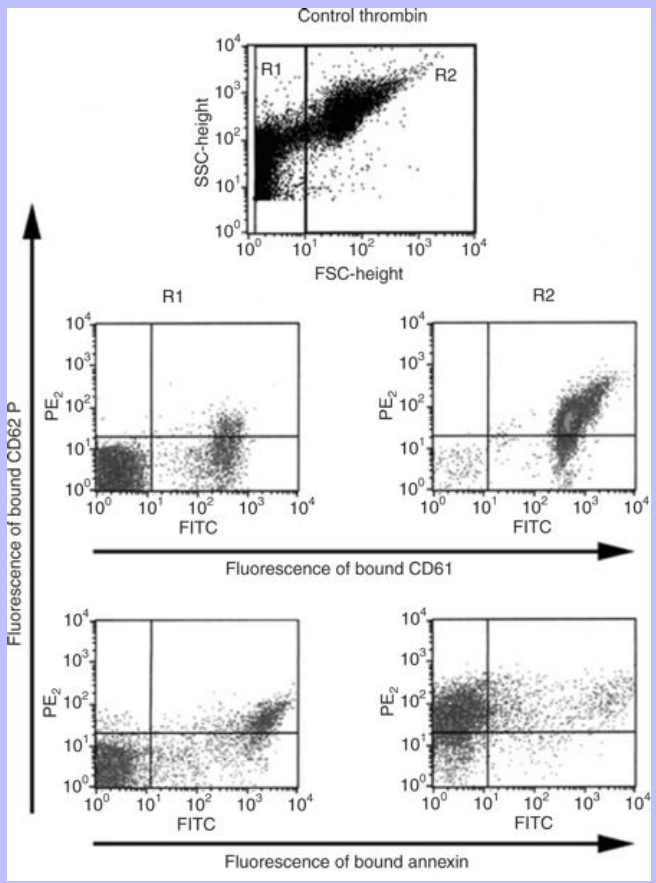
272.3.1.2 Hereditary Platelet Dysfunction

Hereditary platelet function defects (thrombopathias) are rare but likely are underdiagnosed because of logistic difficulties in performing platelet function studies. Diseases are broadly grouped as defects of membrane glycoproteins, storage granules, signal transduction, or procoagulant activity.[20] Breed-specific defects within these functional classifications have been identified in dogs and cats (Table 272-6). Defects in the $GPII_bIII_a$ complex, referred to as *thrombasthenic thrombasthenia,* have been identified in otter hounds and Great Pyrenees as the result of two distinct GPIIb mutations.[30,31] It is likely that the platelet function defects found in different breeds are caused by unique mutations.

272.3.2 von Willebrand Disease

von Willebrand disease (vWD) is the most common canine hereditary hemostatic defect.[32] The clinical signs of vWD overlap with those of other primary hemostatic defects, including mucosal hemorrhage, cutaneous bruising, and prolonged bleeding after injury. Petechiation, however, is not typical of vWD.

Figure 272-8 Flow cytometry analyses of canine platelet response to thrombin stimulation. The dot plot at top displays activated platelets in region R2. Region R1 contains platelet membrane–derived microparticles, debris, and machine noise. The four composite cytograms display the fluorescence intensity of labeled probes bound to the events in R1 or R2. The activated platelets (R2) display high-intensity labeling with CD61 and CD62p probes, denoting the presence of the membrane integrin GPIIIa and externalization of alpha granule constituent P-selectin, respectively. Most thrombin-activated platelets, however, are not labeled with the annexin probe, indicating low surface phosphatidylserine. In contrast, platelet membrane–derived particles (R1) display both P-selectin and phosphatidylserine. In all cytograms, events in the lower left quadrant represent nonspecific background fluorescence.



272.3.3 Disease Classification

Canine vWD is classified into one of three subtypes based on the clinical severity, plasma vWF concentration (vWF:Ag), and vWF multimer composition.[33,34] In general, a single type of vWD predominates in each affected breed (Table 272-7). Type 1 vWD, the most common form, is typically a mild to moderate bleeding diathesis characterized by low plasma vWF:Ag and normal multimer distribution. Type 2 vWD is a moderate to severe bleeding diathesis with a variable reduction in vWF:Ag and a disproportionate loss of high molecular weight (HMW) multimers. Type 3 vWD is a severe bleeding disorder caused by a total lack of vWF.

Table • 272-4 Pathogens that Cause Infectious Thrombocytopenia

TYPE OF AGENT	PATHOGEN
Viral agents	Canine: Distemper virus, herpesvirus, parvovirus, adenovirus Feline: Feline leukemia virus (FeLV), panleukopenia virus, feline immunodeficiency virus (FIV), feline infectious peritonitis (FIP) coronavirus
Arthropod-borne agents	*Ehrlichia* spp. *(E. canis, E. platys, E. ewingii);* also *Babesia*, *Haemobartonella*, *Rickettsia*, *Leishmania*, *Cytauxzoon*, *Borrelia*, and *Dirofilaria* spp.
Fungal and bacterial agents	Septicemia: Various agents *Histoplasma*, *Candida*, and *Leptospira* spp.

Table • 272-5 Drugs that Have Antiplatelet Effects

CATEGORY	DRUG	DISORDER/MODE OF ACTION
Antibiotics and antifungal drugs	Carbenicillin	Thrombopathia: Unknown action
	Cephalosporins	Thrombopathia: Membrane action*
	Chloramphenicol	Thrombocytopenia
	Penicillin	Thrombocytopenia
	Sulfonamides	Thrombocytopenia
Anti-inflammatory drugs	Aspirin	Thrombopathia: Prostaglandin (PG) inhibition
	Ibuprofen	Thrombopathia: PG inhibition
	Naproxen	Thrombopathia: PG inhibition
	Phenylbutazone	Thrombocytopenia and thrombopathia: PG inhibition
Cardiac and respiratory drugs	Aminophylline	Thrombopathia: Phosphodiesterase inhibition
	Diltiazem	Thrombopathia: Calcium blocker
	Isoproterenol	Thrombopathia: Membrane action
	Procainamide	Thrombocytopenia
	Propranolol	Thrombopathia: Membrane action
	Verapamil	Thrombopathia: Membrane action, calcium blocker
Cytotoxic drugs	Azathioprine	Thrombocytopenia
	Chlorambucil	Thrombocytopenia
	Cyclophosphamide	Thrombocytopenia
	Doxorubicin	Thrombocytopenia
Miscellaneous	Dextran	Thrombopathia: Membrane action
	Estrogen	Thrombocytopenia
	Methimazole	Thrombocytopenia

* Membrane action is interaction or interference with membrane receptors.

Table • 272-6 Hereditary Platelet Function Defects

DEFECT	BREED	LABORATORY FINDINGS
Thrombasthenia	Otter hound, Great Pyrenees	Absent or reduced $GPII_bIII_a$ complex, abnormal adhesion, absent or severely reduced aggregation to all stimuli, abnormal clot retraction
Signal transduction	Basset hound	Abnormal cAMP metabolism, defective $GPII_bIII_a$ activation, abnormal adhesion, aggregation only in response to thrombin, normal clot retraction
	Spitz	Abnormal adhesion, absent or trace aggregation in response to most stimuli, normal clot retraction
Storage pool	Persian cat	Chédiak-Higashi syndrome, low dense granule number, failure to secrete ADP and serotonin, abnormal aggregation, normal clot retraction
	American cocker spaniel	Normal dense granule number, abnormal ADP storage and secretion, abnormal ADP-induced aggregation, normal clot retraction
Signal transduction and storage pool	Collie	(Associated with cyclic neutropenia and stem cell defect) Defective dense granule serotonin and ADP release, abnormal aggregation to allstimuli but ADP
Undefined	Boxer	Abnormal aggregation to ADP and collagen, normal shape change, normal granule ATP/ADP content, normal fibrinogen and vWF binding
Procoagulant deficiency	German shepherd	Abnormal membrane phosphatidylserine exposure, abnormal microparticle release, abnormal prothrombinase activity, normal shape change, normal aggregation, normal clot retraction

cAMP, Cyclic adenosine monophosphate; *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *vWF*, von Willebrand factor.

1927

Table • 272-7 Classification of Canine von Willebrand Disease

CLASSIFICATION	vWF PROTEIN	SEVERITY	REPORTED BREEDS
Type 1	Low concentration/all multimer forms present	Variable	Airedale, Akita, dachshund, Doberman pinscher, German shepherd, golden retriever, greyhound, Irish wolfhound, Manchester terrier, schnauzer, Pembroke Welsh corgi, mixed-breed, poodle, Shetland sheepdog
Type 2	Low concentration/disproportionate loss of high-molecular-weight multimers	Moderate to severe	German shorthaired pointer, German wirehaired pointer
Type 3	Absent	Severe	Chesapeake bay retriever, Dutch kooiker, Scottish terrier, Shetland sheepdog Sporadic cases: Cocker spaniel, Eskimo dog, Labrador retriever, pit bull, rottweiler

272.3.3.1 Diagnosis of von Willebrand Disease

The screening test findings compatible with vWD include a normal platelet count, normal coagulation panel, long BMBT, and long PFA closure time, with definitive diagnosis confirmed by the finding of low plasma vWF:Ag (see Figure 272-4). Comprehensive analyses for vWD subtype classification include quantitative, functional, and qualitative vWF assays (Table 272-8).

272.3.3.2 Inheritance and Expression

von Willebrand disease is an autosomal trait; males and females experience the bleeding tendency and transmit the defect to offspring with equal frequency.[35] Expression of type 1 vWD is complex, with evidence for both incomplete dominant and recessive patterns.[36,37] Type 1 vWD is common in Doberman pinschers, and in this breed, clinical signs of vWD are typically seen in dogs with a vWF:Ag of 15% or lower.[38,39] Homozygosity for a splice-site mutation in the vWF gene and for certain vWF marker alleles is associated with a low plasma vWF.[40,41] The clinical severity of type 1 vWD for an individual dog (or human patient) cannot be fully explained by current molecular or biochemical tests. In contrast, type 2 and type 3 vWD in dogs appear to be simple recessive traits. Clinically affected dogs inherit a mutant vWF gene from each parent and express a bleeding tendency. The carrier parents are clinically normal, although their plasma vWF is typically low (less than 50% vWF:Ag). Mutations causative for type 3 vWD have been described in Scottish terriers and Dutch kooiker dogs.[42,43] Carriers (heterozygotes) can be unambiguously identified through breed-specific mutation detection tests.

Table • 272-8 von Willebrand Factor Analyses

TEST	PARAMETER MEASURED	TYPICAL RESULTSWITH vWD	NORMAL VALUES*
Buccal mucosal bleeding time (BMBT)	Primary hemostasis—vessel, platelet, vWF interaction	Type 1: 5 to >12 min Type 3: >12 min Type 2: >12 min	2 to 4 min
Platelet function analyzer (PFA 100) ADP/collagen closure time	vWF-dependent platelet adhesion and platelet aggregation	Type 1: 150 to 200 sec Type 2: >300 sec Type 3: >300 sec	47 to 119 sec
von Willebrand factor antigen (vWF:Ag)	vWF concentration	Type 1: 5% to 20% Type 2: 1% to 5% Type 3: <0.1%	>50%
Ristocetin and botrocetin cofactor activities (vWF:RCo; vWF:BCo)	vWF-dependent plateletagglutination	Type 1: Cofactor activity =vWF:Ag Type 2: Cofactor activity <vWF:Ag Type 3: Cofactor activity absent	>50%
Collagen binding capacity (vWF:CB)	Quantitative measure of vWF bound to collagen	Type 1: vWF:CB =vWF:Ag Type 2: vWF:CB <vWF:Ag Type 3: vWF:CB absent	>50%
vWF multimer composition (Western blot)	Distribution and size of vWF multimeric forms	Type 1: All vWF multimers present Type 2: Low/absent HMW forms Type 3: no vWF	Complete size array

vWF, von Willebrand factor; *ADP*, adenosine diphosphate; *HMW*, high molecular weight.

* Expected values for healthy dogs in authors' laboratory.

272.4 TREATMENT OF PLATELET DISORDERS AND VON WILLEBRAND DISEASE

Effective management of platelet disorders and vWD requires control of active sites of bleeding, stabilization of the patient to reverse signs of blood loss anemia and hypovolemia, and identification and correction of the primary disease that caused or exacerbated the hemostatic defect. Initial treatment modalities include both nontransfusion and transfusion support. Although the BMBT is a useful screening test of primary hemostasis for diagnostic purposes, it is not an accurate predictor of disease severity or surgical hemostasis.

272.4.1 Nontransfusion Therapy

Most animals with thrombocytopenia or acquired platelet function defects are effectively treated through identification and correction of the underlying disease process. Drugs with antiplatelet effects, invasive surgery, and jugular catheterization should be avoided, and cage rest is indicated to minimize trauma in

severely thrombocytopenic patients. Based on the geographic location, history, and initial workup, institution of appropriate therapy for infectious thrombocytopenia (e.g., doxycycline for *Ehrlichia, Rickettsia,* and *Haemobartonella* spp.) is indicated pending confirmatory test results.[8] Immunosuppressive doses of prednisone (2 mg/kg given every 12 to 24 hours) are administered if the diagnostic workup indicates that primary IMT is likely.[11] Primary IMT patients usually demonstrate resolution of petechiae and an increased platelet count within 2 to 5 days of starting therapy. Refractory primary IMT can be effectively treated with vincristine (0.02 mg/kg given intravenously every 7 days).[44] Immunosuppressive therapy for IMT can be considered successful if a stable platelet count (preferably at or above 100,000/μL) is attained. Maintenance involves slow, gradual tapering of immunosuppressive therapy, with minimal exposure to unnecessary drugs, vaccination, or stress conditions to avoid relapse.

Table • 272-9 Guidelines for Transfusion Therapy

PRODUCT	DOSE	INTERVAL BETWEEN REPEAT TRANSFUSIONS
Products for Red Cell Replacement		
Fresh whole blood	12 to 20 mL/kg	Every 24 hours (volume overload limits interval)
Packed red cells	6 to 12 mL/kg	Every 12 to 24 hours
Oxyglobin	10 to 30 mL/kg*	Once
Products for Platelet Replacement		
Fresh whole blood	12 to 20 mL/kg	Every 24 hours (volume overload limits interval)
Platelet-rich plasma	6 to 10 mL/kg†	Every 8 to 12 hours
Platelet concentrate	1 U/10–15 kg‡	Every 8 to 12 hours
Products for von Willebrand Factor Replacement		
Fresh whole blood	12 to 20 mL/kg	Every 24 hours (volume overload limits interval)
Fresh frozen plasma	10 to 12 mL/kg	Every 8 to 12 hours
Cryoprecipitate	1 U/10 kg§	Every 6 to 12 hours (as needed)

* Infusion guidelines for cats (off-label use): Infuse up to maximum dose of 10 mL/kg.

† Platelet count ≥0.5 to 1 $\times 10^9$/mL.

‡ Platelet count ≥5 $\times 10^9$/mL.

§ Unit defined as cryoprecipitate prepared from 200 ml of fresh frozen plasma.

Desmopressin acetate (DDAVP; deamino 8 D-arginine vasopressin) is a synthetic vasopressin analog used in human medicine to treat a variety of hemostatic defects, including acquired platelet function defects and mild vWD.[45] Desmopressin (1 μg/kg given subcutaneously) has been reported to shorten the BMBT and the PFA-100 closure time and to provide surgical hemostasis when administered 30 minutes before surgery to Doberman pinschers with type 1 vWD.[46,47] Desmopressin therapy could be considered for other mild to moderate acquired or hereditary platelet function defects. Close monitoring to determine the extent and duration of response is required, and transfusion should be available if the response to desmopressin is inadequate.

272.4.2 Transfusion Therapy

Transfusion with products to replace red cells (Table 272-9) is indicated for patients with acute blood loss and/or severe anemia that cannot be stabilized with fluid therapy alone.

Transfusion solely to supply platelets (see Table 272-9) rarely indicated or beneficial for thrombocytopenic patients those with acquired platelet function defects. The survival transfused platelets in IMT patients may be less than 1 day, which further limits their clinical utility. Platelet transfusions should be considered, however, in patients with persistent and uncontrolled bleeding or signs of central nervous system hemorrhage. Dogs and cats affected with severe hereditary thrombopathias may benefit from platelet transfusion as prophylaxis for surgery or if they develop severe spontaneous bleeding.[20,48]

Fresh whole blood, as platelet replacement, must be maintained at room temperature, collected in a citrate-based anti-coagulant, and transfused as soon as possible after collection.[49] This product is best used for patients with active bleeding or when no other platelet product is available.

Platelet components are labor intensive to produce, because platelets require special processing and storage techniques to maintain viability. Platelet-rich plasma (PRP) is prepared by centrifugation of whole blood at low G force within hours of collection.[49] The expected platelet yield is approximately 80% of the platelets, in one third volume, of the starting whole blood unit. In accordance with human blood banking standards, units of PRP, prepared from 450-mL units whole blood, are expected to contain at least 50 billion platelets.[50] Low-volume platelet concentrates (PC) are prepared from PRP by a second centrifugation step. Platelet-rich plasma and PC must be maintained at room temperature from the time of collection until transfusion, with administration as soon as possible after collection, and maximum storage of 3 days. A dimethylsulfoxide (DMSO) cryopreserved canine platelet concentrate has recently been offered (Midwest Animal Blood Services, Stockbridge, MI). Pending trials demonstrating its efficacy, this product may widen the availability of platelet transfusion beyond referral centers capable of producing components in-house. Strict attention to aseptic technique is critical during collection and transfusion of platelet products to prevent contamination or disease transmission.

Transfusion to supply active vWF (see Table 272-9) is highly effective in controlling hemorrhage in vWD patients.[51] The best strategy is early, rapid transfusion to increase vWF to hemostatic levels and wound therapy to control hemorrhage from a single site. After initial transfusion, severely affected patients may require a second or third transfusion to sustain hemostasis for an additional 24 to 48 hours. Stabilization of the hematocrit and cessation of active hemorrhage indicate that hemostatic levels of vWF have been attained. Plasma components are the safest and most effective products for treating vWD. Plasma cryoprecipitate is prepared from fresh frozen plasma (FFP) and contains a fivefold to tenfold concentration of active vWF in approximately one-tenth volume of the starting plasma.[49] Cryoprecipitate is the best product for rapid replacement of vWF, but fresh frozen plasma is an acceptable alternative if cryoprecipitate is unavailable. The use of plasma components rather than whole blood prevents sensitization to red cell antigens, eliminates the need for canine type-matched donors, and minimizes the risk of volume overload.

273 CHAPTER • 273 Inherited Coagulopathies

Anthony P. Carr

Hemostasis results from a complex set of interactions. For convenience, the hemostatic response is divided into three processes: (1) primary hemostasis, (2) coagulation, and (3) fibrinolysis. The main components interacting in these processes are the blood vessels, platelets, and plasma proteins. Erythrocytes and leukocytes play a major role as well. After injury to a blood vessel, vasospasm reduces blood flow. Exposed subendothelium initiates platelet adhesion and platelet-platelet cohesion, resulting in the formation of a temporary platelet plug. At the same time, the coagulation cascade is activated by the vessel injury and by substances released by the platelets. The coagulation cascade leads to the formation of fibrin, which reinforces the platelet plug, forming a blood clot. The generation of fibrin leads to activation of fibrinolytic pathways. Numerous mechanisms, including antithrombin III, protein C, protein S, and tissue factor pathway inhibitor, limit coagulation to the area where it is needed. Although hemostasis is often considered an autonomous "system," it is important to remember that this separation is artificial. Hemostasis is intimately tied to the process of inflammation and vice versa.

273.1 PHYSIOLOGY OF HEMOSTASIS

Hemostasis has been extensively studied, yet researchers' understanding of the *in vivo* process is still undergoing revision. For a long time the processes that occurred *in vitro* were thought to be the same as those that occurred *in vivo*. However, this concept was challenged by the fact that some individuals with factor deficiencies failed to show a bleeding tendency, as would be expected if the initial theories were correct. A good example of this situation is factor XII deficiency, in which test results for the intrinsic coagulation pathway are markedly prolonged, yet no abnormal bleeding tendency is detected. The initial work also focused predominantly on the plasma proteins, often ignoring the vital contribution of cellular elements to the clotting process.

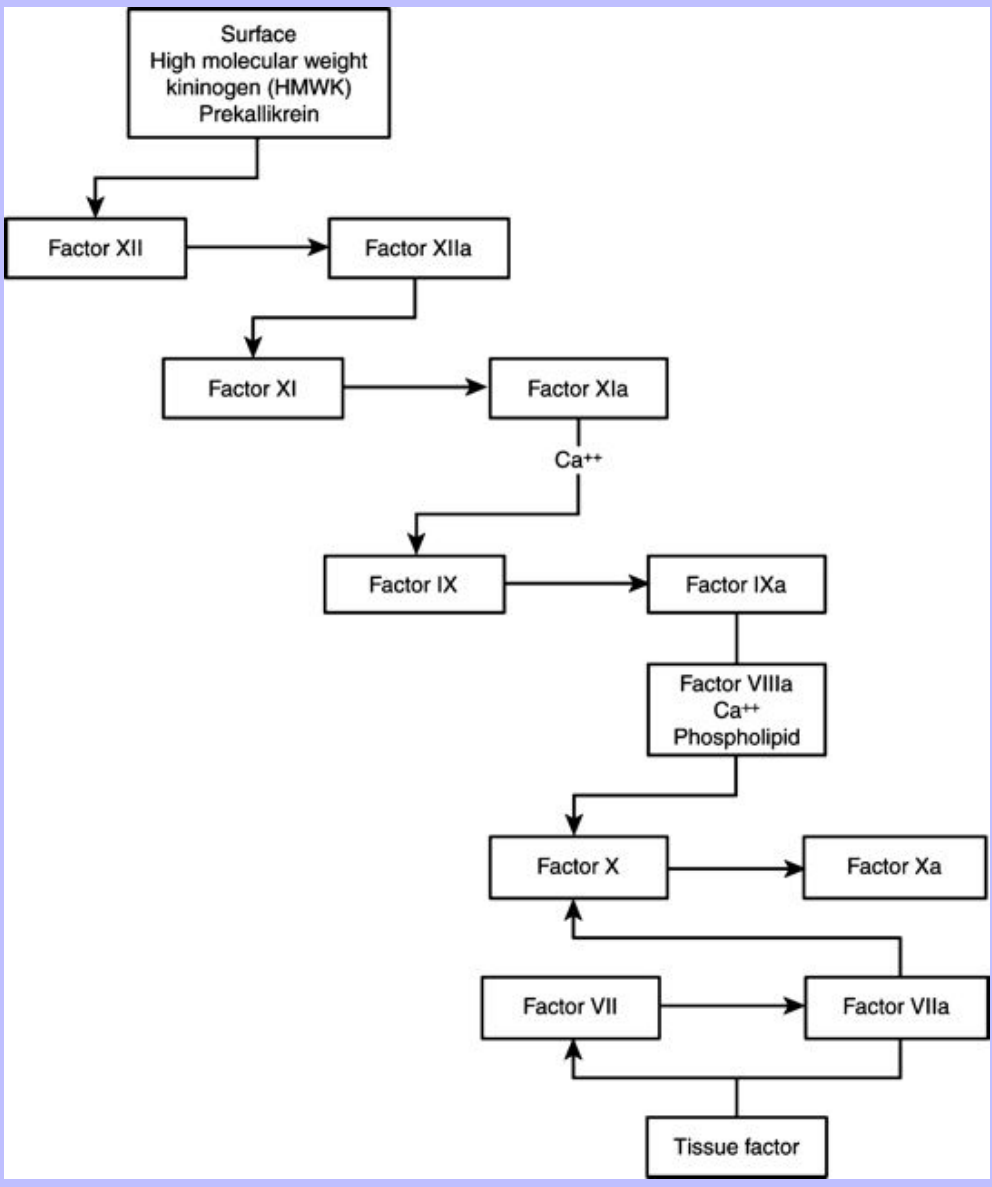
All coagulation factors and cofactors are synthesized in the liver and circulate in the plasma in an inactive form. Factors II, VII, IX, and X are considered vitamin K dependent because they must undergo vitamin K–dependent post-translational modification (gamma carboxylation) before becoming hemostatically active.[1]

273.1.1 Coagulation Cascade

Until recently, the predominant concept of coagulation was that of a cascade that could be divided into the intrinsic, extrinsic, and common pathways. An understanding of this theory is helpful to the clinician, because it reflects the processes that occur with the commonly run coagulation assays. Figure 273-1 shows the intrinsic and extrinsic pathways. The extrinsic pathway was relegated to a relatively minor role. The name *extrinsic* is based on the fact that initiation of clotting with this pathway required the addition of tissue thromboplastin, a substance that does not normally occur in blood, to the test sample. Tissue thromboplastin consists of phospholipid membrane that contains tissue factor. The addition of tissue thromboplastin results in the conversion of factor VII to factor VIIa, which proceeds to form factor Xa from factor X, thereby initiating the common pathway (Figure 273-2) and ultimately leading to the formation of fibrin.

The one-stage prothrombin time (OSPT) tests the extrinsic system. For this test, an excess of tissue thromboplastin is added to the blood sample, and the time that elapses until a clot forms is noted. One reason the extrinsic system was relegated to a minor role was that individuals with hemophilia have normal OSPT values; also, with the intrinsic pathway, it was possible to initiate clotting without the presence of tissue factor.[2]

Figure 273-1 Intrinsic and extrinsic pathways of coagulation. The intrinsic pathway is initiated by conversion of factor XII to factor XIIa, whereas the extrinsic pathway is activated by the conversion of factor VII to factor VIIa.



The intrinsic pathway is initiated by the contact system, which consists of factors XII and XI, high-molecular-weight kinogen, and prekallikrein; initiation occurs with exposure to a negatively charged surface. Both the activated clotting time (ACT) and the activated partial thromboplastin time (aPTT) test this

part of the clotting cascade. Individuals with hemophilia have markedly prolonged aPTT times, because factors VIII and IX are part of the intrinsic pathway.

The common pathway is initiated by activation of factor X, which forms a complex on a phospholipid membrane surface with factor V, factor II (prothrombin), and calcium. This complex, referred to as *prothrombinase,* then generates thrombin. The presence of factor V accelerates the generation of thrombin several hundredfold. Thrombin binds fibrinogen and converts it to soluble fibrin monomers. The monomers polymerize and are cross-linked by factor XIIIa to form insoluble fibrin.

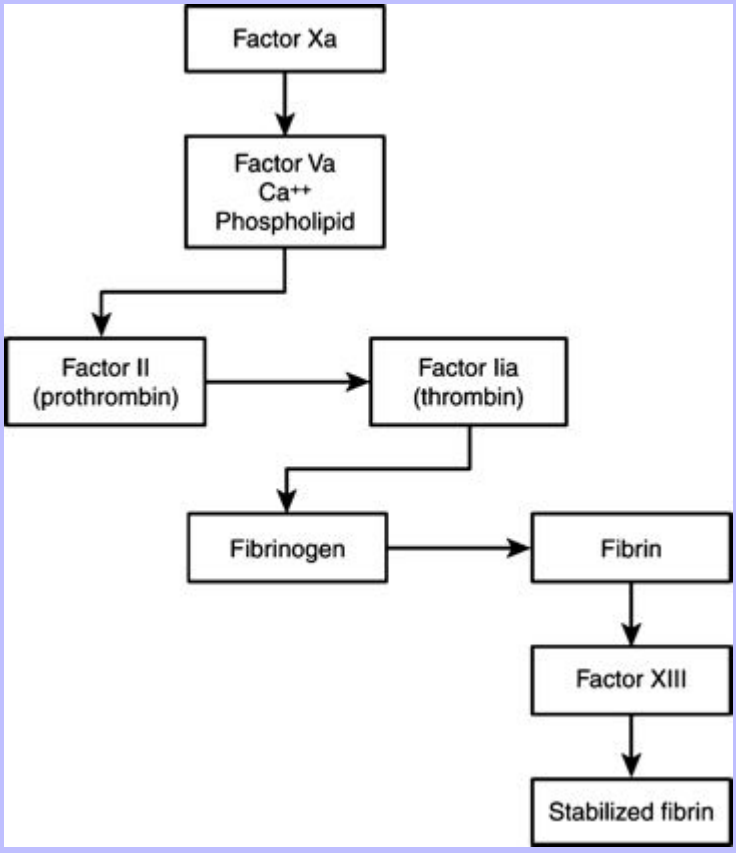
Figure 273-2 The common pathway of coagulation is initiated when factor X is converted to factor Xa by either the intrinsic or the extrinsic pathway.



273.1.2 Revised Theory of Coagulation

The current understanding of the clotting process has resulted from a variety of observations. Traditionally, the intrinsic system has been considered more important than the extrinsic pathway, because it could proceed without requiring the addition of a substance not usually present in the circulation. A challenge to this assumption arose when some individuals from various species were found to be deficient in the contact

system. These individuals had markedly prolonged aPTT results but no detectable predisposition to bleeding. The extrinsic system also was not thought to be important because, as mentioned previously, individuals with hemophilia have normal OSPT values despite a marked bleeding tendency. This is seen when the OSPT test is run in the standard fashion, in which an excess of tissue thromboplastin is used. When less thromboplastin is used, individuals with hemophilia also have prolonged coagulation times. These observations, combined with new research tools that allowed clotting to be studied in more detail, led to a major revision in the theory of how clotting is initiated and sustained. It would be surprising if the current theory remains unaltered in the future.

Factor VII activation is seen as the initiating event for clotting *in vivo*. Factor VII activation occurs when tissue factor is present. Tissue factor is expressed by cells underneath the endothelium, therefore trauma results in clotting. Other cells, such as monocytes and endothelial cells, also can express tissue factor when stimulated by such substances as cytokines and endotoxin. This explains why coagulation abnormalities are so common with a variety of inflammatory and infectious conditions. Production of the factor VIIa–tissue factor complex results in the generation of small amounts of the active factors Xa and IXa. Factor Xa combines with tissue factor pathway inhibitor (TFPI) to rapidly stop further generation of active factors by the factor VIIa–tissue factor complex.[3]

Continued coagulation depends on pathways other than those that initiate clotting.[2] A possible explanation for this is that the thrombin generated initially is able to activate factor XI to factor XIa, and the clotting cascade then can proceed as classically outlined. Because factor XI can be activated directly by thrombin, it becomes clear that contact activation is not a prerequisite for *in vivo* clotting. It may also be that factor IX plays a vital role in promoting further clotting. Factor IX becomes fully activated when both factor Xa and the factor VIIa–tissue factor complex cleave off parts of the molecule. Once factor IXa has been formed, it can lead to further factor Xa generation and thereby to thrombin formation.

Despite its promise, the revised theory of coagulation leaves many questions unresolved, including the variable bleeding tendency seen with factor XI deficiency.

A possible explanation for the inability of the revised theory to explain all the clinical abnormalities seen may be that the theory focuses solely on the coagulation factors and thus does not account for the various cellular components involved in hemostasis.[4] These cellular components differ in their receptors and other properties, which allows for a different coagulation response when the cellular component varies, even if the plasma protein constituents remain the same. An example of this is tissue factor. The amount of tissue factor expressed does not solely determine how effectively a cell can initiate coagulation; the process also depends on the cell's ability to support prothrombinase assembly.[4] Given the complex interactions among cells, coagulation proteins, and inflammatory mediators, it is not surprising that our understanding of the basic physiologic process of clotting is incomplete.

273.1.3 Inhibitors of Coagulation

When coagulation is required, it is vital that it be prevented from becoming a widespread event in the organism; it must be limited to the area where the insult has occurred. A variety of mechanisms help inhibit coagulation, and the most important of these is antithrombin III (AT III). When complexed with endogenous heparin sulfate or exogenously administered heparin, AT III rapidly inactivates thrombin. It can also inactivate Xa and IXa effectively, unlike other activated factors. Each molecule of AT III is consumed with inactivation of a factor. Continued generation of factor Xa by the factor VIIa–tissue factor complex is blocked by TFPI. TFPI is present in plasma and also can be released by activated platelets.

The protein C–protein S system inactivates factors Va and VIIIa. Both of these proteins are vitamin K dependent and are located on the surface of the endothelial cells. They are activated when thrombin is bound to thrombomodulin. Thrombomodulin-bound thrombin is no longer active as a procoagulant molecule, yet it still is able to cleave protein C, thereby activating it.[2]

273.1.4 Fibrinolysis

Along with activation of coagulation, the mechanisms that degrade the clot and allow formation of scar tissue also are activated. The degradation of fibrin is mediated by plasmin, which is generated by the action of plasminogen activators on plasminogen. Tissue plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA) are the main types of activators that occur naturally in dogs and cats. Streptokinase, also a plasminogen activator, is produced by certain streptococci.

When a clot forms, plasminogen is incorporated into the clot. The presence of thrombin causes the endothelium to release t-PA. The affinity for plasminogen is low without a cofactor being present. However, when t-PA is associated with fibrin, it has high catalytic efficacy for cleaving plasminogen.[2] The action of t-PA is predominantly limited to the vascular space, whereas u-PA acts more extravascularly. Once plasmin has been formed, it begins to degrade fibrin. This results in the production of various fibrin degradation products. Some of these degradation products are specific to fibrin, some can also be produced when fibrinogen is cleaved.

1931

1932

Excessive fibrinolysis also must be prevented, and this is achieved through two main processes: alpha$_2$-antiplasmin inactivates free plasmin rapidly (although it is much less active against fibrin-bound plasmin), and tissue plasminogen activator inhibitor 1 (PAI-1) inactivates t-PA and u-PA.

273.2 INHERITED HEMOSTATIC ABNORMALITIES

Inherited disorders of hemostasis can involve coagulation factor deficiencies, defects of platelet adhesion resulting from decreased levels of von Willebrand factor (vWF), defective platelet function, and blood vessel defects. Inherited coagulation defects related to various coagulation factor deficiencies have been reported in dogs and cats. These defects may be inherited or may arise *de novo* as a result of a genetic mutation.

273.2.1 Hemophilia A (Factor VIII Deficiency)

The most commonly seen congenital coagulation abnormality is hemophilia A. The bleeding tendency associated with this disease is a result of a deficiency in functional factor VIII.[5–9] Factor VIII is located in the intrinsic pathway and acts to significantly increase the rate at which IXa generates factor Xa. With a lack of factor VIII activity, less fibrin is formed; this results in the typical signs of a coagulopathy, such as body cavity bleeding and large hematomas. Hemorrhage into joints may occur as well. An initial platelet plug may form, but fibrin reinforcement for the plug is delayed, reduced, or absent, and the result is rebleeding. Hemophilia A is inherited as a X-linked recessive trait, meaning that most affected individuals are male. This form of hemophilia occurs in humans, dogs and occasionally in cats.[10] The severity of the bleeding is variable. Generally, factor VIII activity must be less than 5% of normal for bleeding to occur spontaneously. Hemorrhage can be severe and occasionally fatal; this is not uncommon in the neonatal period. Patients with hemophilia A have a prolonged aPTT and a normal OSPT. A definitive diagnosis is made by specific factor assay.

273.2.2 Hemophilia B (Factor IX Deficiency)

Hemophilia B, or Christmas disease, has also been described in dogs and cats.[11–14] The disease is caused by a sex-linked deficiency of factor IX, which is a vitamin K–dependent factor. Factor IX is responsible for activation of factor X. Hemophilia B has been identified in at least 19 breeds of dogs as well as mixed breeds.[15] The bleeding tendency seen with this disease is variable but can be severe. As with hemophilia A, the aPTT is prolonged without prolongation of the OSPT. Definitive diagnosis depends on specific factor assay. If serum is added to the plasma on which the aPTT is run, the prolongation will correct, because serum contains factor IX.[16]

273.2.3 Factor XII Deficiency (Hageman Trait)

Occasionally an incidental prolongation of the aPTT in cats is detected, although a bleeding tendency is not present. This finding results from low levels of factor XII, also called *Hageman factor,* an important part of contact activation *in vitro*. This deficiency generally does not compromise hemostasis.[17] The condition is inherited as an autosomal recessive trait and has been found in dogs as well[1]; it also is a normal finding in some marine mammals, birds, and reptiles.[16] Factor analysis is required to make a definitive diagnosis.

273.2.4 Vitamin K–Dependent Factor Deficiency

Vitamin K–dependent factor deficiency is a rare inherited coagulation defect involving all the vitamin K–dependent factors (II, VII, IX, and X) that has been described in Devon rex cats.[18] It probably is an autosomal recessive trait. Bleeding is severe in affected animals, which show prolongation of both the OSPT and aPTT.

273.2.5 Other Coagulopathies

Various other factor deficiencies have been reported in dogs and cats,[1,16] but these problems are rarely seen in practice.

273.3 DIAGNOSIS

A variety of tests are available for diagnosis of hemostatic abnormalities, some of which can be performed in a practice setting. Most coagulation tests require specialized equipment and extensive experience, therefore most of them must be performed in a reference laboratory. A variety of bedside coagulation monitors have been evaluated for use in veterinary medicine.[19]

In-house evaluation of coagulation abnormalities certainly can include the activated clotting time (ACT). This test requires that 2 mL of blood be drawn into a tube containing diatomaceous earth as a contact activator. The tube is incubated at 37° C. The ACT evaluates the intrinsic and common pathways of coagulation. Prolongation of the ACT may be seen with hemophilia A or B, factor XI or factor XII deficiency, vitamin K–antagonist rodenticide intoxication, and heparin therapy. The ACT relies on platelet phospholipids for coagulation, therefore severe thrombocytopenia can lead to increased values. Reported normals were 64 to 95 seconds and 67 to 85 seconds in dogs and 65 seconds or less in cats.[20–22]

Hemostatic testing requires collection of a sample of optimum quality. Venipuncture that involves multiple passes through tissue to obtain a sample is not appropriate for coagulation testing. Holding the vein off too long also can lead to activation of platelets and the fibrinolytic system. The tissue packed into the needle acts to activate coagulation prematurely. Hemolysis and severe lipemia (which often causes hemolysis) can also prevent accurate results. It often is preferable to use vacuum tubes for collection and to use the first sample for tests other than coagulation. The most commonly used anticoagulant is sodium citrate, and the ideal ratio is one part citrate to nine parts blood. The sample should be promptly centrifuged and the plasma harvested. The plasma then should be frozen in a plastic or siliconized glass tube. Plasma should be shipped frozen, because coagulation factors rapidly become inactivated at room temperature.

Reference laboratories can perform two valuable clotting time tests, the aPTT, which tests intrinsic function, and the OSPT, which tests extrinsic function. These tests are also available with point-of-care devices. It is important to remember that reference ranges vary among laboratories and testing methodologies, therefore no universally applicable reference ranges are available. The aPTT tests many of the same factors as the ACT but is considerably more sensitive. A prolonged aPTT with a normal OSPT is a common finding with hemophilia or factor XII deficiency. A prolonged OSPT with a normal aPTT usually is seen only when vitamin K antagonists have been recently ingested; factor VII deficiency is extremely rare. The OSPT predominantly tests the function of factor VII, the coagulation factor with the shortest half-life, as well as common pathway deficiencies. Both the aPTT and OSPT are prolonged with vitamin K deficiencies, severe liver disease, and disseminated intravascular coagulation and when vitamin K–antagonist rodenticide poisoning occurs more than 12 to 24 hours before testing.

1932

1933

A variety of other assays are available through reference laboratories. Specific factor analysis can be run. It is vital that the laboratory that runs the factor analysis have considerable experience with veterinary samples, because there can be discordant results if the same protocols are used as in humans.

273.4 TREATMENT

Treatment of hemostatic abnormalities requires careful assessment and determination of the particular abnormality. Many of the diseases described are not amenable to cure, and at best short-term control is possible. An exception is the combined vitamin K–dependent factor deficiency, in which vitamin K supplementation can normalize the clotting ability. In humans there is considerable interest in developing gene therapy for most of these inherited coagulation disorders. Currently this is not an option in pets, therefore the goal is to control clinical signs and avoid situations in which bleeding may occur. It is especially important to avoid trauma in an animal with bleeding tendencies, especially trauma produced iatrogenically through biopsy, surgery, venipuncture, restraint, or intramuscular administration of medications. It is also important to avoid medications that can interfere with primary hemostasis, such as nonsteroidal anti-inflammatory drugs and phenothiazines.

Treatment of inherited disorders of hemostasis consists of transfusion therapy, which generally is instituted only when life-threatening hemorrhage is present or prior to surgery. Which type of transfusion is most appropriate depends on the patient's presenting signs. If anemia is present, use of fresh whole blood may be expedient, because it replaces red cells and coagulation factors. If anemia is not present, the use of plasma is preferred. Fresh frozen plasma contains all the coagulation factors in their active form and can be used to treat any coagulopathy. Slowly thawing fresh frozen plasma and decanting off the supernatant generates cryoprecipitate and cryosupernatant. Cryoprecipitate contains factor VIII, fibrinogen, and vWF in high concentrations. This makes cryoprecipitate the blood component of choice for therapy of von Willebrand disease, fibrinogen deficiency, and hemophilia A. The highly concentrated nature of cryoprecipitate allows the coagulation factors from many units of plasma to be transfused without the worry of volume overload. Cryosupernatant can be used in the treatment of coagulopathies that do not involve the factors removed in the cryoprecipitate.

274 CHAPTER • 274 Acquired Coagulopathies

Robert M. DuFort

Linda Matros

274.1 VITAMIN K DEFICIENCY

Vitamin K deficiency is one of the most commonly encountered acquired coagulopathies in veterinary medicine. Vitamin K is required for the activation of a group of proteolytic enzymes known as *serine proteases,* which include coagulation factors II, VII, IX, and X, and the anticoagulant proteins C and S. If left untreated, vitamin K deficiency results in alterations in the extrinsic, intrinsic, and common coagulation pathways and ultimately clinically manifests as bleeding.

Vitamin K is a fat-soluble vitamin found in three forms: K_1 (phytonadione), K_2 (menaquinone), and K_3 (menadione). Vitamin K_1 is found in green, leafy vegetables and vegetable oils. It is absorbed via the lymphatics in the proximal small bowel. Bile acids and dietary fats facilitate absorption of vitamin K_1. Vitamin K is also synthesized by microflora in the ileum and colon. Vitamin K_3 is a synthetic form. Oral doses are absorbed via capillaries in the colon. The daily requirement of vitamin K is small (1.25 µg/kg/day in the dog), and the liver stores several days' supply. Consequently, animals fed a commercial diet rarely experience vitamin K deficiency (Box 274-1).

Antagonism of vitamin K is by far the most common cause of vitamin K deficiency. Vitamin K antagonism is brought about by the ingestion of anticoagulant rodenticides.

The vitamin K–dependent coagulation factors (II, VII, IX, and X) are synthesized by the liver as inactive proteins, which contain glutamyl residues that must be carboxylated for the proteins to become active. The carboxylation reaction requires reduced vitamin K. As the coagulation proteins become carboxylated, vitamin K is oxidized by the enzyme vitamin K epoxidase to become vitamin K epoxide. To carboxylate other coagulation protein molecules, the vitamin K epoxide must again be reduced by vitamin K epoxide reductase. Anticoagulant rodenticides act by inhibiting vitamin K epoxide reductase. As a result, vitamin K epoxide and inactive (noncarboxylated) coagulation factors accumulate in the blood (Figure 274-1). The half-lives of coagulation factors II, VII, IX, and X are short (41, 6.2, 13.9, and 16.5 hours, respectively).

274.1.1 Box • 274-1 Conditions Associated with Vitamin K Deficiency

Neonate born to malnourished mother

Decreased synthesis of vitamin K by intestinal microflora (due to chronic antibiotic therapy)

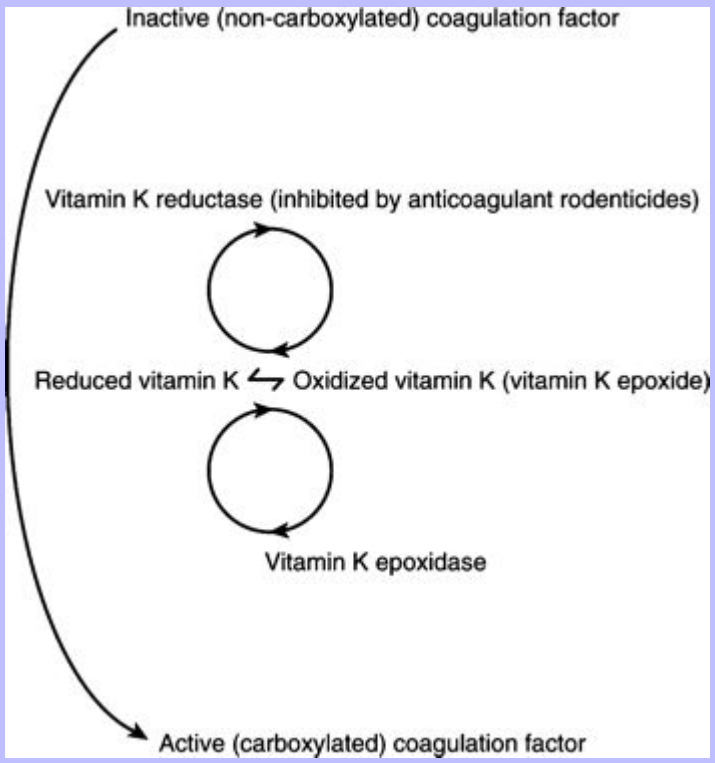
Decreased vitamin K absorption

Complete bile duct obstruction

Pancreatic exocrine insufficiency

Lymphangiectasia

Figure 274-1 Vitamin K carboxylation cycle.



Anticoagulant rodenticides were developed as a result of the observation of an acquired coagulopathy in cattle that had ingested moldy sweet clover. A coumarin derivative in sweet clover is converted to dicoumarol by a fungus. The first-generation anticoagulants, warfarin and pindone, were developed for vermin control and as human antithrombotic medicines after this discovery. The second-generation anticoagulant rodenticides (bromadiolone, brodifacoum, and diphacinone) are more potent because of their longer half-lives and lower incidence of acquired drug resistance. Despite the longer half-lives of the second-generation anticoagulant rodenticides, poisoning of companion animals that ingest poisoned rodents is an uncommon event. Various concurrently administered drugs (Box 274-2) and coexisting conditions (Box 274-3) may exacerbate the toxicity of anticoagulant rodenticides.

To diagnose anticoagulant rodenticide poisoning, the clinician must assess the history and clinical signs and evaluate the results of appropriate laboratory tests. The histories of potentially poisoned pets vary from direct observation of ingestion to the passing of suspicious material in the feces. Potential exposure to anticoagulant rodenticides may be a relative certainty or may be unknown, depending on the animal's environment. The onset of clinical signs normally occurs 2 to 5 days after ingestion of the anticoagulant rodenticide, and signs may

escalate quickly after they are first detected. Clinical signs are the result of hemorrhage, which may vary from mild to severe. Severe hemorrhage can result in hypovolemia and organ dysfunction. Bleeding into the thoracic cavity or cranium is especially critical.

Laboratory test results may be normal or abnormal, depending on the amount of anticoagulant ingested and the time elapsed since ingestion. The first laboratory test to show an abnormal (prolonged) result is the PIVKA (proteins induced by vitamin K absence or antagonism) test, followed by the prothrombin time (PT), and eventually the partial thromboplastin time (PTT). The PIVKA test, a sensitive indicator of anticoagulant rodenticide ingestion, may be prolonged as early as 12 hours after ingestion; the PT may require 36 to 72 hours to become abnormal. The PT is affected by numerous other coagulation disorders, such as disseminated intravascular coagulation (DIC), hepatic disease, and hereditary factor deficiencies. In contrast, the PIVKA test is sensitive primarily to the presence of precursor proteins, which accumulate in the absence of vitamin K. *1934*
Comparison studies have shown that the PIVKA test has greater sensitivity and specificity than both the PT and *1935*
the activated partial thromboplastin time (aPTT) in the diagnosis of dogs with anticoagulant poisoning.

274.1.3 Box • 274-3 Conditions That Exacerbate Anticoagulant Rodenticide Toxicity

High lipid diet

Facilitates rodenticide absorption

Decreases anticoagulant protein binding

Uremia

Promotes platelet inhibition

Decreases protein binding

Decreases excretion of unbound anticoagulant

Thrombocytopenia

Disseminated intravascular coagulation

Measurement of the anticoagulant rodenticide in the serum or tissues of an animal confirms the diagnosis of anticoagulant toxicosis. High-performance liquid chromatography and gas chromatography tests capable of identifying specific anticoagulants are available in many diagnostic laboratories. The results of these tests are not compromised by previous therapy with vitamin K, therefore a diagnosis can still be made even in successfully treated animals.

Therapy varies with the stage of the disease. With an acute known ingestion, emetics, adsorbents, and cathartics are used to minimize absorption. Most clinicians choose to begin vitamin K therapy even in asymptomatic patients regardless of the success of attempts to limit absorption. Vitamin K_1 is the treatment of choice. The initial treatment is administration of vitamin K_1 by subcutaneous injection at a dosage of 2.5 to 5 mg/kg. The dose should be divided and given in several sites. Oral vitamin K_1 therapy follows in 6 to 12 hours, at a dosage of 1.25 to 2.5 mg/kg given twice daily. If absorption of the rodenticide is thought to be minimal, treatment may be discontinued after 7 days. The PT should be tested 48 hours after termination of therapy. If the PT is prolonged, the patient is treated with oral vitamin K_1 for 2 more weeks. If the initial post-therapy PT is normal, a second PT test should be done 48 hours later. If the second post-therapy PT is normal, vitamin K therapy may be terminated.

274.2 LIVER DISEASE

The liver is critical to coagulation homeostasis. It is the site of synthesis of most of the procoagulants (clotting factors), the anticoagulants (antithrombin III, $alpha_2$-macroglobulin, $alpha_1$-antitrypsin, $alpha_1$-acid glycoprotein, and proteins C and S), and the fibrinolytic proteins (plasminogen, plasminogen activators, plasminogen proactivators, antiplasmins, and inhibitors of plasminogen activators and proactivators). Liver disease may result in hemorrhage caused by decreased coagulation factor synthesis, synthesis of abnormal coagulation factors, or excessive consumption. Ironically, even the most severe liver disease is rarely accompanied by bleeding. There are several reasons for this. The liver produces a large quantity of coagulation factors. Fibrinogen, for example, can be measured in concentrations up to 0.4 g/dL in the plasma of normal animals. It is commonly stated that coagulation factor concentrations must fall below 15% for coagulation to be compromised. Edema and anasarca due to hypoalbuminemia, which occur at 75% to 80% liver compromise, are rarely accompanied by bleeding,

even with provocation (liver biopsy). The liver also has a tremendous regenerative capacity and can return to normal function after many acute hepatopathies. Some coagulation factor concentrations actually increase with liver disease (i.e., fibrinogen, factor V, and von Willebrand factor [vWF]). The liver also is the largest macrophage-containing organ in the body, with tremendous phagocytic activity capable of rapidly clearing activated coagulation factors and products of fibrinolysis (fibrin degradation products [FDPs]).

Although 66% to 85% of patients with hepatopathies have abnormal results on one or more coagulation tests, fewer than 2% actually develop hemorrhage. When bleeding occurs, it usually is associated with concurrent disease (thrombocytopenia, thrombopathy, or cardiovascular disease). Factors that determine whether liver disease results in hemorrhage are the nature and severity of the disease and the rate of onset.

274.2.1 Box • 274-4 Potential Sequelae of Neoplasia That May Result in Thrombosis or Hemorrhage

Thrombocytopenia

Thrombopathy

Disseminated intravascular coagulation

Microangiopathy

Endothelial invasion by neoplastic cells

Treatment with chemotherapeutic agents

A prospective evaluation of coagulation tests in cats with different types of liver disease showed the PIVKA test to be more sensitive than either the PT or the aPTT for evaluating cats at risk for increased bleeding. Hepatobiliary disease, which disrupts enterohepatic circulation of bile acids, leads to a depletion of coagulation factors and an increase in procoagulant proteins (PIVKAs) by decreasing the intestinal absorption of vitamin K. The degree of vitamin K deficiency parallels the severity of liver disease and the probability of clinically significant bleeding. Because the PIVKA test is the first coagulation test to become abnormal in states of vitamin K deficiency, it appears to be superior to either the PT or APTT in identifying cats at risk for increased hemorrhage from liver disease.

274.3 NEOPLASIA

Neoplastic disease may result in thrombosis or bleeding by several mechanisms (Box 274-4).

In dogs with mammary carcinoma, abnormalities in one or more coagulation tests are found in two thirds of the patients. The frequency of abnormal test results correlated with the stage of disease. Dogs with stage III or stage IV neoplasia had the highest number of abnormal test results.

Chemotherapeutic agents may further exacerbate bleeding tendencies (Table 274-1). Studies have shown that up to 83% of untreated dogs had laboratory evidence of abnormal coagulation. In cats with neoplasia, 20% had coagulation abnormalities. Among the patients with abnormal laboratory results, thrombocytopenia was most common (36%), followed by a prolonged PTT (32%), and altered fibrinogen concentrations (25%). Canine lymphoma/leukemia and hemangiosarcoma are neoplasms that are commonly associated with hemostatic abnormalities. Treatment of the hemorrhage must first address the inciting cause, the neoplasia.

1935
1936

Table • 274-1 Chemotherapeutic Agents That May Affect Coagulation

DRUG	MECHANISM
Bleomycin, CCNU, cytosine arabinoside, melphalan, methotrexate, platinum, doxorubicin, Actinomycin D	Thrombocytopenia
Vincristine, vinblastine	Thrombocytosis
Melphalan, vincristine	Thrombopathy
L-Asparaginase	Inhibition of protein (clotting factor) synthesis
Actinomycin D	Vitamin K antagonism
Melphalan	Dysfibrinogenemia
Doxorubicin, daunorubicin	Increased fibrin and fibrinogen lysis

274.4 ACQUIRED INHIBITORS OF COAGULATION

Acquired anticoagulants are uncommonly recognized in veterinary medicine. These inhibitors may be directed against one or more specific coagulation factors.

There are several types of inhibitors. The most common type comprise the immunoglobulins of the IgG class. They occur most often in patients receiving multiple whole blood or plasma transfusions. These immunoglobulins have also been associated with therapy with certain drugs (e.g., penicillin, phenytoin) and with immune-mediated diseases (e.g., systemic lupus erythematosus), liver disease, lymphoproliferative diseases, DIC, and other conditions. They may result in abnormal coagulation test results, thrombosis, or hemorrhage, depending on the coagulation factor against which they are directed.

Immunoglobulins should be suspected when coagulation test abnormalities do not fit the clinical presentation. Prior administration of antithrombotic drugs or improper sample collection must be ruled out. Because their effect on coagulation test results occurs by a mechanism different from that produced by a factor deficiency, they may be identified with a plasma mixing procedure. If a factor deficiency is present (i.e., hemophilia A or B), the addition of plasma from a species-specific pool corrects the coagulation screening test. This same procedure does not correct coagulation test results if an inhibitor is present.

In contrast to the immunoglobulin class of inhibitors, nonspecific inhibitors are not targeted on any single coagulation factor; rather, they interfere with the interactions of clotting factors on a phospholipid surface. These nonspecific inhibitors affect the aPTT more than the PT and also fail to correct in mixing studies. The release of heparin, as can be seen with canine mast cell tumors, and metalloproteinases (found in snake venom) are other examples of acquired coagulation inhibitors.

274.5 THROMBOSIS

A delicate balance must be maintained between procoagulant, anticoagulant, and fibrinolytic factors. A change in the blood flow, vascular endothelium, or coagulation factors can result in thrombosis as well as hemorrhage.

Thrombophilia is a term that describes the hypercoagulable (prethrombotic) state, which may be due to a familial, congenital, or acquired abnormality that results in a predisposition to thrombosis. *Thrombosis* is a secondary disease process associated with many primary diseases, including immune-mediated hemolytic anemia, hyperadrenocorticism, protein-losing enteropathy, systemic amyloidosis, and canine parvovirus.

Pulmonary thromboembolism (PTE) has been observed in up to 30% of canine cancer patients. A retrospective study of dogs diagnosed with autoimmune hemolytic anemia (AIHA), found evidence of thromboembolism in 20 of 25 dogs necropsied. The type of thrombi that forms depends on local blood flow characteristics. Coagulation, or red, thrombi are primarily made up of red blood cells and fibrin. They occur in areas of slow or occluded blood flow, such as veins. At the other extreme are platelet, or white, thrombi, which form in areas of high blood flow, such as at heart valves. They are composed primarily of platelets and fibrin. Mixed thrombi are an intermediate type found primarily in the pulmonary vasculature.

The clinical signs of a thrombus depend on the organ affected, but they are ultimately due to compromised blood flow to the organ. The thrombus may occlude blood flow locally, or a portion of the thrombus may break free and lodge downstream, where the vessel caliber is smaller and the blood flow slower. Pulmonary thrombosis is associated with acute dyspnea. Renal arterial thromboembolism may be associated with acute renal failure. Detection of thromboemboli is difficult without specialized diagnostic techniques, such as angiography, venography, Doppler ultrasonography, or ventilation-perfusion scintillation scans. The results of routine coagulation tests such as the PT and PTT may be shortened, but they often are within normal limits. For this reason, an awareness of conditions that may result in a hypercoagulable state (e.g., glomerulonephritis) must be kept in mind.

With glomerulonephritis, severe proteinuria may ensue. One of the proteins lost is antithrombin III (AT III), which is about the size of albumin. AT III can be measured in many university and commercial laboratories. AT III levels are a good predictor of the potential for thrombi formation. AT III values between 60% and 75% are associated with an increased risk of thrombosis. Values less than 60% are often associated with irreversible organ damage. Other specialized laboratory tests, such as the chromogenic factor VII assay, platelet aggregation assays, and protein C assay, may be performed is some university coagulation laboratories.

Treatment is directed toward reducing thrombogenesis, in addition to thrombolytic therapy. Reduction of thrombogenesis is achieved with anticoagulant therapy (heparin and warfarin) and reduction of platelet function through the use of platelet inhibitors (aspirin, dipyridamole, and ticlopidine). Thrombolytic therapy includes the use of tissue plasminogen activator (t-PA), streptokinase, or urokinase. Heparin therapy depends on an adequate plasma concentration of AT III. With a low AT III concentration, one or more plasma transfusions may be required for heparin to be effective. Coumadin and other warfarin products inhibit vitamin K–dependent coagulation factors, but they require several days to achieve the desired effect.

274.6 DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC), also called *consumptive coagulopathy,* is the end result of systemic thrombosis. It is a well-recognized clinical syndrome in dogs but is rarely diagnosed in cats. DIC is always a secondary disease. The inciting causes of DIC are the same as those for thrombosis. The primary disease causes widespread thrombosis, which results in the consumption of clotting factors and platelets and initiates uncontrolled fibrinolysis. These disturbances in the coagulation system lead to massive hemorrhage, tissue hypoxia, organ failure, and often death. DIC may be acute and uncompensated or chronic and compensated. Laboratory test abnormalities may vary, depending on the current stage of disease. DIC may be seen in up to 50% of dogs with splenic hemangiosarcoma. Hyperthermia is one of the inciting diseases that may

have a more favorable prognosis, because this condition can be treated fairly rapidly. Death is coming if organ dysfunction from thrombi or anemia secondary to hemorrhage is severe.

The five objectives of the treatment of DIC are: (1) to ensure adequate tissue perfusion, (2) to eliminate the initiating cause, (3) to support target organs susceptible to microthrombi, ischemia, and hemorrhage, (4) to replace blood components, and (5) to provide heparin therapy. 1936 1937

Clinically suspected cases of DIC can be verified by laboratory testing. Typically, the patient's platelet count drops, and the aPTT, PT, and thrombin time (TT) increase. Fibrin degradation products (FDPs) are elevated, and the fibrinogen level is decreased from its previous value. A retrospective survey of 252 dogs diagnosed with DIC showed thrombocytopenia (86%), a prolonged PT (61%), an increased aPTT (92%), an increased TT (32%), and increased FDPs (95%). Interestingly, on examination of red cell morphology, schistocytes were noted in only 10% of the cases.

Traditionally, assays for FDPs were used to diagnose and manage disseminated intravascular coagulation. However, these assays lacked specificity, because they used polyclonal antibodies against fibrinogen, fibrin, and fibrin fragments. They also required serum samples collected in special FDP tubes, because heparin interfered with the test. For these reasons, interest is growing in a newer test, the D-dimer test. D-dimer is a protein formed as a result of plasmin degradation of cross-linked fibrin. During blood coagulation, fibrinogen is converted to fibrin by the action of thrombin. The resulting fibrin monomers polymerize to form a insoluble gel of non-cross-linked fibrin. This fibrin gel is further converted to cross-linked fibrin by thrombin-activated factor XIII to form an insoluble fibrin clot. Production of plasmin, the major clot-lysing enzyme, is triggered by the formation of a fibrin clot. Although fibrin and fibrinogen are both cleaved by plasmin to yield FDPs, only degradation products from cross-linked fibrin contain D-dimer. Therefore an elevated D-dimer level is a specific marker of clot lysis. This test has an extraordinary negative predictive value. In other words, a negative D-dimer test excludes DIC with a confidence level of 99.5%. The test can be run in the clinic by a semiquantitative rapid latex agglutination method using blood samples collected in ethylenediamine tetra-acetic acid (EDTA) or heparin. Although the rapid latex agglutination test lacks the necessary sensitivity for reliable diagnosis of pulmonary thromboemboli, recently a more sensitive enzyme-linked immunosorbent assay (ELISA)-based assay has become available and is showing promise in this area.

275 CHAPTER • 275 Leukocyte Disorders

Charles W. Brockus

Collectively, leukocytes are identified in the peripheral blood as granulocytes (neutrophils, eosinophils, and basophils) and mononuclear cells (monocytes and lymphocytes). These cells actively participate in the innate and adaptive immune system. The activity or morphology of leukocytes can be affected by drug therapy, toxins, infectious organisms, neoplastic disorders, and/or hereditary factors.

Leukocyte disorders occur in dogs and cats, from neonates to aged animals, and cause a variety of clinical features ranging from normal to moribund. In addition, combinations of morphologic and/or functional abnormalities can occur, ranging from unique morphology with no clinical consequence to normal morphology associated with severe clinical signs. Neutrophilic or lymphocytic cell functions are usually impaired in functional abnormalities, and morphologic changes often include all leukocytes.

Most leukocyte disorders are rare and are reported once and/or are observed in a specific breed (e.g., smoke blue Persian cats, gray collies, Jack Russell terriers, Irish setters), implicating a specific hereditary pattern associated with the signalment of the particular breed. The history and physical examination, therefore, often provide important initial information about an abnormality.

Treatment often is unnecessary for morphologic anomalies and is unavailable or impractical for lethal diseases associated with leukocytes. Therefore identification of these anomalies and disorders is important, so as to avoid unnecessary diagnostic testing and treatments.

275.1 PELGER-HUËT ANOMALY

Heterozygous Pelger-Huët anomaly (P-H) is a benign congenital disorder of leukocyte development. It is thought to be transmitted as an autosomal dominant trait in dogs and cats; however, incomplete penetrance has been observed in Australian shepherds.[1,2] The heterozygous form is present in dogs and cats because the homozygous form is lethal *in utero*. The homozygous phenotype is characterized by skeletal abnormalities in rabbits; however, the rare humans with P-H homozygotes appear normal and have survived into their nineties.[1]

The distinguishing cytologic characteristic of P-H is hyposegmentation of nuclei in granulocytes and monocytes in the presence of a fully mature, coarsely clumped chromatin pattern.[1] Nuclear morphology often is variable; the nuclei may be round, oval, dumb-bell shaped, peanut shaped, band, or even bilobate.[1] The bilobate shape consists of two nuclear lobes connected by a fine filament, often referred to as a *pince-nez* or *eyeglass* form nucleus.[1] Careful attention to granulocyte morphology and the presence of hyposegmented nuclei in eosinophils and other cell lines may yield indications of this anomaly. Female Barr bodies are absent or extremely rare in P-H.[1]

Pelger-Huët anomaly has been reported sporadically in both mixed-breed and purebred dogs, including Australian shepherds; cocker spaniels; German shepherds; English-American (Walker) foxhounds; Boston terriers; Australian cattle dogs (blue heelers); border collies; basenjis; black and tan, blue tick, and redbone coonhounds; and Samoyeds.[1] An incidence of 9.8% has been reported for Australian shepherds.[2] P-H has been reported in only eight domestic shorthair cats.[1]

Biochemical assays are normal in P-H dogs, including nitroblue tetrazolium (NBT) dye reduction, hexose monophosphate shunt activity, superoxide generation, chemiluminescence, protein iodination, phagocytosis, and bactericidal activity.[1]

Cytochemical staining with Sudan black B, naphthol ASD chloracetate esterase, peroxidase, alkaline and acid phosphatase, alpha-naphthyl-acetate esterase, and periodic acid–Schiff (PAS) has not detected abnormalities in dog neutrophils.[1]

Ultrastructurally, nuclear changes associated with P-H include nuclear hyposegmentation, nuclear clefts, coarse heterochromatin, and normal cytoplasmic granules.[1]

275.1.1 Hematologic Manifestations

Hematologic manifestations of P-H often are reported as a persistent degenerative left shift without toxic changes. These findings are unexpected on a routine complete blood count (CBC) from a clinically normal animal.[1] Earlier precursors, such as myelocytes, metamyelocytes, and bands, may be reported; however, the chromatin of these cells is fully matured (well clumped).[1] Because P-H often is confused with a degenerative left shift, it is of practical importance that the anomaly be recognized. Unnecessary, expensive, and potentially invasive laboratory tests and treatments can be avoided with proper diagnosis. Many dogs are treated with a variety of antibiotics without response because of this suspected degenerative left shift. A veterinary clinical pathologist can assist in the diagnosis of P-H.

P-H must be differentiated from pseudo–P-H, which often is a transiently acquired condition that resolves with proper diagnosis and treatment.[1] Pseudo–P-H has been associated with a number of diseases, including various forms of leukemia and preleukemic conditions, and with drug therapy, such as with antineoplastic drugs and ibuprofen.[1] Drug-associated changes are idiosyncratic and resolve after treatment is withdrawn.

275.1.2 Treatment

Treatment of P-H is not necessary because neutrophil function is not altered.

275.2 CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome (CHS) is a rare inherited autosomal recessive trait found in humans; beige mice; rats; Arctic foxes; a killer whale; Hereford, Japanese black, and brangus cattle; mink; and smoke blue Persian cats.[3–5] This syndrome has not yet been identified in dogs.

CHS is typically characterized by partial oculocutaneous albinism, photophobia, neurologic abnormalities, bleeding abnormalities, and recurrent infections, which generally result in death at an early age.[3] Some researchers have not observed an increased tendency to develop infections in CHS cats, but a colony of CHS cats demonstrated neonatal kittens that were markedly more susceptible to infections (bacterial, viral), and some died from hemorrhage, which contributed to a lower average survival time compared with normal cats.[6] Susceptibility to bacterial infections is associated with multiple defects in the defense system. Neutropenia occurs as a result of impaired marrow release of mature neutrophils. Defective intracellular killing of phagocytosed bacteria also is a factor.[3]

Persian cats with the hereditary genes for CHS have a “blue smoke” coat color that is lighter than the blue smoke coats of Persian cats without CHS.[4] Ocular abnormalities also are present, such as photophobia and lighter irises (light green, light yellow, or light yellow-green). Many affected cats also have congenital cataracts and a red fundic light reflection (compared to the yellowish green of normal Persian cat fundi), as well as less fundic pigmentation.[4] Tapetal regions may not be apparent, and the underlying choroidal vasculature is only partly visible.[4] The tapetal defect is associated with tapetal rod degeneration in tapetal cells in 2-to 4-week-old kittens.[3] Abnormal auditory brain stem responses have been the only neurologic abnormalities identified in CHS cats.[7]

Although the gene abnormality associated with CHS has not been identified in cats, it has been defined as the homologous *beige* gene in mice and humans, which is a 5 kilobase pair deletion.[3] The function of this gene is unknown.[3] CHS was hypothesized to be caused by microtubular formation abnormalities, but this has been disproven.[3]

275.2.1 Hematologic Manifestations

Hematologically, neutrophils, eosinophils, and basophils contain enlarged, lightly eosinophilic cytoplasmic granules that can be observed with Wright's staining (Romanowsky stain).[3] Occasionally, monocytes and lymphocytes may contain a single eosinophilic cytoplasmic granule.[3] Histologically, melanocytes in hair shafts contain enlarged melanin granules, and renal tubular epithelial cells contain enlarged granules.

Prolonged bleeding times (three times normal), manifested as hematomas after surgical procedures, are the result of a platelet storage pool defect (SPD). Impaired platelet aggregation associated with a virtual absence of adenosine diphosphate (ADP) and serotonin (dense granules) may account for the abnormal aggregation.[3] Platelet counts and coagulation times (prothrombin time [PT] and partial thromboplastin time [PTT]) are within reference intervals.[4]

275.2.2 Diagnosis

A presumptive diagnosis can be made by observation of a Persian cat with a light blue smoke color, lightly colored irises, red fundic reflection, depigmented fundic area, and bleeding tendencies.[4] Also, a hair shaft examination can be performed. Hair is extracted from a cat suspected of having CHS and from a normal cat. The hair shafts are placed on a microscopic slide, immersion oil is added, and a cover slip is gently pressed over the hair shafts.[4] Examination under low or high dry power reveals that, unlike the normal hair shaft, the hair of the CHS cat shows enlarged, clumped melanin granules.[4]

With Romanowsky staining, CHS cytoplasmic granules in neutrophils appear as light eosinophilic inclusions that must be differentiated from Döhle bodies associated with neutrophil toxicity.[4] If the composition of the granules is in question, the differentiation can be made using peroxidase staining (CHS granules stain black).[4]

275.2.3 Treatment

Cats with CHS do not require continuing treatment; however, great care should be taken to control hemorrhage due to the platelet SPD and prolonged bleeding times. Platelet transfusions can temporarily

correct the bleeding time if surgical procedures are to be performed.[3] Long-term correction of neutrophil and platelet function in CHS is possible only through bone marrow transplantation (BMT).[3] BMT performed in cats has corrected the neutrophil and platelet defects, but no effect has been seen on lysosome distribution in liver or kidney cells.[3] Neutrophil function improves temporarily after treatment with recombinant canine granulocyte-colony stimulating factor (rcG-CSF) or interleukin-2 (IL-2) in cats.[3]

Although the blue smoke coat color is quite beautiful in Persian cats with CHS, this is an undesirable trait to propagate. Breeders should be counseled against using affected cats or carrier cats, which are phenotypically normal. Because CHS is an autosomal recessive trait, both the sire and dam that produce offspring affected with CHS are obligate carriers and should be removed from the breeding stock. Administration of drugs that affect platelet function, such as cyclo-oxygenase inhibitors, is contraindicated in CHS cats.[3]

1938

1939

275.3 CANINE LEUKOCYTE ADHESION DEFICIENCY

Canine leukocyte adhesion deficiency (CLAD) is a fatal defect inherited as a homozygous autosomal recessive trait in Irish setters and rare Irish setter–cross-breed dogs. It is characterized by a defect in neutrophil adhesion and function. Heterozygous dogs appear healthy in all respects. Initially, this trait was reported in 1975 as canine granulocytopathy syndrome.[8] An Irish setter had persistent soft tissue infections, lymphadenopathy, omphalophlebitis, gingivitis, and persistent profound leukocytosis (primary neutrophilia).[8]

A 1987 case report identified an Irish setter–cross that did not express leukocyte Mo1, leukocyte function–associated antigen-1 (LFA-1), or Leu M5 glycoproteins using CD11/CD18 antibodies, indicating a common beta$_2$-integrin subunit disorder.[8] A defect in neutrophil chemotaxis, induced aggregation, and phagocytosis of opsonized particles also were detected in this dog.[5]

275.3.1 Clinical Features

Clinical, radiologic, and pathologic information was obtained from a study of 12 Irish setter puppies 8 to 15 weeks of age from six different litters.[9] These dogs presented with generalized lymphadenopathy, gingivitis, salivation, skin lesions (ulcers and local dermatitis), generalized pain, weakness, recurrent fever, vaginitis, poor weight gain, anorexia, emaciation, furunculosis (without the formation of a neutrophilic exudate), dull haircoat, and lameness with bone lesions (thickened mandibula, distal radius, ulna, tibia, and fibula). All the dogs in the study were euthanized and underwent postmortem examination. Histopathology of affected tissues showed a lack of neutrophil infiltration (impaired neutrophilic exudate formation).[9] CLAD dogs do not respond well to antibiotic therapy and thus rarely live beyond 6 months.[9]

275.3.2 Pathologic Features

Neutrophils in dogs with the homozygous form of this hereditary trait have a deficiency of leukocyte surface glycoproteins associated with leukocyte adherence and egress into surrounding tissues.[8,9] These cells appear morphologically normal by light microscopy. Dogs present within weeks of birth with associated clinical signs.

The family of glycoproteins referred to as beta$_2$-integrins (CD11/CD18) consist of alpha subunits (CD11a, CD11b, CD11c, CD11d) noncovalently bonded with a common beta subunit (CD18).[10] These subunits make

up CD11a/CD18 (LFA-1; $\alpha_L\beta_2$), CD11b/CD18 (Mac-1/Mo-1; $\alpha_M\beta_2$), CD11c/CD18 (gp 150,95; $\alpha_X\beta_2$), and CD11d/CD18 ($\alpha_d\beta_2$) cell surface receptors.[1] CD8 glycoprotein is critical to formation of the integrin heterodimers for cell-cell adhesion events.[8,10,11] In addition, beta$_2$-integrin heterodimer CD11b/CD18 serves as major receptor for C3b opsonic complement and is necessary for phagocytosis and respiratory burst activation. Heterozygous dogs have normal expression of CD11b/CD18. Failure to express beta$_2$-integrin CD18 is the reason neutrophils are unable to adhere to vascular endothelium and transmigrate in response to released chemotactic factors in inflamed tissues. Because neutrophils cannot adhere to the endothelium, they do not reach the site of infection or inflammation. Recruitment signals from infected or inflamed tissues continue to cause the release of cytokines, stimulating granulocytopoiesis (production and release of neutrophils). Continued marrow stimulation and inability of neutrophils to adhere result in a persistent leukocytosis (primarily neutrophilia) that occasionally is greater than 100,000/μL.[10] Neutrophil function also was found to be altered by defective bactericidal activity, reduced glucose oxidation by the hexose monophosphate shunt, and increased capacity to reduce NBT dye.[5]

The presence of a single nucleotide missense mutation, resulting in failure to express detectable beta$_2$-integrin CD18, is responsible for clinical disease in Irish setters.[10] CD11b also is absent in affected Irish setters, but CD11c expression was not different from that in control dogs. Whether CD11b is absent because of lack of expression or because of the absence of CD18 is unknown.[11]

275.3.3 Diagnosis

An oligonucleotide ligation assay (OLA), which detects the missense mutation of CD18, was developed to identify carriers of this lethal gene.[12] In one study, screening of 208 Irish setters in the United Kingdom identified 19 carriers, or a 9% carrier rate.[12] This mutation has not been detected in any other breed in which OLA screening was performed.[10] Another study that tested 339 Irish setters from 10 countries (Scandinavia, continental Europe, and Australia) using a newly developed pyrosequencing technique to identify a single mutation in the beta$_2$-integrin gene (CD18) gene, supported the previous single mutation concept found with OLA.[12] The pyrosequencing technique identified 72 heterozygous carriers, as well as two homozygous dogs, which eventually developed CLAD.[12] The pyrosequencing technique also identified carriers and indicated widespread presence of the disorder in many countries.[12] Genetic testing using pyrosequencing can identify heterozygous dogs for removal from breeding lines. Recently, a case of CLAD in an Irish setter–cross was identified using polymerase chain reaction (PCR) testing, and carrier status was identified during a PCR survey in a number of distantly related red and white setters.[8] This PCR detection test identified the same mutation in all CLAD dogs previously tested.[8]

275.3.4 Treatment

No effective treatment has been found for this disorder.

275.4 CYCLIC HEMOPOIESIS

Cyclic hemopoiesis (CH), also known as *cyclic hematopoiesis, cyclic neutropenia,* or *gray collie syndrome,* is a lethal, autosomal recessive, hereditary disease of gray collies associated with a dilute haircoat. The condition was

first described in the 1960s as the "lethal gray syndrome," and a similar disorder is still called cyclic neutropenia (CN) in human medical texts. CH is a unique disease that affects the marrow pluripotential stem cell; it disrupts normal hemopoiesis, an effect characterized by cyclic changes in neutrophil, monocyte, platelet, eosinophil, and reticulocyte numbers.[13] Heterozygous dogs have a normal coat color and do not have clinical signs of CH.

275.4.1 Hematologic Manifestations

Marked neutropenia that occurs in cycles of 12 to 14 days is associated with severe recurrent bacterial infections at the nadir.[13] Neutrophils may be completely absent from the peripheral circulation for 2 to 4 days, an interval followed by neutrophilia as high as 70,000/μL.[13] Monocytes, eosinophils, lymphocytes, and platelets also cycle at 14-day intervals with normal to high cell counts but are out of phase with neutrophils with absent to high fluctuating cell counts.[13,14] Interestingly, hemopoietic growth factors such as erythropoietin, thrombopoietin, granulocyte colony-stimulating factor (G-CSF), IL-1, and IL-6 concentrations also fluctuate in this disorder.[13] A microcytic, normochromic anemia is present on the CBC.

1939

1940

Changes in marrow aspirates, which occur in an alternating myeloid to erythroid ratio pattern, precede changes in the peripheral cell counts, suggesting a marrow stem cell disorder.[13]

275.4.2 Clinical Features

CH dogs all have gray or diluted coat color, often are smaller than littermates at birth, and usually present at 6 to 8 weeks of age with recurring episodes of neutropenia, accompanied by clinical signs such as fever, gingivitis, gingival ulcers, lymphadenopathy, excessive bleeding, pneumonia, ocular and nasal mucopurulent discharge, diarrhea, subcutaneous abscesses, conjunctivitis, keratitis, adenitis, anorexia, weight loss (malabsorption), lethargy, and intermittent lameness.[13,15] Neonatal deaths may result from omphalophlebitis or pneumonia.[13] Younger dogs with CH often die of overwhelming infection; those housed in a laboratory setting often die of hepatic and renal amyloidosis associated with organ failure.[15] Systemic amyloidosis is a prominent feature in CH and has been found in dogs as young as 8 weeks old; nearly 100% of dogs older than 30 weeks are affected.[14] Organs affected include the kidneys, liver, spleen, pancreas, adrenal glands, and intestinal submucosa.[15] Amyloidosis has been attributed to cyclic activation of the acute-phase response by cytokines produced during periods of monocytosis, with interrelated hormonal, immune, and endocrine interactions.[13] Serum amyloid A protein, as well as fibrinogen, von Willebrand factor, and other acute-phase proteins, are produced and circulated during the monocytosis.[13] Rarely do affected gray collies reach sexual maturity.[15]

275.4.3 Pathologic Features

The definitive pathogenesis of CH in gray collies is unknown; however, impaired marrow progenitor cell survival in CN in humans has been observed, and a defect in G-CSF signal transduction has been suggested.[16,17] In addition, ultrastructural, genetic, and molecular studies in humans with CN suggest that the disorder is due to mutations in a neutrophil azurophilic (primary) granule enzyme, neutrophil elastase (ELA-2).[16,17] A 75% decrease in early myeloid-committed colonies associated with accelerated spontaneous apoptosis was observed compared with controls. It was concluded that ineffective production of neutrophils is due to accelerated apoptosis of bone marrow progenitor cells, with conformational changes in protein structure

resulting in alterations in subcellular functions or substrate specificity and/or binding properties of neutrophil elastase.[16]

Although the hereditary pattern of CN is autosomal dominant in humans and autosomal recessive in gray collies, similar marrow and genetic changes may occur, but this remains to be proved.

CH in gray collies appears to be a hormonally inter-related disease with wide fluctuation of cytokines and responsive changes in the marrow. Furthermore, CH can be transferred to healthy dogs by BMT, which supports the theory of a disorder of the pluripotential stem cell.[13]

CH dogs also have a platelet storage pool disease characterized by a lack of dense granules (serotonin and Ca^{+2}), resulting in aggregation defects; however, prolonged bleeding times have not been reported.[13] Administration of rcG-CSF corrects the hemopoietic fluctuations but does not correct the SPD, which suggests that these defects are not secondary to CH.[13]

275.4.4 Treatment

Fluctuations of all cell lines resolve in CH dogs treated with rcG-CSF, with neutrophilia occurring at higher doses.[14] Also, recombinant canine stem cell factor (rcSCF) at high doses (i.e., equal to or greater than 20 µg/kg/24 hours) eliminated neutropenic periods and blunted oscillations, but neutrophilia only occurred at doses of 100 µg/kg/24 hours.[18] Treatment with a combination of rcSCF (20 to 50 µg/kg/24 hours) and rcG-CSF (0.5 to 1.0 µg/kg/24 hours) indicated a synergistic effect, with neutrophil counts above those of either drug given separately.[18] Long-term therapy was effective without untoward side effects. The risk of neutralizing antibody formation can arise with chronic administration of recombinant human G-CSF (rhG-CSF).[13] Early BMT eliminates cell cycling and produces a clinical cure. Treatment with lithium or endotoxin injections eliminates cell cycling, but unwanted side effects can occur. Administration of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3 administration are mildly effective but do not prevent cycling. Glucocorticoids, androgens, and intravenous gamma globulin are ineffective at treating this condition.[14,15,18]

CH is a highly undesirable trait in collies. Because it is an autosomal recessive trait, both the sire and dam that produce affected offspring are obligate carriers and should be removed from the breeding stock. Heterozygous dogs are phenotypically normal, therefore breeders should be counseled against using carriers. Laboratory tests are not available, and test mating is the only method of identifying carriers. Gray collies may not appear at every breeding; therefore, for a dog to be declared free of this trait, it must be mated with a known heterozygote and produce 16 normal pups. This is both expensive and impractical.

Normal canine neutrophil elastase deoxyribonucleic acid (DNA) sequence has been reported, and studies are ongoing to determine if the ELA-2 gene in CH has mutations similar to those in humans with CN. A PCR test may be developed, and a more practical, inexpensive test to identify heterozygous dogs may be offered. Testing has been done only on humans affected with CN and has not been used to identify carriers of this trait.

275.5 BIRMAN CAT NEUTROPHIL GRANULATION ANOMALY

Birman cats are an exotic, long-haired breed with Siamese-type coloring and four distinctive white paws. Neutrophil granulation anomaly is a hereditary trait characterized by increased granularity of neutrophils. It is

transmitted in an autosomal recessive manner in purebred Birman cats.[5,19] The cytoplasm of affected neutrophils contains numerous fine, normal-sized, deep pink to purple granules that appear similar to azurophilic granules found in promyelocytes. Neutrophil function is not compromised.[19] Normally, azurophilic granules become indistinct with Romanowsky stain in the myelocyte stage of development but seem to persist throughout the maturing process in this anomaly.[19]

Ultrastructurally, granules are elongated and dumb-bell shaped and do not stain for mucopolysaccharides. Bactericidal activity is no different from that of unaffected neutrophils, and other peripheral leukocytes appear morphologically normal.[19] Neutrophilic cytoplasmic granules observed in cats with certain mucopolysaccharide storage diseases (MPS types VI and VII) appear larger.[19] The abnormality therefore was concluded to be an alteration in the contents of cytoplasmic granules, with increased affinity for acid dyes without clinical consequences.[19] Treatment is not necessary, because functional abnormalities are not noted. The main concern is to differentiate this anomaly from MPS (types VI and VII) and toxic granulation.[5] A study of 78 highly inbred Birman cats found that 46% of the cats were affected.[19]

275.6 HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome (HES) is a disease of unknown origin that occurs primarily in cats. It is questionable whether the disorder occurs in dogs, although one case of disseminated eosinophilic disease similar to idiopathic HES was recently reported.[20] Characteristics of this disease are persistent peripheral eosinophilia and organ infiltration by eosinophils, which eventually cause organ failure and death.[21,22] The bone marrow, spleen, liver, mesenteric lymph nodes, and gastrointestinal tract were the organs reported to contain eosinophilic infiltrates most frequently.[21,22] Difficulty arises in distinguishing between HES and eosinophilic leukemia (EL), because the two conditions may be variants of the same disease.[21] In one study, a female predisposition for HES was reported in cats (male to female ratio of 4:11).[21]

275.6.1 Hematologic Manifestations

The presentations of HES and EL are similar. Peripheral blood eosinophil examination and bone marrow aspiration may be helpful in differentiating the disorders. With EL there often are more immature eosinophils in the peripheral blood, which results in a more severe anemia. The myeloid to erythroid (M:E) ratio in bone marrow is greater than 10:1.[21,22] Peripheral eosinophil counts in HES range from 3500/μL to 130,000/μL, and the cells appear mature. Occasionally, mild anemia also is present.[21,22]

275.6.2 Clinical Features

Clinical signs, which are relatively nonspecific and vary with the organ or organs affected, include diarrhea, weight loss, anorexia, pyrexia, and pruritus.[21,22] It is difficult to establish the longevity of cats with HES; however, some cats may have exhibited clinical signs related to HES for 3.5 years.[22]

275.6.3 Physical and Pathologic Features

Physical findings are variable and include thickened bowel loops, abdominal masses, lymphadenopathy, and/or cutaneous disorders. As mentioned previously, the organs most commonly infiltrated with eosinophils are the bone marrow, gastrointestinal tract, spleen, mesenteric lymph nodes, and liver, but any organ can be affected.[21,22]

275.6.4 Treatment

HES is a progressively fatal disease that has no effective treatment. However, Gleevec (imatinib mesylatem, formerly STI571) has been used in humans with excellent results. Corticosteroids, hydroxyurea, and alpha interferon also have been used in humans with variable results; however, when these drugs are effective, unwanted side effects are common.

275.7 SEVERE COMBINED IMMUNODEFICIENCY IN JACK RUSSELL TERRIERS

Severe combined immunodeficiency (SCID) was recently described as an autosomal recessive trait in a litter of Jack Russell terriers. Twelve of 32 siblings died of opportunistic infections between 8 and 14 weeks of age.[23] An additional litter was whelped, and four of seven pups displayed SCID, characterized by lymphopenia, agammaglobulinemia, thymic dysplasia, and peripheral lymphoid aplasia.[23] A deficiency of DNA-dependent–protein kinase catalytic subunit (DNA-PKcs), an enzyme involved in DNA repair, occurs.[23] DNA-PKcs deficiency results in faulty V(D)J recombination.[23] Combinations of the V(D)J gene segment recombinations are very important for diversification of antigen-binding sites of antibodies.[23] Blocking of this V(D)J recombination arrests lymphocyte development at the prolymphocyte stage; the result is nonfunctional B and T lymphocytes, agammaglobulinemia and, consequently, SCID.[23]

275.7.1 Treatment

Bone marrow transplantation is the only option; however, gene therapy appears promising for future treatment.

275.8 CANINE X-LINKED SEVERE COMBINED IMMUNODEFICIENCY

Canine X-linked severe combined immunodeficiency (X-SCID) is an autosomal recessive, lethal, inherited trait with some unique modes of inheritance. Female carriers of the X-SCID gene typically appear normal. They contain only one copy of the γc gene and are unable to produce normal protein, but they have a second “normal” gene that produces adequate protein for normal function.[24] Because males retain only one copy of the X chromosome, they cannot produce normal protein when the abnormal gene is inherited, and thus are affected. Because transmission of only one X chromosome is necessary for this trait to appear, carrier females need not breed with an affected male.[24]

275.8.1 Clinical Features

Affected dogs are male, fail to thrive, and present with recurrent or chronic infections near the time of waning maternal antibodies.[24] Clinical signs are more evident as the pups get older. Recurrent infections, which begin around 6 to 8 weeks of age, include pyoderma, diarrhea, and respiratory infections.[24] Infections are usually bacterial, are unresponsive to antibiotics, and eventually become overwhelming systemic infections.[24] These dogs rarely survive beyond 3 to 4 months of age and usually die of a generalized staphylococcal infection.[24] Several X-SCID dogs, inadvertently vaccinated with a modified live distemper virus vaccine, died rapidly of vaccine-induced distemper.[24] One dog raised in a gnotobiotic environment developed acute monocytic leukemia at 20 months of age.[24]

275.8.2 Pathologic Features

A small, dysplastic thymus that weighs about 10% that of age-matched controls is the primary feature of X-SCID dogs.[24]

275.8.3 Immunologic Abnormalities

Although X-SCID dogs have reduced lymphocyte counts, profound lymphopenia is not a prominent finding (counts commonly are greater than 1000/μL).[24] When tested by fluorescence-activated cell sorting (FACS) analysis, newborn X-SCID dogs have peripheral lymphocyte phenotypes consisting of elevated B cells and markedly reduced or absent T cells.[24] Absolute numbers of peripheral T cells are decreased even though the relative percentages are normal.[24] The T-lymphocyte blastogenic response to T-cell mitogens and specific antigens is markedly depressed to absent.[24] X-SCID dogs also are hypogammaglobulinemic. Concentrations of immunoglobulin M (IgM) are normal, but IgG concentrations are dramatically reduced, and IgA antibodies are absent.[24]

275.8.4 Treatment

Bone marrow transplantation is the only treatment option for complete resolution of this disorder in dogs; however, gene therapy may be promising in the future. Transplantation has been attempted with some success, but these dogs developed cutaneous papillomas within 1 year.[24] An understanding of the hereditary and genetic basis of X-SCID and proper client and breeder counseling are highly recommended to control or eliminate this disorder in future generations.

1941

1942

275.9 DEFECTIVE NEUTROPHIL FUNCTION IN THE DOBERMAN PINSCHER

Eight intensively line-bred Doberman pinschers developed chronic respiratory disease (rhinitis and pneumonia) and occasional skin disease (seborrhea sicca).[25] In all the dogs, neutrophils were normal in number and appearance.[24] The neutrophils were found to have normal phagocytosis but defective bactericidal activity, as determined by the NBT test.[25] Immunoglobulins were normal to increased; lymphocyte function was normal for the mitogens in seven of eight dogs; neutrophil chemotaxis was normal; and complement C_3 concentrations were

increased. Superoxide production was normal, except that opsonized zymosan stimulation produced less superoxide than in controls.[25]

275.9.1 Treatment

Many of these dogs survived for years and responded well to intermittent antibiotic therapy for recurrent bacterial infections of the respiratory tract.[25] The mode of inheritance was not determined due to inadequate pedigree and documentation.[24] The actual cause of the disorder was not determined. The condition somewhat resembles chronic granulomatous disease (CGD) or C_3b receptor deficiency in humans, but those diseases are usually life-threatening, unlike the disease in these Dobermans.[25]

275.10 LETHAL ACRODERMATITIS IN BULL TERRIERS

Lethal acrodermatitis in bull terriers is an autosomal recessive, inherited lethal trait with similarities to lethal trait A46 in Black Pied Danish cattle and acrodermatitis enteropathica in humans.[26]

275.10.1 Clinical Features

Lighter pigmentation at birth, growth retardation, progressive acrodermatitis, chronic pyoderma, chronic paronychia, diarrhea, pneumonia, and behavioral changes are observed on presentation, with historical evidence of deglutition and disordered mastication.[26] Behavioral changes include early aggressiveness, diminished activity, and prolonged staring at objects. These dogs have a median survival time of 7 months.[26] Laboratory findings include neutrophilia, consistently low alkaline phosphatase (observed in zinc deficiency) and alanine aminotransferase activities, low serum zinc concentrations, and frequent hypercholesterolemia.[26]

275.10.2 Pathologic Features

Skin lesions include parakeratosis, hyperkeratosis, and pyoderma. T-lymphocyte numbers were significantly reduced in lymphoid tissues.[26] Lymphocyte blastogenesis responses were decreased, and dysgammaglobulinemia was present.[26] Neutrophilic, phagocytic, and bactericidal activities were normal.[26]

275.10.3 Treatment

No effective treatment has been described. The response to high-dose zinc supplementation was poor.[26]

275.11 IMMUNODEFICIENCY OF SHAR PEIS

Immunodeficiency of Chinese Shar Peis is a recently described, late-onset, multiple immunodeficiency syndrome involving antibody and cell-mediated responses of unknown origin associated with recurrent infections and malignancy.[27]

275.11.1 Clinical Features

The mean age of clinical onset was 3 years (range, 4 months to 8 years).[27] The clinical presentation involves several organ systems and includes intermittent fever, recurrent skin infections, respiratory infections, and gastrointestinal abnormalities, including ulcerative colitis. Several dogs developed intestinal adenocarcinoma, lymphoma, and paracortical lymphocyte depletion.[27]

275.11.2 Immunologic Manifestations

Deficiencies in immunoglobulin concentrations, specifically IgM, IgA, and occasionally IgG, were identified.[27] B-and T-cell abnormalities were observed in affected dogs, including deficiencies in lymphocyte proliferation that occurred concurrently with normal or increased percentages of T-and B-cell lymphocytes, decreased median stimulation index of blastogenesis, and decreased *in vitro* responsiveness of peripheral blood mononuclear cells to pokeweed mitogen.[27] Also, when serum from affected Shar Peis was added to cell cultures from normal dogs, a suppressive effect was seen.[27]

Even with the variety of clinical presentations, nearly all affected dogs were characterized by a common deficiency involving cell-mediated and immunoglobulin deficiencies.[27]

275.11.3 Diagnosis

Assessment of the immunologic profile, along with the signalment, history, and clinical data, helps identify affected Shar Peis. However, given the high prevalence of healthy Shar Peis with low IgA concentrations, this finding alone cannot identify affected immunodeficient dogs.[27]

275.11.4 Treatment

Supportive care is the current treatment and should be given until the cause of this disorder can be completely classified.

275.12 IMMUNODEFICIENCY OF WEIMARANERS

Weimaraners affected with immunodeficiency have been reported, including an initial inbred group with thymic abnormalities and growth hormone deficiency.[28] Many other weimaraners subsequently were described with *in vitro* neutrophil abnormalities and decreased IgG and IgM.[29] One dog also had neutrophilic phagocytic dysfunction.[30] Affected weimaraners present with varying but recurrent infections that occasionally respond to antibiotics, but these dogs often die of recurrent infections within a year. Inbreeding has not been noted except in the original thymic deficiency group; however, one sire was implicated in five affected dogs (including two pairs of litter mates) and also was the grandsire of two other affected dogs.[31] Siblings of this dog also produced two affected dogs.[31] Obvious genetic associations are present, and many abnormalities have been identified, but no single specific disorder. The recurrent nature of this disorder may indicate a periodicity to the defect, which potentially makes specific detection difficult.[31]

275.12.1 Clinical Features

Weimaraners are presented for veterinary care between the ages of 3 and 42 months (average age is 10 months). Body condition and size are normal, but the dog has a variety of disorders, including acute onset of high fever; profound depression; vomiting; diarrhea; pain in the joints, spine, or abdomen; lymphadenopathy; bleeding tendencies, mainly in the form of epistaxis; hematemesis; melena; hematochezia; hematuria; dacryohemorrhysis (bloody tears); marked congestion and ulceration of mucous membranes; conjunctivitis; pedal pyoderma; recurrent subcutaneous masses thought to be associated with subcutaneous injection sites; and neurologic signs (ataxia, disorientation, head pressing, seizures and Horner syndrome). Episodes of sickness occur every 2 weeks to 7 months, with clinically normal intermediate periods or incomplete recovery. The recurring episodes of clinical illness often respond rapidly to antibiotics and/or corticosteroids but eventually become unresponsive, and death usually occurs within 1 year.[31]

1942 1943

275.12.2 Hematologic Manifestations

Leukocytosis is observed, ranging from 31,000/μL to 64,200/μL, with a distribution of 72% to 92% neutrophils (mature and immature).[31] White blood cell (WBC) counts between episodes are normal or mildly elevated. Normal WBC morphology is observed by light and electron microscopy. Clotting times are within reference interval.[31]

275.12.3 Immunologic Manifestations

In the dogs studied, significant abnormalities were not noted in metabolic or phagocytic function, but glucose oxidation showed high resting levels consistent with an infection at the time of testing.[31] A single case report identified decreased neutrophil phagocytosis using opsonized *Escherichia coli* labeled with fluorescein isothiocyanate.[30] Other *in vitro* testing revealed decreased neutrophil chemoluminescence and decreased IgG and IgM concentrations.[29]

275.12.4 Diagnosis

A presumptive diagnosis is based on recurrent presentation of a young weimaraner that becomes progressively less responsive to treatment. Specific testing to identify diseased individuals is not available. Test mating, with careful evaluation and observance of the progeny for immunologic abnormalities, may be the only way to identify a defect.

275.12.5 Treatment

Supportive care has been the only treatment used. Bone marrow transplants have not been attempted.

275.13 LYSOSOMAL STORAGE DISEASES

Many lysosomal storage diseases (LSDs) have been identified in dogs and cats; however, all are rare, and only a few present with microscopic abnormalities in peripheral blood leukocytes. Only the observable leukocyte

morphologic changes are discussed. Specific leukocyte activity has not been tested, but delineation of microscopic characteristics may be a simple method of identifying and/or classifying many storage diseases.

Hematologic alterations in the leukocytes of dogs and cats are associated with sphingomyelinosis (Niemann-Pick disease); alpha-mannosidosis; mucopolysaccharidosis (MPS) I, VI, and VII; GM_1-gangliosidosis; GM_2-gangliosidosis; and fucosidosis.

Leukocytes in MPS I, VI, and VII must be differentiated from toxic changes in neutrophils and from Birman cat neutrophil granulation anomaly.

Sphingomyelinosis has been reported in Siamese, Balinese, and domestic shorthair cats, as well as in boxer dogs and a miniature poodle. The disease is caused by a deficiency of sphingomyelinase, which results in accumulation of sphingomyelin, cholesterol, and gangliosides in the brain, liver, spleen, and bone marrow. Large, vacuolated macrophages may be observed in the peripheral blood.

Alpha-mannosidosis, reported in Persian, domestic shorthair, and domestic longhair cats, is caused by a deficiency of alpha-mannosidase, which leads to accumulation of mannose oligosaccharides in the central nervous system, skeleton, and spleen. Lymphocytes, granulocytes, and monocytes in peripheral blood appear vacuolated.[32]

MPS I occurs in Plott hounds, other breeds of dogs, and domestic shorthair cats. This LSD is caused by a deficiency of alpha-L-iduronidase. Some observers have reported small, pink granules in neutrophil cytoplasm.[33]

MPS VI is reported in Siamese cats and in miniature schnauzers, miniature pinschers, and Welsh corgis. This LSD is caused by a deficiency of arylsulfatase. Peripheral neutrophils, lymphocytes, basophils, eosinophils, and monocytes are affected. The cytoplasm of neutrophils often appears foamy and contains uniform small, metachromatic granules, often within a vacuole.[32] Lymphocytes in MPS VI have been divided into three distinct types: normal appearing, those containing vacuoles with small, dark, metachromatic granules; and a few containing empty vacuoles.[32] Nearly all monocytes contain vacuoles, and a moderate percentage have dark granules in these vacuoles.[32] Eosinophils contain cytoplasmic vacuoles, and basophils contain large, reddish purple cytoplasmic inclusions or granules.[32] Basophils have the largest granules.[32]

MPS VII, reported in the dog and domestic shorthair cat, is caused by a deficiency of beta glucuronidase. Neutrophils and lymphocytes contain deep purple cytoplasmic inclusions that should not be confused with toxic changes. Granules stain purple with toluidine blue dye.[33]

GM_1-gangliosidosis has been reported in domestic shorthair, Korat, and Siamese cats, as well as in English springer spaniels, Portuguese water dogs, beagles, and Alaskan huskies. It is caused by a deficiency in beta galactosidase. Lymphocytes contain small, distinct, clear cytoplasmic vacuoles.[33]

GM_2-gangliosidosis, reported in domestic shorthair and Korat cats and in German shorthaired pointer dogs, is caused by a deficiency of beta hexosaminidase. Neutrophils contain dark blue granules, and lymphocytes contain prominent azurophilic cytoplasmic granules.[33]

Fucosidosis of English springer spaniels is caused by a deficiency of alpha-L-fucosidase. The lymphocytes of these dogs contain cytoplasmic vacuoles.[33]

276 CHAPTER • 276 Non-Neoplastic Diseases of the Spleen

Helio Autran de Morais

Robert T. O'Brien

"Spleen is like the tongue of an ox [or] the sole of the foot; slightly bowed out on the left side, a little concave on the inner side, toward the stomach. It has an uneven surface and is a little rough with some tubercles …"

"Similarly [according to] other physicians the spleen [is] the receptacle of melancholy as the gall bladder of gall; wherefore the spleen causes one to laugh."

William Harvey (1653)

For many years, the ability to laugh was considered a sign that the spleen was working well. Regarded as the repository of the most noxious substance of the body, black bile (in Greek, *melanos kholis*), the spleen prevented the onset of melancholia by containing the bodily fluid that produced this mental state. Our understanding of the spleen has greatly improved over the past centuries. However, evaluation of this organ remains mostly morphologic, based on palpation, radiographs and, especially, ultrasound examination, followed by cytology or histopathology. No biochemical tests have been designed to assess splenic function. Consequently, although splenomegaly is common in clinical practice, it often is hard to isolate the cause.

276.1 PREVALENCE OF SPLENIC DISEASE IN DOGS AND CATS

The prevalence of splenic disorders in dogs and cats cannot be easily estimated. Splenomegaly may be asymptomatic, and in the absence of splenomegaly, it is difficult to determine, on the basis of clinical signs, that the spleen is responsible for the animal's condition. Most prevalence studies in dogs and cats are based on either necropsy or biopsy findings. Necropsy-based studies overestimate diseases with a poor prognosis or with no clinical relevance. Diseases that are treated by surgery are overestimated in prevalence studies based on biopsies but are underestimated in prevalence studies based on necropsy data. This might explain the absence of hemangiosarcoma and the low ratio of hemangiosarcoma to hematoma in necropsy studies in dogs. Based on biopsy samples submitted to a regional diagnostic laboratory from 1372 dogs[1] and 455 cats,[2] spleen samples from dogs represented 1.3% of all submissions, and spleen samples from cats represented 0.3%. However, these percentages do not represent true prevalence, because biopsies from all species were included in the total submission number.[1]

In two necropsy surveys, non-neoplastic diseases represented approximately 50% of feline splenic disorders.[2,3] Congestion, lymphoid hyperplasia, capsulitis, extramedullary hematopoiesis, and hyperplastic nodules accounted for more than 50% of the cats with non-neoplastic splenic disease. Unfortunately, those were pathologic descriptions, and the underlying disease was not apparent in many cases. In two retrospective studies that looked at the prevalence of arrhythmias in dogs with splenic masses,[4,5] hematomas were found in 17%[5] to 44%[4] of the cases. In a prospective study that looked at the prevalence of arrhythmias in dogs undergoing splenectomy, 38% of the dogs had neoplasia and 32% had hematomas.[6] Nodular hyperplasia, immune-mediated disease

unresponsive to medical therapy, and splenic torsion each accounted for 10% of the cases. Nodular hyperplasia, hematoma, extramedullary hematopoiesis, congestion, and lymphoid hyperplasia were the most common non-neoplastic lesions found in the spleens of dogs at necropsy or biopsy.[1,7–9] In a lifetime study of beagles chronically exposed to radioactive radium and strontium, splenic abnormalities were present in 105 of the 865 dogs. Hyperplastic nodules, with or without hematoma, and diffuse lymphoreticular hyperplasia accounted for 66% of the splenomegaly found in these dogs.

Thus the ratio of non-neoplastic to neoplastic splenic disease in dogs varies among studies. Populations that included all cases of splenomegaly or masses[1,8] show a higher than 50% prevalence of non-neoplastic diseases. A higher prevalence of tumors is found in populations that underwent splenectomy[6,9] and in dogs with splenic masses and arrhythmias.[4,5] Non-neoplastic masses, therefore, are as common as neoplastic masses in the spleen of dogs, and the importance of hemangiosarcoma has been overemphasized.[10]

276.2 CLINICAL MANIFESTATIONS OF SPLENIC DISEASES

Owner complaints for dogs and cats with splenic disorders are usually vague, and these signs may arise from the primary disease. Common complaints include vomiting, anorexia, weakness, collapse, abdominal enlargement, and weight loss. Polyuria and polydipsia may occur; the mechanism is unclear, but it resolves after splenectomy. Clinical signs are usually related to abdominal distention caused by a mass, uniform splenomegaly, or intra-abdominal bleeding. Lethargy and collapse may occur as a result of hypovolemia, arrhythmias, or anemia.

Signs related to the underlying disorder may also be present (Box 276-1). Ventricular tachyarrhythmias appear to be highly prevalent in dogs with splenic masses (hematoma, hemangiosarcoma, or leiomyosarcoma).[4–6] Particularly if the mass has ruptured.[6] Dogs that undergo splenectomy, regardless of the reason, are also prone to arrhythmias during and after surgery.[6]

The most reliable clinical sign of splenic disease is palpable splenomegaly. However, not all splenomegalies are abnormal. Breed variations in spleen size exist, particularly in dogs. For example, German shepherds have larger spleens; in some other breeds (e.g., miniature schnauzer, cocker spaniel, greyhound) the spleen is located more caudally in the abdomen and may be perceived as enlarged under palpation.[11] Not all enlarged spleens are palpable.

The major laboratory abnormalities accompanying splenic disease are related to the underlying systemic illness. 1944 1945
Changes in blood cell counts may be due to the primary disease or may be caused by the abnormal spleen. Erythrocyte counts are usually normal or decreased but can be increased in patients with splenomegaly associated with polycythemia vera.[12] Schistocytosis, which is highly indicative of a neoplastic splenic disorder, was observed in 23% of patients with splenic tumors but in only 3% of dogs with non-neoplastic disease.[9] Granulocyte and platelet counts also can be decreased, normal, or increased.

276.2.1 Box • 276-1 Clinical Signs of Splenic Disease in Dogs and Cats

Abdominal distention

Splenomegaly

- Splenic mass
- Intra-abdominal bleeding
- Arrhythmias
- Nonspecific signs and signs of the underlying disorder
  - Lethargy
  - Weakness
  - Collapse
  - Anorexia
  - Polyuria/polydipsia
  - Diarrhea
  - Pale mucous membranes
  - Jaundice

Extramedullary hematopoiesis can occur in the spleen. Because the spleen is capable of hematopoiesis but does not retain the normal inhibitory mechanisms present in the bone marrow, it releases young blood cells into the circulation.[10] Increased nucleated red blood cells and immature white blood cells (leukoerythroblastic effect) may appear in the peripheral blood in patients with splenic disorders.

276.2.2 Diagnostic Approach to a Patient with Splenomegaly

Splenomegaly can be detected by physical examination or by abdominal radiographs or ultrasound. Although splenomegaly can be identified by palpation, the severity of the enlargement cannot be reliably assessed in dogs with this technique alone. Differentiating between a splenic mass (localized splenomegaly with at least one large mass) and diffuse splenomegaly (uniform enlargement of the spleen) helps narrow the number of potential diagnoses (Box 276-2). Fine needle aspiration of the spleen may secure the final diagnosis or characterize the type of inflammation present. A sequential approach to diagnosis of the origin of the splenic mass, splenomegaly, or splenic nodular disease, using ultrasonographic findings and cytology, is shown in Figures 276-1, 276-2, and 276-3, respectively.

276.2.2.1 Abdominal Radiography

Radiographically the spleen is apparent in both dogs and cats. The dorsal extremity (head) is commonly seen on ventrodorsal projections in the cranial left abdomen caudal to the gastric fundus and cranial to the left kidney along the left body wall. On this projection, the splenic head is triangularly shaped. The body of the spleen may be directed transversely across the abdomen immediately caudal to the stomach, along the left body wall, or anywhere in between. In dogs the ventral aspect (tail) is often seen along the ventral body wall immediately caudal to the liver in the lateral projection. Distension of the stomach may caudally displace the tail. The tail of the spleen is uncommonly seen in cats.

Generalized splenomegaly may increase splenic length. The spleen may also fold up from the ventral wall, extending to varying lengths up the right body wall, or it may expand more caudally, toward the urinary bladder. In the cat, visualization of the splenic tail along the ventral body wall supports a diagnosis of splenomegaly. Alternatively, with generalized enlargement or focal masses, the spleen produces a mass effect, causing caudal displacement of intestines. The spleen is a very common origin for masses in the midcranial and left cranial abdomen. Atypical splenic location, with changes in shape, may occur in dogs with splenic torsion. Concurrent peritoneal effusion is common. Lesions rarely cause changes in splenic radiopacity.

276.2.2.2 Abdominal Ultrasonography

Ultrasonography is a very effective tool for evaluating the size, shape, and vascular supply of the spleen. There are no objective criteria for normal splenic size. As a rule, cats have a much smaller spleen than dogs of similar size. Normal variations in dogs include capsular invagination (hyperechoic foci adjacent to splenic veins), a bent spleen, or a portion folded back upon itself. Generalized isoechoic enlargement may be a normal variation in German shepherds and other dog breeds and in some cats. Overall spleen length and evidence of intestinal displacement are the criteria used to assess for splenomegaly. A true decrease in splenic size (microsplenia) may occur with acute anemia due to contraction of the spleen. Ultrasonography is more sensitive than radiography for detecting alterations in the shape and outer margination of the spleen. Irregularities in shape and focal changes in echogenicity are the major criteria for characterization of splenic disease in dogs and cats.

Nodular disease is easily detected in the middle and tail regions of the spleen. Often the head of the spleen is within the rib cage, and masses in the dorsal extremity may require a rigorous examination using an intercostal approach. Benign masses may be hypoechoic, hyperechoic or mixed echoic. Benign masses cannot be differentiated from malignant masses with grey scale ultrasonography alone. Extramedullary hematopoiesis and nodular hyperplasia (Figure 276-4), which are common regenerative lesions, are usually hypoechoic and are seen in the spleens of older dogs. These lesions are much less common in cats.

Certain lesions have a more characteristic sonographic appearance. Myelolipoma, a benign tumor seen in older dogs, is both very echogenic and attenuating. The result is a classic hyperechoic and indistinctly shadowing lesion (Figure 276-5). Unlike with mineralization, the attenuation is not complete, and the internal architecture of the lesion can be seen to varying depths.

The spleen has a high prevalence for vascular disease because it is attached at only one pole and is prone to harbor diffuse neoplasia. Splenic torsion and diffuse tumor invasion may result in uniform diffuse hypoechogenicity or a more mixed “Swiss cheese” appearance (Figure 276-6). In suspected cases of torsion

or thromboembolism, Doppler examination of the splenic veins is an important step for verifying lack of venous return. As with portal vein flow, splenic venous flow is low velocity and essentially nonpulsatile. Power Doppler examination is especially valuable, because this modality is more sensitive to very low velocity flow. Thrombosis may occur after mechanical torsion or tumor vascular invasion or with thromboembolic diseases. Regional infarctions are commonly seen in dogs with disseminated intravascular coagulation (DIC) and autoimmune conditions, such as immune-mediated hemolytic anemia and immune-mediated thrombocytopenia. Infarcted regions are usually peripheral, hypoechoic, and swollen (Figure 276-7). Necrosis, which may be seen with chronic severe vascular disease, results in the formation of free gas in the spleen and free fluid in the peritoneum.

An additional ultrasonographic modality for evaluation of focal nodular and vascular diseases of the spleen is contrast harmonic ultrasonography. With this technique, second-generation ultrasound contrast agents, which are liposome-encapsulated inert gas spheres, are injected intravenously; these agents are small enough (3 to 5 μm) to pass through the pulmonary circulation without causing embolization. Harmonic ultrasound software technology allows detection of sound waves that are multiples of the transmitted frequency. Ultrasonographic contrast bubbles are very powerful generators of harmonic frequencies, and combined with tissue signal suppression, they create a novel method for imaging perfusion of organs. These contrast media, which can be used as blood pool agents, cause infarcted regions to appear hypoechoic compared with the surrounding normally perfused spleen. Preliminary studies indicate that ultrasound contrast agents may help discriminate between malignant and benign masses by exploiting differences in blood supply. Hemangiosarcomas have very poor overall perfusion and distinct peripheral vessels. This perfusion pattern has been noted in hemangiosarcomas in the liver, lung, peritoneum, and spleen. In the liver, metastatic nodules have a more rapid wash-in and wash-out compared to normal liver or benign liver nodules. Benign nodular hyperplastic nodules in the spleen have good overall perfusion.

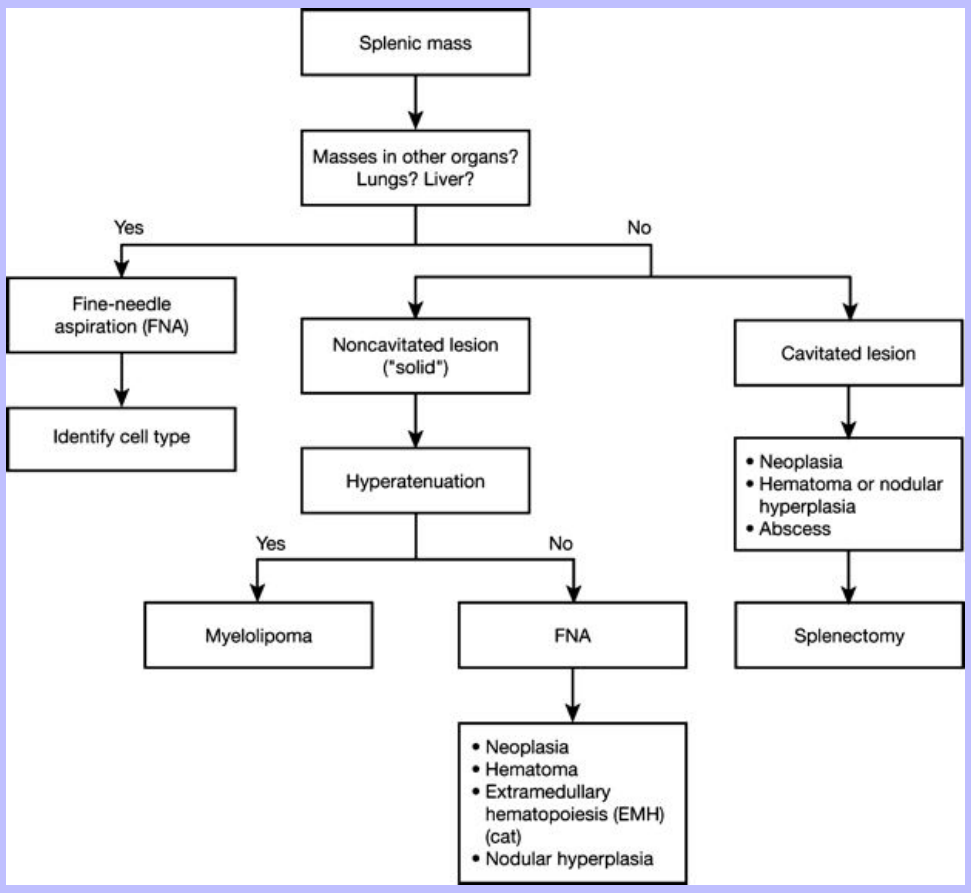
276.2.2.3 Fine Needle Aspiration

Although imaging of the spleen only rarely results in a diagnosis, an aspirate may provide a cytologic sample and the answer. Core biopsy is possible but not usually necessary. Most diseases of the spleen exfoliate well and are suitably sampled with fine needle techniques. Of the fine needle techniques, the variation that seems to provide the most cells without undue hemodilution involves no negative pressure with the attached syringe and multiple thrusting motions with the needle. With the plunger already pulled back in the barrel of the syringe prior to insertion of the needle, it thereafter is easy to expel the contents of the needle by depressing the plunger. This technique works well for nodular hyperplasia and extramedullary hematopoietic benign nodules, metastatic carcinomas, and hematopoietic tumors. Solid sarcomas may not exfoliate well with aspiration techniques, and a core sample may provide a better result. Cavitated lesions should be sampled only with the utmost care, if at all.

1946

1947

Figure 276-1 Algorithm for the clinical approach to a splenic mass.



Fine needle aspiration appears to be safe even in presence of coagulopathies or thrombocytopenia.[13] As a general rule, all abnormal spleens that *do not have cavitated lesions* should be aspirated. Aspiration is not necessary in patients with splenic torsion when lack of adequate blood flow can be determined by Doppler ultrasonography, or in patients with myelolipoma if only lesions with the classic acoustic properties are present. Aspiration also may not be required for diffuse homogeneous splenomegaly, with no clinical signs, that is attributable to splenic disorders in patients with a known cause of congestion (e.g., tranquilizer therapy, portal hypertension, right-sided heart failure), or for “classic” infarct lesions in asymptomatic patients.

Fine needle aspiration can provide the final diagnosis in infectious disease when the organism can be identified and in neoplastic disorders. Aspirates of normal spleen reveal small lymphocytes with occasional medium and large lymphocytes and rare neutrophils. A few macrophages and plasma cells may be present.[14] Precursors of all three cell lines may be seen in patients with extramedullary hematopoiesis, but erythroid cells are more common. In hyperplasia resulting from antigenic reaction, an increase in medium and large lymphocytes and in macrophages and plasma cells is seen.[14] Patients with splenitis have an increase in inflammatory cells. Identification of the predominant cell type narrows the number of potential

diagnoses. Inflammation can be further characterized based on the predominant cell type; that is, suppurative, granulomatous, pyogranulomatous, eosinophilic, or lymphoplasmacytic. The most common causes of each type of inflammation are presented in Box 276-2.

276.2.2.4 Splenic Biopsies/Splenectomy

Biopsy of the spleen can be performed in patients in which the primary diagnosis of a mass is not obtained by fine needle aspiration. Care should be taken with impression smears made from splenic biopsy samples. Impressions inadvertently made of the capsular surface, rather than the parenchyma, reveal uniform sheets of loosely attached mesothelium, which are nondiagnostic.[14] Splenectomy should be considered in animals with splenic necrosis or cavitated masses without metastasis.

276.2.2.5 Other Diagnostic Tests

In addition to imaging techniques and fine needle aspiration, urinalysis, a complete blood count, and a biochemical profile are necessary in all patients with splenomegaly. Cats must be tested for infection with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV). Chest radiographs should be obtained in patients with splenic masses to rule out metastasis, and bone marrow examination may be indicated in patients with alterations in blood cell lines.

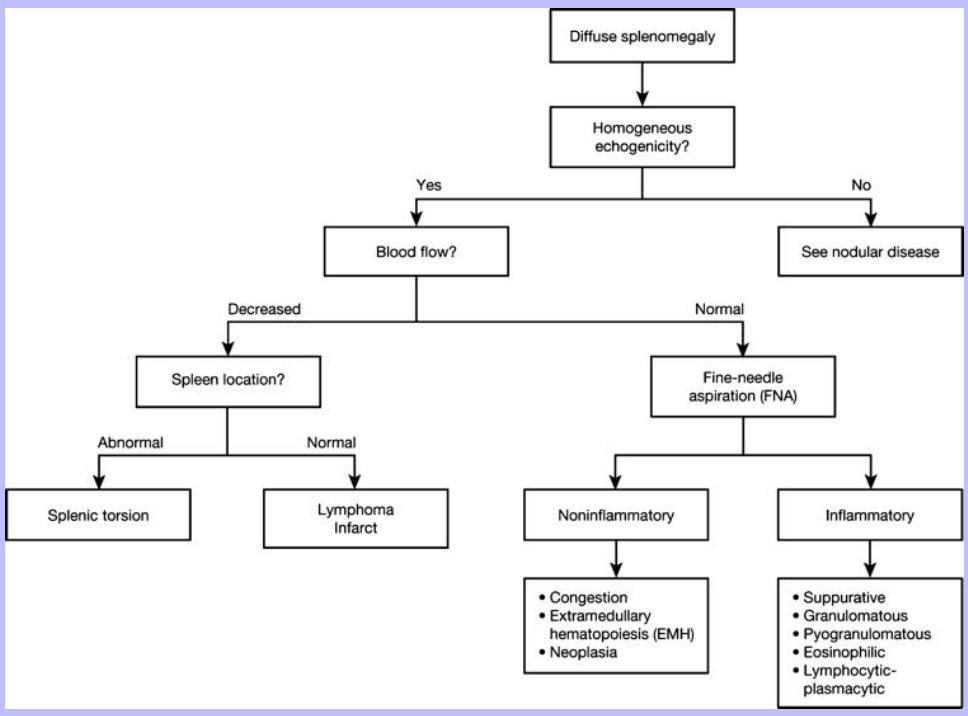

Figure 276-3 Algorithm for the clinical approach to splenic nodular disease.

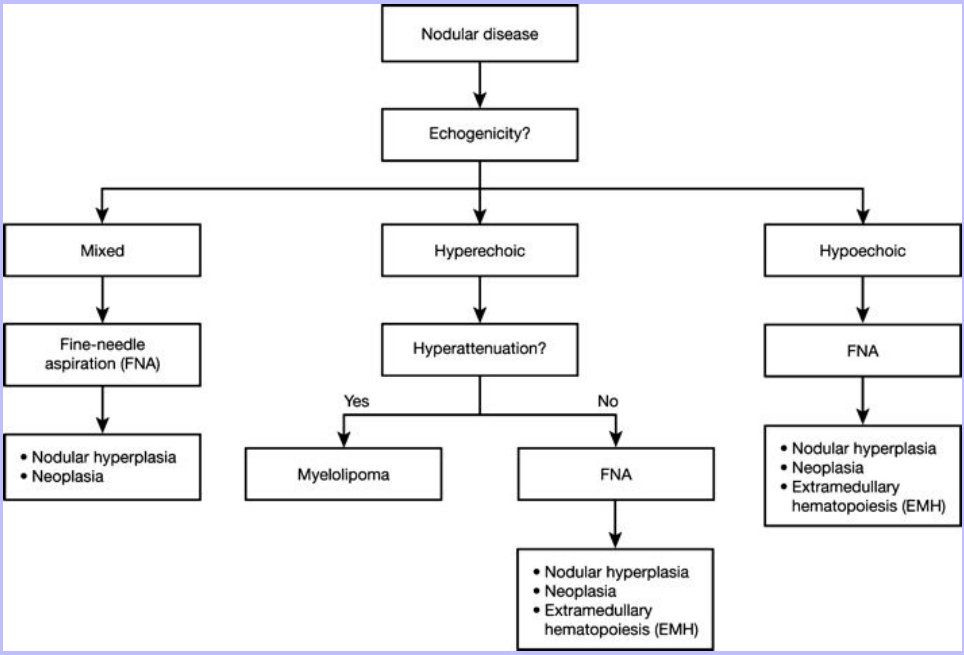

Figure 276-4 Nodular hyperplasia. Note the contrast enhancement pattern on precontrast **(A)** and postcontrast **(B)** images.

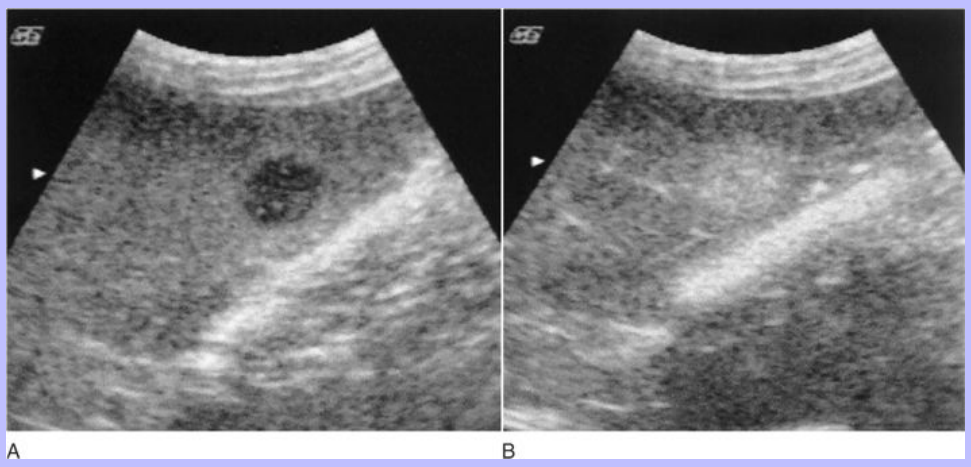


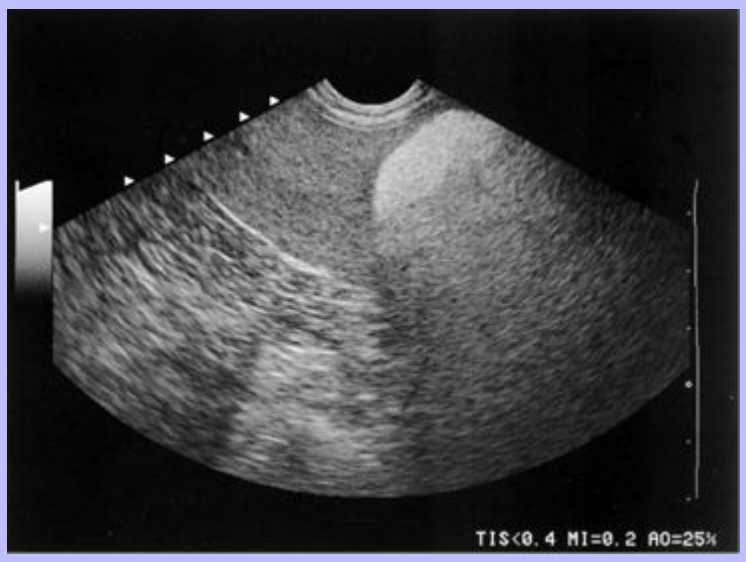
276.3 COMMON CAUSES OF SPLENOMEGALY IN DOGS AND CATS

Generalized splenomegaly may occur with congestion, splenic hyperplasia/extramedullary hematopoiesis, inflammation, or cellular infiltration, whereas splenic masses usually are due to neoplasia, hematoma, abscess, or nodular hyperplasia.

276.3.1 Congestion

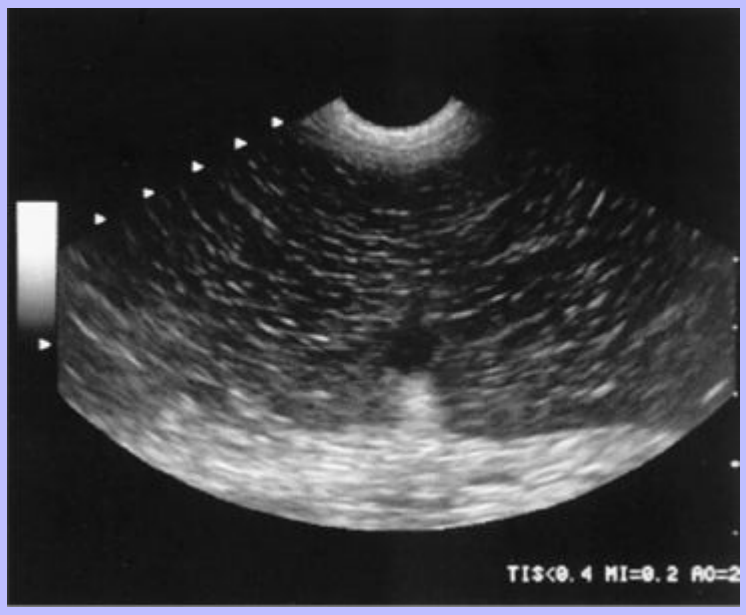
Congestion is commonly seen as a consequence of sedation or anesthesia, portal hypertension, or splenic vein thrombosis. Administration of phenothiazine sedatives (e.g., acepromazine) or ultra-short-acting barbiturates (e.g., thiopental) produces substantial splenomegaly. Splenomegaly can be severe, because up to 30% of the blood volume can be pooled in the spleen. Administration of propofol to dogs, however, did not produce statistically significant splenomegaly.[15]

Figure 276-5 Myelolipoma. Note the hyperechogenicity and hyperattenuation pattern.



Congestion may also occur secondary to portal hypertension with hepatic disease and with systemic venous hypertension in right-sided heart failure or intrathoracic caudal vena cava compression. Chronic congestion of the spleen may lead to splenic hyperplasia. No changes in echogenicity were subjectively noted in congested spleens, although signifi-cant increased attenuation and a trend toward increased backscatter (echogenicity) were noted.[15] Diffuse changes in splenic echogenicity in patients with a known cause of congestion, therefore, are likely due to another underlying condition.

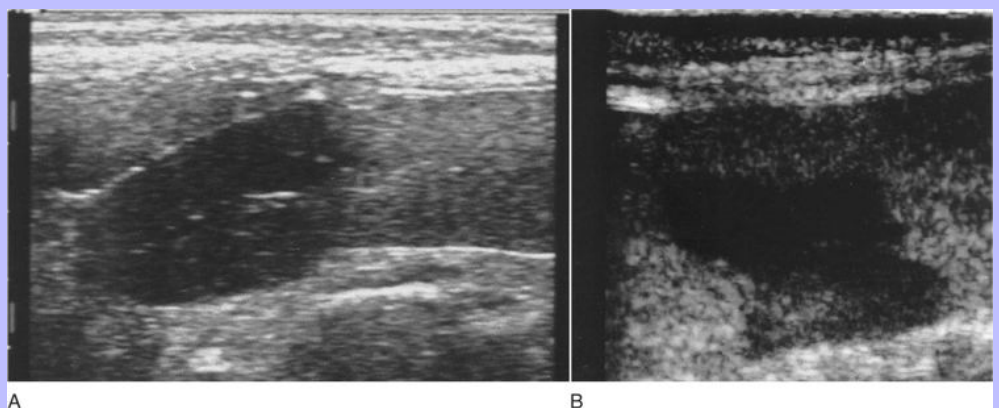
Figure 276-6 Splenic torsion. Note the “Swiss cheese” echogenic pattern of splenic necrosis.



1949

1950

Figure 276-7 Infarcted spleen in two dogs. **A,** Note the hypoechoic infarcted portion of the spleen on grey scale ultrasound image. **B,** On the contrast harmonic ultrasound image, the infarcted portion is not seen on grey scale ultrasound but is hypoechoic compared with surrounding well-perfused, contrast-enhanced spleen.



Splenic pedicle torsion is a special cause of congestion in dogs. It usually develops in large, deep-chested dogs, especially the German shepherd and Great Dane.[16] Males represented 79% of the cases in one study.[16]

Acute torsion causes profound systemic signs, including shock and abdominal discomfort, whereas chronic torsion is associated with vague signs such as vomiting, anorexia, lethargy, and icterus. Radiographically, a decrease in abdominal detail, displacement of other abdominal organs, and loss of visualization of the body of the spleen in the left cranial abdomen are seen on the ventrodorsal view. In the lateral view, the spleen is enlarged, abnormally positioned or shaped, and may have intrasplenic gas.[17] Ultrasonographically, the spleen is diffusely enlarged and abnormally located. It is usually hypoechoic, with decreased flow through splenic veins. In one study, intravascular thrombi could be identified in 50% of the cases.[16] Supportive therapy should be instituted immediately in these patients, and the spleen should be removed surgically. If appropriately treated, splenic torsion carries a favorable prognosis.[16]

276.3.2 Splenic Infarction

Infarcts can be observed in patients in hypercoagulable states associated with liver disease, renal disease, or hyperadrenocorticism.[18] They also can occur with pre-existing uniform splenomegaly[18] or splenic torsion.[16] Splenic infarction is a sign of abnormal coagulation or blood flow, and the clinical signs are related to the underlying cause. Ultrasonographically, infarct regions are usually peripheral and have hypoechoic, swollen areas. After contrast injection, they appear hypoechoic compared with the surrounding normally perfused spleen. Infarcted regions may resolve with appropriate therapy of the underlying disease.

276.3.3 Splenic Hyperplasia/Extramedullary Hematopoiesis

The splenomegaly seen with splenic hyperplasia and extramedullary hematopoiesis reflects *work hypertrophy* resulting from removal of abnormal blood cells from circulation, increased activity of mononuclear phagocytic and lymphoid cells, and increased blood cell production. In immune-mediated hemolytic anemia and thrombocytopenia, the spleen serves as a site of antibody production and also as an important site of removal of antibody-sensitized cells. Chronic increased destruction of red blood cells in some non-immune-mediated hemolytic diseases also appears to cause hyperplastic splenomegaly in dogs and cats.[19] Chronic antigen stimulation by infectious agents (e.g., bacterial endocarditis), blood parasites, or immune-mediated disease can stimulate hyperplasia of mononuclear phagocytic and lymphoid cells.

In work hypertrophy, the spleen is uniformly enlarged and may be hypoechoic on ultrasonographic examination. Cytologically, small lymphocytes still predominate, but an increase is seen in medium and large lymphocytes, and plasma cells are commonly observed.[14]

Extramedullary hematopoiesis (EMH) may accompany splenic hyperplasia in patients with concomitant anemia, thrombocytopenia, or leukopenia. It is a very common cytologic diagnosis in dogs with uniform splenomegaly[13] and may also occur with a variety of splenic neoplasms. EMH is also common in cats; it was diagnosed in 21% of the cats in one study.[20] A nodular pattern is more common in cats with EMH. The presence of nucleated red blood cells in peripheral blood suggests a diagnosis of EMH. Cytologically, precursors of all three cell lines may be observed with the disease.[14] A finding of hematopoietic precursors with large amounts of vacuoles in the background suggests a myelolipoma rather than EMH.[14]

276.3.4 Nodular Hyperplasia/Hematoma

Nodular hyperplasia is a non-neoplastic regional proliferation of component cells normally found in the parenchyma of the canine spleen.[21] Nodular hyperplastic lymphoid proliferation is the most common form of nodular hyperplasia in dogs, but it is not common in cats.[1,2] A high percentage of splenic lesions in dogs have features of hematomas and nodular hyperplasia, which suggests that these disorders are different stages of the same process. Lymphoid elements are usually observed with superimposed hematomas.[1] It has been suggested that marginal zoning distortion caused by nodular hyperplasia disrupts regional splenic blood flow in and around the hyperplastic nodule, eventually leading to hematoma formation.[1] Cats have a "nonsinusal" type of spleen and a different architecture and blood flow pattern of the intermediate circulation bordering the white pulp.[2] Those differences could make the spleen of cats less vulnerable to disrupted blood flow and hematoma formation.

1950

1951

Nodular hyperplastic lesions are usually hypoechoic on ultrasonographic examination. Splenic hematomas in dogs are associated with large splenic masses. A history of trauma is rare.[22] Most dogs with splenic hematoma are relatively healthy and do not have acute splenic rupture,[19] although they may develop hemoabdomen.[23] Large hyperplastic nodules and splenic hematomas cannot be differentiated from hemangiosarcoma grossly. Splenectomy is the treatment of choice for hematomas and hyperplastic nodules large enough to cause splenomegaly.[24]

A particular variation of the hyperplastic nodule in dogs is the fibrohistiocytic nodule.[21] Nodular fibrohistiocytic proliferation is characterized by a mixed population of histiocytoid or spindle cells intertwined with hematopoietic elements, plasma cells, and lymphocytes. These nodules appear to form a continuum between lymphoid nodular hyperplasia and malignant splenic fibrous histiocytoma.[21] Histologically, the lymphoid to fibrohistiocytic ratio is the most important predictor of survival in these dogs. A higher proportion of lymphoid to fibrohistiocytic cell types was associated with increased long-term survival.[21]

276.3.5 Inflammatory Splenomegaly

Inflammatory splenomegaly (splenitis) is a uniform splenomegaly that usually occurs secondary to infection. In addition to the inflammatory response associated with hyperplasia, patients with splenitis also have increased numbers of other inflammatory cells. It is important to classify the splenitis according to the predominant cell type, because different etiologic agents are associated with different types of inflammation. Some overlap exists, and the same organism can cause a different inflammatory response in different patients. For example, lymphoplasmacytic splenitis has been observed in patients with FIP, histoplasmosis, and blastomycosis. Care must be taken in diagnosing suppurative splenitis in patients with peripheral neutrophilia or eosinophilic splenitis in patients with peripheral eosinophilia. The most common causes of splenitis, based on the predominant inflammatory response, are presented in Box 276-2. Infectious agents that can cause splenitis or can lead to splenomegaly by causing chronic antigen stimulation, disturbances of blood flow, or chronic anemia are listed in Box 276-3.

276.4 PATIENT WITH A SPLENIC NODULE

Splenic nodules without associated splenomegaly are a relatively common finding in older dogs undergoing abdominal ultrasonography for unrelated reasons. Most splenic nodules in this age group are benign and may require no further action. Myelolipomas can be easily identified, whereas lymphoid hyperplasia, EMH, and splenic infarcts may be more difficult to differentiate from an early neoplastic lesion. Further diagnostics should be attempted in breeds with a high-risk for hemangiosarcoma; in patients with systemic tumors likely to involve the spleen (e.g., lymphoma, hemangiosarcoma); and in animals with hematologic abnormalities, fever, or other signs of systemic infectious disease.[25] Fine needle aspiration should be attempted for all splenic nodules. The main risk associated with this procedure is contamination of the abdominal cavity with tumor cells in the case of hemangiosarcoma. Hemangiosarcoma is not likely to manifest itself as one or few small nodules, but it may be a risk in predisposed breeds. A more conservative approach involving repeating the ultrasonographic examination in 4 weeks has been suggested.[25] Any increase in the size of a nodule over this period should be pursued aggressively. It should be remembered that a change in diameter from 1 to 1.2 cm is associated with a doubling in volume for a spheric mass.[25]

276.5 PATIENT WITH SPLENIC DISEASE

Diffuse splenomegaly is usually managed medically. Most diseases that cause diffuse splenomegaly are systemic in nature, and treatment should be directed at the underlying cause. Splenic torsion in dogs is the exception to the rule. A few tumors and myeloproliferative disease can also benefit from removal of the spleen. Splenectomy can be considered in patients with immune-mediated anemia or thrombocytopenia refractory to therapy. It is important to show bone marrow hyperplasia in the cell line with decreased peripheral numbers, before splenectomy is performed. Removal of the spleen is the treatment of choice for patients with splenic masses.

Removal of the spleen may predispose the patient to infections. Splenectomized humans are more likely to die of sepsis, but this predisposition has not yet been confirmed in dogs and cats. A few organisms that infect blood cells (e.g., as in babesiosis, hemotropic mycoplasmosis, and ehrlichiosis) are known to occur more often in splenectomized patients. Ideally, dogs and cats should be tested before splenectomy and treated accordingly if infected.

277 CHAPTER • 277 Systemic Lupus Erythematosus

Michael Stone*

No single definition describes systemic lupus erythematosus (SLE). Veterinary patients with SLE classically demonstrate at least two separate manifestations of autoimmunity in addition to the presence of antinuclear antibody (ANAs). However, some patients demonstrate clinical features of multisystemic autoimmunity, yet lack serum ANAs.

277.1 PATHOGENESIS

Autoimmune disease may be defined as a clinical syndrome caused by the activation of T cells or B cells, or both, in the absence of an ongoing infection or other discernible cause. In SLE, immune system dysregulation that leads to immune complex formation is postulated to induce tissue damage (type III hypersensitivity); however, direct antibody-mediated cytotoxicity (type II hypersensitivity) and cell-mediated autoimmunity (type IV hypersensitivity) also occur.

277.1.1 Effectors

The primary mediators in the development of SLE are pathogenic antibodies, pathogenic immune complexes, and autoreactive T cells.

277.1.1.1 Pathogenic antibodies

Individuals with SLE produce antibodies directed against a broad range of nuclear, cytoplasmic, and cell membrane molecules. Autoantibodies may cause damage through the formation of immune complexes, opsonization of target cells, and interference with cellular physiology. Antibodies may penetrate living cells and bind to cytoplasmic or nuclear structures, altering cell function and contributing to disease by mechanisms other than classic complement-mediated injury.[1]

* The author thanks Dr. Susan Cotter for her review of this manuscript.

277.1.1.2 Pathogenic immune complexes

Immune complexes, which are formed whenever an antibody meets an antigen, are normally removed by the mononuclear phagocyte system. With continued production of autoantibody to a self-antigen, the mononuclear phagocyte system may become overloaded. Circulating immune complexes are deposited in the walls of blood vessels in which there is a physiologic outflow of fluid (e.g., glomeruli, synovia, and the choroid plexus). Some immune complexes are “tissue tropic” and prone to binding to tissues because of a cationic charge or because the antibodies the complexes contain are directed against tissue components. Trapped immune complexes activate complement, attracted neutrophils release lysosomal enzymes, and the result is tissue damage.[2]

277.1.1.3 Autoreactive T-cells

T cells may directly cause tissue damage in SLE. Dermatologic lesions, polymyositis, and vasculitis have been associated with cytotoxic T cell–mediated damage.[3]

277.1.2 Genetics

In mice, more than 25 genes that can contribute to an autoimmune diathesis have been identified.[1] Most of these genes are associated with the major histocompatibility complex (MHC), encoding cytokines, antigen co-receptors, cytokine-or antigen-signaling cascades, co-stimulatory molecules, molecules involved in pathways that promote or inhibit apoptosis, and molecules that clear antigen or antigen-antibody complexes. For example, a consequence of the inheritance of Fe receptors that weakly bind immunoglobulin may be impaired ability to clear immune complexes, which predisposes the individual to the sequelae of circulating immune complexes. Protective genes exist that prevent the development of SLE even if multiple susceptibility genes are inherited. SLE is clearly inherited in dogs, and experimental colonies of dogs with the disease have been established.[4–6] SLE in dogs has been associated with the allele DLA A7, along with a negative (or "protective") association with DLA Al and B5.[7] Dogs with a specific allotype of the fourth component of complement may be predisposed to SLE,[8] as are dogs with decreased serum IgA.[9] SLE may occur more frequently in purebred cats, which also suggests a genetic influence.[10]

277.1.3 Environmental Factors

The lower than expected rate of SLE concordance among identical human twins strongly suggests the existence of an environmental trigger.[3] Exposure to ultraviolet (UV) light causes disease flares in as many as 50% of humans with SLE, and the same effect has been reported in both dogs[5,11] and cats.[12] In humans, the importance of gender is demonstrated by the fact that 90% of SLE cases occur in women, particularly during their reproductive years. However, this gender distribution has not been identified in either the dog or cat. Exposure early in life to infectious agents may suppress the development of allergic and autoimmune disorders.[13] It has been suggested that the increase in allergies and autoimmune diseases recognized in humans is related to decreased exposure to endotoxin during early development. Adequate stimulation may be important in the ontogeny of the normal immune system.[14]

277.1.4 Drugs

Certain drugs may induce SLE-like disease in humans (Box 277-1).[15] However, this disease is probably different from true SLE. The clinical manifestations of drug-induced lupus in humans are predominantly arthritis, serositis, fatigue, malaise, and low-grade fever; nephritis and central nervous system (CNS) diseases are rare. The manifestations disappear in most patients within a few weeks of discontinuation of the offending drug, never to reappear unless the individual is re-exposed to the drug.[3] Propylthiouracil has been associated with hemolytic anemia, thrombocytopenia, and the development of antinuclear antibodies in cats.[16] Methimazole has been associated with the development of antinuclear antibodies in cats, but clinical signs of SLE have not been reported.[17] Hydralazine has been associated with the development of antinuclear antibodies in dogs.[18]

277.1.5 Infectious Agents

No infectious agents have been identified that cause SLE. However, it is possible that infectious agents or their antigenic products (or both) can worsen SLE in patients with the appropriate predisposing genes. Microbial antigens have the potential to initiate autoreactivity through molecular mimicry, polyclonal activation, or the release of previously sequestered antigens. The immunogenicity of autoantigens may be increased by inflammation in the target organ, which explains the flares of immune-mediated disease induced by vaccination or infection. Molecular mimicry describes infection with an agent that has antigens immunologically similar to host antigens but sufficiently different to allow an immune response. As a result, tolerance to autoantigens breaks down, and the pathogen-specific immune response cross-reacts with host tissues.[19] The feline viruses feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) can induce disease in cats that is similar to SLE, and serum ANAs may develop in the early stages of FeLV infection.[20] Whether FeLV-or FIV-induced disease is truly similar to SLE is a matter of debate.[21] Feline ehrlichial disease has also been associated with the development of antinuclear antibodies.[22]

Table • 277-1 Clinical Signs in Dogs and Cats Suspected of Having Systemic Lupus Erythematosus

	INCIDENCE (DOGS)		INCIDENCE (CATS)	
CLINICAL SIGN	RATIO*	PERCENTAGE	RATIO	PERCENTAGE
Nonerosive polyarthritis	236/302	78	9/25	36

CNBD, The incidence could not be determined from the published literature.

* Ratio of the number of patients affected to the number of patients described.

In summary, the ability to manufacture pathogenic immunoglobulin and to sustain its production depends on three main factors: (1) inheritance of an appropriate number of susceptibility genes, (2) lack of protective genes, and (3) an environmental stimulus that sets the whole process in motion.

277.2 CLINICAL FINDINGS

The clinical signs reported in dogs and cats with SLE are summarized in Table 277-1. It must be noted that the process of deriving criteria from diagnosed cases is inherently circular, because the criteria are based on diagnosed cases of SLE.

Nonerosive polyarthropathy is the most frequent primary sign in dogs. The smaller joints (carpi, tarsi, elbows, stifles) are most frequently involved. Synovial fluid analysis reveals neutrophilic inflammation with greater than 10,000 cells/mm^3. Articular symptoms are also common in cats, some of which may demonstrate joint swelling and abnormal synovial fluid, yet lack signs of lameness. Fever is frequently reported in both dogs and cats and may be either persistent or intermittent.

In humans, biopsy demonstrates involvement of the kidney in almost all SLE patients.[23–25] Renal involvement may be benign and asymptomatic or relentlessly progressive and fatal. The earliest manifestation is proteinuria. In dogs, proteinuria and glomerular lesions are also common. Biopsy may reveal mesangial and/or endothelial hypertrophy, proliferative and/or membranous glomerulonephritis, and sclerotic changes. Proteinuria and/or glomerulonephritis are also commonly reported in the cat.

Cutaneous manifestations in dogs may include erythema, scaling, crusting, depigmentation, and alopecia. Ulcers may develop on the skin and in the mucocutaneous junctions and oral cavity. Preferential localization of lesions may occur in areas poorly protected by the haircoat, and exposure to sunlight may exacerbate the lesions. Biopsy reveals inflammatory infiltrates at the dermoepidermal junction and vacuolar change in the basal columnar cells. Immunofluorescence stains demonstrate immunoglobulin and complement deposits in the epidermal basement

membrane. Cutaneous lesions reported in 15 feline patients with SLE included erythema, ulceration, and crusting and depigmentation of the face, ears, and paws in seven cats; biopsy results consistent with pemphigus foliaceus or plasmacytic pododermatitis in four cats; ulcerative stomatitis in three cats; and seborrheic dermatitis in one cat.[10,12,21,30]

Only rarely is anemia, leukopenia, or thrombocytopenia the presenting feature of human SLE without concomitant problems of the skin, joints, CNS, or cardiopulmonary system. In dogs, although it is common to find anemia of chronic inflammation, Coombs'-positive anemia is uncommon. Thrombocytopenia may be severe enough to cause bleeding, but antiphospholipid syndrome and thromboembolic disease should also be considered as possible causes in these cases. Leukopenia has been frequently reported. Complement concentrations were decreased in three of eight dogs suspected of having SLE.[8] As in dogs, hemolytic anemia is uncommon in cats, and thrombocytopenia is rare. Complement levels were decreased in one cat studied.[10]

Thrombosis associated with the "lupus" anticoagulant was reported in one dog with SLE.[34] The "lupus" anticoagulant is an antibody directed against membrane phospholipids. The antibody causes *in vitro* prolongation of the activated partial thromboplastin time (aPTT), hence the paradoxical name *anticoagulant*. However, *in vivo* the antibody causes platelet activation and hypercoagulability.

Table • 277-2 American College of Rheumatology Revised Criteria for the Classification of Systemic Lupus Erythematosus*

CRITERION	DEFINITION
Malar rash	Fixed erythema, flat or raised over the malar eminences, that tends to spare the nasolabial folds
Discoid rash	Erythematous, raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur
Photosensitivity	Skin rash as a result of unusual reaction to sunlight
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
Arthritis	Nonerosive arthritis involving two or more peripheral joints
Serositis	Pleuritis (pleuritic pain or rub, or evidence of pleural effusion) *or* pericarditis (pericardial effusion)
Renal disorder	Persistent proteinuria *or* cellular casts, which may be red cell, hemoglobin, granular, tubular, or mixed type
Neurologic disorder	Seizures *or* psychosis (either in the absence of offending drugs, known metabolic derangements, or electrolyte imbalance)
Hematologic disorder	Hemolytic anemia (with reticulocytosis) *or* leukopenia (less than 4000/mm^3 on two or more occasions) *or* lymphopenia (less than 1500/mm^3 on two or more occasions) *or* thrombocytopenia (less than 100,000/mm^3 in the absence of offending drugs)
Immunologic disorder	Anti-DNA (antibody to native DNA in abnormal titer) *or* anti-Sm (presence of antibody to Sm nuclear antigen) *or* positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant, or (3) a false-positive serologic test for syphilis
Antinuclear antibodies (ANAs)	An abnormal ANA titer at any point in time and in the absence of drugs known to be associated with "drug-induced lupus"

Modified from Tan EM: The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 25:1271, 1982.

* For the purposes of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any four or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

Memory impairment, headache, epilepsy, and personality changes may accompany SLE in humans. Sole involvement of the CNS without other clinical or laboratory features of SLE is unusual. In animals, subtle behavioral disturbances may go unrecognized. In cats, reported CNS involvement has included racing around the house; twitching of the ears, tail, and hindlimbs; repeated licking of paws and tail base; generalized seizures; hyperesthesia along the dorsum; restless crying; disorientation; ataxia; loss of conscious proprioception; nystagmus; and ventroflexion of the neck.[10] Polymyositis was suspected in several dogs and cats. Polyneuritis, characterized by hyperesthesia of the nerve courses, has been reported in a dog.[11]

In humans, chest pain with or without pleural effusion is the most common sign of cardiopulmonary involvement. Fibrosis, pulmonary embolism, capillary leakage, or serositis may affect the lungs. The heart valves, myocardium, or conducting system may be affected, and pericardial effusion may develop. Neutrophilic myocarditis was demonstrated in four dogs with SLE.[28] Serositis of the pleura or pericardium was not observed in cats, although subclinical lung changes were noted on the thoracic radiographs of one cat.[10]

277.3 DIAGNOSIS

Criteria have been developed for the diagnosis of SLE in humans (Table 277-2), and these criteria may be modified to apply to veterinary patients (Table 277-3). A veterinary consensus would be helpful to allow comparison of future studies. Veterinary patients with SLE classically demonstrate at least two separate manifestations of autoimmunity, along with testing positive for ANAs. Patients with three or more separate manifestations of autoimmunity may also be considered to have SLE even in the absence of detectable ANAs. In dogs, the syndrome most commonly recognized is immune-mediated polyarthritis in association with immune-mediated skin disease, glomerulonephritis, hemolytic anemia, or thrombocytopenia. Similar signs occur in cats, but neurologic signs may be more common in this species.

1954

1955

Table • 277-3 Proposed Criteria for Diagnosis of Systemic Lupus Erythematosus in Dogs and Cats*

CRITERION	DEFINITION
Antinuclear antibodies (ANAs)	Abnormal ANA titer in the absence of drugs or infectious or neoplastic conditions known to beassociated with abnormal titers
Cutaneous lesions	Depigmentation, erythema, erosions, ulcerations, crusts, and/or scaling, with biopsy findings consistentwith systemic lupus erythematosus
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
Arthritis	Nonerosive, nonseptic arthritis involving two or more peripheral joints
Renal disorders	Glomerulonephritis or persistent proteinuria in the absence of urinary tract infection
Anemia and/or thrombocytopenia	Hemolytic anemia and/or thrombocytopenia in the absence of off ending drugs
Leukopenia	Low total white cell count
Polymyositis or myocarditis	Inflammatory disease of the skeletal or cardiac muscles
Serositis	Presence of a nonseptic inflammatory cavity effusion (abdominal, pleural, or pericardial)
Neurologic disorders	Seizures or psychosis in the absence of known disorders
Antiphospholipids	Prolongation of the activated partial thromboplastin time that fails to correct with a 1:1 mixture of the patient's and normal plasma, in the absence of heparin or fibrin degradation products

Modified from references 28 and 36–39.

* A diagnosis of SLE is established if a patient manifests three or more criteria simultaneously or over any period of time.

Diagnostic tests for patients suspected of having SLE should include hematology, biochemistry, urinalysis, imaging, joint fluid cytology, histopathology of the skin and/or kidney, and serum ANA determination. Cats should also be tested for FeLV and FIV. Infectious and neoplastic disease must be excluded through imaging; culture of urine, blood, and/or joint fluid; serology for tick-borne and fungal diseases; and trials of therapeutic antibiotics. In tick-infested areas, a 3-to 7-day course of doxycycline should be considered before a diagnosis of immune-mediated disease is made.

Immunodiagnostic investigations may include Coombs' testing, platelet autoantibodies, rheumatoid factor, coagulation testing for antiphospholipid antibodies, serum immunoglobulin, complement, circulating immune complex concentrations, and endocrine autoantibodies (i.e., thyroglobulin). Immunohistologic investigation may include immunoperoxidase and immunofluorescence staining and electron microscopy evaluation.[40]

Biopsy results may support a diagnosis of SLE but are rarely diagnostic by themselves. When the skin is biopsied, care must be taken to avoid ulcers or erosions, because an intact epidermis is necessary to substantiate the diagnosis. Oral biopsy specimens are rarely beneficial, because ulcers, which are inherently not diagnostic, are common in this location. Erythematous areas adjacent to ulcers yield the best diagnostic results.[41]

The diagnosis of SLE in cats is less well defined. In some studies, all cats that tested positive for ANAs were diagnosed with SLE, but whether all these patients truly had SLE is debatable. Another unanswered question is how to categorize patients that test positive for FeLV or FIV. Some reports include FeLV-positive cats, whereas others exclude them.[10,21,29–31,42] Because of the possibility of ehrlichial disease, it has been recommended that all cats be treated with a course of doxycycline before the diagnosis of immune-mediated disease is made.[43]

277.4 SPECIFIC TESTS

277.4.1 Lupus Erythematosus Cell Preparation

For the lupus erythematosus (LE) cell preparation, clotted blood is mashed to release free nuclei. Circulating antibody directed against nucleoprotein binds and opsonizes the nuclear complex. An LE cell is recognized as a neutrophil that contains phagocytized nuclear material. Interpretation depends on the experience and diligence of the technician, and false-negative results are common.[26,27,44] Because of technical problems and difficulty with sensitivity and specificity, the LE cell test has been largely replaced by the more sensitive ANA test. LE cells rarely may be seen on smears of pericardial, pleural, peritoneal, joint, cerebrospinal, or blister fluid and when present are highly suggestive of SLE.

277.4.2 Antinuclear Antibodies

Antinuclear antibodies are a heterogeneous population of antibodies directed against various nuclear antigens. ANAs may be detected using frozen sections of rat liver or cultured cell lines (e.g., Vero cells, HEp-2 human epithelial cells). The relative merits of each substrate are the subject of debate, and there is no universally accepted protocol used by veterinary laboratories. The result of an ANA test is commonly reported as a serum titer and pattern of nuclear staining. The most commonly observed patterns in SLE are speckled or homogenous staining, but no clear association exists between patterns and the nature of clinical disease. A clinically significant titer must be distinguished from low ANA titers that may be present in as many as 10% of normal animals and in animals with any chronic inflammatory, infectious, or neoplastic disease.[45,46]

In humans, substrates tend to remain comparable in their ability to detect common ANAs but differ substantially in the quantitation of antibody titer.[47] In dogs, it has been suggested that multiple substrates be used to increase the sensitivity of the test.[48] Two canine studies found markedly different ANA results when rat liver and HEp-2 cell substrates were compared[48,49]; however the results were well correlated in a third report.[50] Feline ANA test results were found to have a low coefficient of correlation when identical sera were sent to different laboratories.[51]

1955
1956

The most appropriate substrate, conjugate, and methodology for ANA testing remains undefined, and each laboratory's value should be interpreted individually. ANA-negative SLE cases have been described in veterinary patients,[5,26–28] and a positive ANA test result should be neither required nor sufficient in itself to make a diagnosis of SLE.

277.4.3 Autoantibodies

Suspicion of SLE in humans leads to testing for specific antibodies that provide diagnostic and prognostic information (Table 277-4). Research in this area may be helpful for further characterizing immune-mediated diseases in veterinary patients. Autoantibodies also have been studied in veterinary patients (Table 277-5).

277.4.3.1 Antibodies to DNA

Serum antibodies may recognize denatured (single-stranded) or native (double-stranded) DNA. Anti-single-stranded DNA has low diagnostic value in humans and has not been studied in veterinary medicine. Anti-double-stranded (native) DNA is highly specific for the diagnosis of human SLE, even though only 60% to 83% of patients test positive. Anti-double-stranded DNA has been identified only infrequently in dogs with SLE.

277.4.3.2 Extractable nuclear antigens

ENAs are molecules extracted from the soluble fraction of cell nuclei (DNA and histone proteins are insoluble and therefore excluded). More than 20 saline-extractable antigens have been identified, and the term *ENAs* generically refers to this group of nuclear proteins. The binding of serum antibodies to commercially available tissue extracts is the basis for serologic testing. Important ENAs include Sm, Ro, and La. In veterinary medicine, antibodies against ENAs do not yet have the diagnostic and prognostic significance they do in human patients.

Table • 277-4 Autoantibody Associations in Human Systemic Lupus Erythematosus

EPITOPE	COMMENTS
ds-DNA	Highly specific for the diagnosis of systemiclupus erythematosus
Sm	Associated with membranous nephropathy
RNP	Associated with Raynaud phenomenon, pulmonary and muscle involvement
SS-A/Ro	Associated with cutaneous manifestations, sicca complex, neonatal lupus
SS-B/La	Associated with neonatal lupus
Phospholipid	Associated with thrombocytopenia, thrombosis infertility

* Ratio of the number of patients that tested positive to the number of tested patients.

277.4.3.3 Antihistone antibodies

Histones are a group of proteins that bind the DNA helical structure into supercoil formation. Histone antibodies are characteristic of drug-induced SLE in humans. One group of investigators detected antihistone antibodies in 61% to 72% of dogs with SLE.[11,52,53] Antihistone antibodies have been detected in canine sera by other investigators; however, no significant difference in concentration was seen between ANA-positive and ANA-negative sera,[49] and antihistone antibodies were detected with conditions other than canine SLE.[54] The use of antihistone antibodies as an indicator of drug-induced SLE in veterinary patients has not been reported.

277.4.4 Antiphospholipid Antibodies

Antiphospholipid antibodies bind to phospholipids found on many cells. These antibodies interfere with the function of procoagulant phospholipids in clotting tests *in vitro*. Patients with the lupus anticoagulant have a prolonged aPTT that fails to correct with a 1:1 mixture of the patient's plasma and normal plasma. In humans, the presence of these antibodies is associated with thrombocytopenia, thrombosis, and fetal loss. Antiphospholipid antibodies were described in one dog with SLE,[34] in two of 20 dogs with hemolytic anemia,[58] and in one cat with SLE.[59]

277.5 MANAGEMENT

Sunlight should be avoided if photosensitization occurs. Patients with mild lameness may require only intermittent therapy with nonsteroidal anti-inflammatory drugs. Dogs may be given carprofen (4.4 mg/kg orally once daily), etodolac (15 mg/kg orally once daily), or meloxicam (0.1 mg/kg orally once daily). Meloxicam also has been used safely in the cat.[60]

More severe signs necessitate corticosteroid administration. Prednisone (2.2 mg/kg/day given orally) is recommended in most instances; 1 mg/kg/day may be effective in less severe cases. Full doses are administered until the disease is in complete remission, defined as resolution of clinical signs and radiographic or laboratory changes initially present. After remission has been attained, the dose is tapered, generally by half, for 4 weeks. The animal then is re-evaluated, and if signs of disease are absent (per physical examination and laboratory testing), the dose is again halved. Tapering is repeated monthly until the animal either relapses or stops medication. The recommended minimum duration of therapy is 6 months. If relapse occurs during taper, the dose should be increased to the most recently effective dose and held there for a few months. If the maintenance requirement is unacceptable because of side effects, an additional immunosuppressive agent is added.

Some cats do not respond to prednisone. Cats that don't respond well to prednisone should be treated with an alternative steroid (e.g., prednisolone, methylprednisolone, triamcinolone, or dexamethasone) before additional immunosuppressant therapies are started.

Combination immunosuppression therapy is very helpful because the additional agent often allows the use of a lower dose of corticosteroid. Azathioprine (Imuran) is most frequently used in dogs. The dose is 2.2 mg/kg given orally once daily until remission occurs. The same dose then is administered every other day. A complete blood count (CBC) should be evaluated after 7 days and then every 2 weeks while the patient is receiving daily treatment. The development of neutropenia or thrombocytopenia requires drug cessation until the bone marrow

recovers. Once the animal is receiving every other day therapy, a CBC should be evaluated every 3 months, but bone marrow suppression at this dose is unusual.

Prednisone and azathioprine are frequently used in combination. The drugs are administered together once daily and tapered after remission has been attained. The method of tapering is somewhat arbitrary. If signs of prednisone intolerance are experienced, prednisone is tapered first; if bone marrow disease is encountered, azathioprine should be tapered or discontinued first. If the disease was difficult to bring into remission, only one drug should be tapered at a time; if the disease easily went into remission, the two drugs may be tapered concurrently. Tapering should be performed every 4 weeks, with a minimum duration of therapy of 6 months.

Azathioprine is not recommended for use in cats. Instead, chlorambucil may be administered along with corticosteroids for cats that require additional immunosuppression. Chlorambucil (Leukeran) is administered to cats at a dosage of 15 mg/m^2 (4 mg for most cats) given orally once daily for 4 days and then repeated every 3 weeks. Potential side effects include anorexia and bone marrow suppression. A CBC should be evaluated 5 to 7 days after each course of treatment. If after two or more evaluations the CBC remains normal (no leukopenia), further monitoring may be done less frequently. If leukopenia is detected (absolute neutrophil count less than 3000/μL), the dose of the next administration should be decreased 25%. Signs of infection (loss of appetite along with fever) during the expected white blood cell nadir (3 to 10 days after administration) should be aggressively treated with intravenous fluids and broad-spectrum antibiotics. In cats, the chlorambucil dosage should be tapered before the prednisone is tapered.

Novel therapeutic approaches include prednisone (1 to 2 mg/kg orally once daily) combined with levamisole (2 to 5 mg/kg, to a maximum dose of 150 mg orally every 48 hours).[11] Prednisone is tapered and discontinued after 2 months, whereas levamisole is given continuously for 4 months and then stopped. If relapse occurs, levamisole is readministered, again for 4 months. Approximately 75% of dogs treated with such therapy were reported to attain remission. Side effects included agranulocytosis, excited behavior, and aggressiveness.[39]

In humans, an antimalarial drug (e.g., hydroxychloroquine) may provide additional relief. Antimalarial agents have multiple sun blocking, anti-inflammatory, and immunosuppressive effects, although their mechanism of action is not completely understood.[61] Their use has not been reported in dogs or cats with SLE.

277.6 PROGNOSIS

The natural course of SLE in veterinary patients is not known. Patients may be well controlled and medications may be tapered, but relapses should be anticipated. Routine evaluation should include hematology, biochemistry, urinalysis, and serum ANA determination every 1 to 3 months. The ANA titer may correlate with clinical severity and may fall with clinical improvement, but the antibody may persist at a low titer during clinical remission. It has been suggested that therapy should be more aggressive when the clinical presentation includes renal disease.[10,39]

278 CHAPTER • 278 Immune-Mediated and Infective Arthritis

David Bennett

Immune-mediated and infective arthropathies are characterized by an elevated white cell count in the synovial fluid, mainly comprising neutrophils. Synovial fluid analysis is mandatory for diagnosis of these so-called inflammatory arthropathies, and it distinguishes them from the more common degenerative arthropathies.[1]

Infective arthritis is defined as an inflammatory arthropathy caused by an infective agent that can be cultured from the affected joint or joints; however, it is not always possible to culture the organism, and it is important to assume infection if only a single joint is affected. Bacteria are the most common cause of infective arthritis.

The immune-mediated diseases are generally polyarthropathies, although some of the more uncommon infections can involve multiple joints. Although the etiology of immune-mediated arthritis is unknown, certain microbial infections have been implicated. One mechanism is immune complex formation in response to microbial infection, either locally in the joint or systemically with deposition into the joint.[2] Transportation of microbial antigens to joints, with a subsequent immune response, is another possibility. Canine distemper viral antigens and antibodies have been identified in the immune complexes from the synovia of dogs with immune-mediated arthritis[3]; macrophages containing distemper antigens have also been demonstrated in the synovial membrane.[4]

In addition, it is likely that certain individuals are genetically predisposed to immune-mediated arthritis; certain DLA-DRB1 alleles (DRB1 002, 009, and 018) have been associated with immune-mediated arthritis in the dog; furthermore, it appears that a conserved amino acid motif in the third hypervariable region in some DRB1 alleles of both humans and dogs is associated with immune-based arthritis in both species.[5]

The theory of molecular mimicry has also been proposed; that is, antibodies against certain bacteria or viruses may cross-react with cartilage components. Some researchers think that polyclonal B-cell activation, as may occur in a persistent or serious infection, may lead to the emergence of autoantibodies against joint "self-antigens." For example, autoantibodies against heat shock proteins may stimulate immune complex formation in joints or may even cross-react with cartilage epitopes.[6] Potential antigens may also originate from nonmicrobial sources, such as tumor antigens, drug antigens/haptens, and dietary antigens. Once the joint inflammation has been established, by whatever mechanism, various autoantigens, such as altered collagen, are produced. These autoantigens stimulate an immune response, thereby helping to perpetuate the inflammation.[7,8]

Obviously lameness is an important clinical feature, although many immune-mediated polyarthropathies present as cases of "pyrexia of unknown origin." Only about one third of infective arthropathies have systemic signs. Lameness may be an obvious limp, although generalized stiffness is most often seen with the immune-mediated polyarthropathies. Bacterial infections generally have an acute onset, although a more chronic, insidious onset is possible, the so-called low-grade infections. The joint is usually swollen and painful on manipulation, and heat may be detectable.

The immune-mediated arthropathies also tend to have a sudden onset, with multiple joints swollen and painful in a bilaterally symmetric fashion. In some cases obvious joint swelling and pain may not be apparent, but multiple arthrocenteses and fluid analyses confirm the diagnosis. Multiple synovial fluid analyses should be performed in all cases of "pyrexia of unknown origin"; immune-mediated polyarthritis is the single most common diagnosis of such cases in a referral practice.[9]

Local lymphadenopathy is common with both the infective and the immune-mediated arthropathies. Diseases of other body systems are common with the immune-mediated arthropathies, although these can occur with certain infections as well.

278.1 BACTERIAL INFECTIVE ARTHRITIS (SEPTIC ARTHRITIS, SUPPURATIVE ARTHRITIS)

Beta-hemolytic streptococci of Lancefield group G, staphylococci, hemolytic *Escherichia coli, Pasteurella* sp., and *Erysipelothrix* sp. are the bacteria most commonly isolated from septic joints.[10,11] Less commonly isolated organisms include *Corynebacterium, Salmonella, Brucella,* and *Pseudomonas* spp. and anaerobic organisms. In some cases a mixed infec-tion may be present, involving both aerobic and anaerobic bacteria.

Infection can be introduced by direct penetration of a joint, as can occur with bite wounds, iatrogenic infection after open joint surgery, or arthrocentesis, or through road accident injuries. Most joint infections in cats are associated with bite wounds incurred in fights. However, in most dogs, infection occurs by the hematogenous route, and the source of infection is often unknown. Pre-existing joint disease and/or prior surgical intervention predisposes the joint to opportunistic infection as a result of seeding of organisms in the compromised synovial tissues. Trauma can predispose a joint to subsequent infection and lameness; an initial mild injury may resolve, but the lameness returns a few days later after hematogenous localization of infection to the joint. Bacterial infections may also spread to joints from infected foci in neighboring soft tissues or bone.

Most cases involve only a single joint, but two joints may be affected at the same time, or a second joint may be affected some time after the first (Figure 278-1). Involvement of more than two joints most often occurs secondary to a severe systemic bacterial infection, such as bacterial endocarditis[12] or omphalophlebitis, that has a significant bacteremic component. Bacterial endocarditis can result in a true infective arthritis or in an immune-mediated arthritis. These dogs often have lesions of other body systems, and a cardiac murmur is often present. Ultrasonography may show the vegetative endocarditic lesion.

Bacterial infective arthritis affects dogs of all ages. The larger breeds are most often affected, and the male to female ratio is 2:1. The radiographic features vary with the type of infection and its duration. The earliest radiographic change is soft tissue swelling (Figure 278-2). A marked periosteal reaction often develops in the later stages, and calcification of the joint capsule may be seen. Subchondral bone erosions may appear as discrete radiolucencies or as more extensive bone destruction (Figure 278-3). Patchy sclerosis of subchondral bone is often seen. Some infected joints show an overall loss of bone density (see Figure 278-3). Leukocytosis, as a result of neutrophilia and a left shift, is an inconsistent finding.

Figure 278-1 Photograph of an infected elbow joint. The synovium is thickened and hemorrhagic. There is no obvious destruction of the cartilage, which suggests that this is a relatively early lesion.

Figure 278-2 A mediolateral radiograph of an infected stifle joint. Only soft tissue changes are present. There is loss of the infrapatellar fat pad and distension of the caudal joint capsule. These changes are not specific for bacterial infective arthritis. They indicate a synovial effusion, but synovial fluid analysis is essential to demonstrate an inflammatory arthropathy; also, if only a single joint is involved, the cause is likely to be infection.

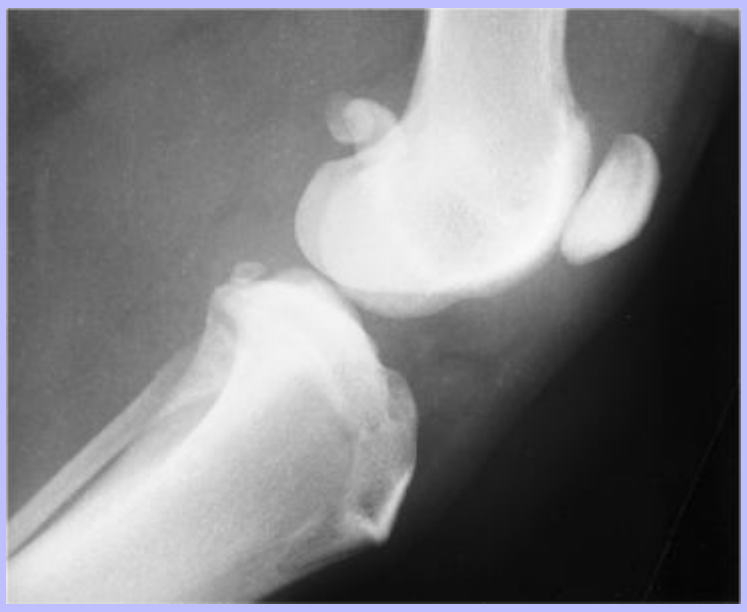

Figure 278-3 Craniocaudal radiograph of an infected stifle joint showing more advanced pathology. Bony destruction is obvious, as shown by an increased intercondylar notch and bony loss at the articular margins of the femur and tibia. Overall loss of bone density of the distal femur also is present. There is evidence of previous surgery, specifically a tibial plateau leveling osteotomy for cranial cruciate ligament failure.

The diagnosis of bacterial infective arthritis is confirmed by culture of the organism from synovial fluid or synovial membrane (or both); however, negative cultures are not uncommon. Blood cultures are sometimes

worthwhile if the animal is pyrexic. Bacterial sensitivity testing should be performed on positive cultures to aid therapeutic planning.

The mainstay of therapy is a prolonged course of systemic antibiotics, which should be initiated in all suspect cases pending confirmatory laboratory results. A broad-spectrum bactericidal antibiotic is used. Ampicillin, clavulonate-potentiated amoxicillin, and cephalosporins are all useful. The antibiotic should be changed only if indicated by subsequent antibiotic sensitivity tests. If anaerobic infection is suspected or if the response to the initial antibiotic is poor, metronidazole is used in combination with other antibiotics. Local gentamicin beads or sponges can be used with resistant infections.[13]

Systemic antibiotic therapy is continued for at least 4 to 6 weeks, or for 2 weeks after complete resolution of clinical signs. Joint lavage and drainage are particularly indicated if the clinical signs are severe or if the patient is an immature animal with open growth plates. Rest of the joint, by means of strict confinement and support bandaging, is important in the early stages. Analgesics are generally necessary, and the nonsteroidal anti-inflammatory drugs are ideal for this. During the recovery phase, controlled exercise, such as passive flexion and extension or gentle lead walks, should be initiated to maintain range of movement in the joint. The level of exercise can be gradually increased after the first 4 weeks.

1959

1960

278.2 LYME ARTHRITIS

Lyme disease is a tick-borne, multisystemic illness that affects humans and a number of domestic animals. It is caused by infection with the spirochete *Borrelia burgdorferi,* which is primarily transmitted by ticks of the *Ixodes* genus.[14–16] The most common presenting sign in dogs is acute lameness associated with a migratory monoarthritis or pauciarthritis. True polyarthritis is rare, although an immune-mediated arthritis has been reported. Episodes of lameness typically last only a few days, although repeat episodes may occur. Other manifestations include neurologic and cardiac signs. Radiographs of affected joints may be normal or may show only soft tissue swelling in the joints.

A diagnosis of Lyme disease is difficult to establish with certainty. *B. burgdorferi* is notoriously difficult to culture from clinical cases. Serologic testing is of value, although subclinical and asymptomatic infections can occur. Approximately 20% of normal dogs with a history of a tick bite are seropositive for *B. burgdorferi,* therefore the mere presence of a positive serum anti-*Borrelia* antibody test in a lame dog is insufficient to establish a diagnosis of Lyme disease.[15]

Lyme disease is treated with antibiotics, such as tetracycline, penicillin derivatives, and erythromycin. A response normally is seen within 7 days of the start of treatment, but antibiotic therapy should be continued for at least 2 weeks after resolution of all clinical signs. Most cases have an excellent prognosis, particularly if diagnosed and treated promptly.

Cats undoubtedly are exposed to *B. burgdorferi,* in that 4.2% to 15% of normal cats are seropositive for the organism, but little evidence of clinical disease exists in this species.[17–19] The reason for this is unclear, but the cat's immune response does differ from the dog's in that felines shown an early response to OspA and B antigens.[18]

278.3 BACTERIAL L-FORMS AND ARTHRITIS

L-form bacteria are cell wall–deficient bacteria, and these organisms have been associated with pyogenic subcutaneous abscesses and arthritis in cats. The infection spreads locally and hematogenously to involve other joints and subcutaneous sites. The infection is resistant to many antibiotics but is susceptible to tetracyclines.

278.4 MYCOPLASMAL ARTHRITIS

Mycoplasmal infection of joints may arise as a result of the spread of organisms from localized sites of active or latent infection in the mucous membranes of the airways, conjunctivae, or urogenital tract. This is most likely to occur in debilitated or immunodepressed animals. *Mycoplasma gatae* and *Mycoplasma felis* have been associated with polyarthritis and tenosynovitis in cats. Infection with *Mycoplasma spumans* is associated with a polyarthritis syndrome of young greyhounds[20,21]; it is essentially a nonsuppurative polysynovitis, usually associated with severe destruction of articular cartilage.

Animals with mycoplasmal arthritis present between the ages of 3 and 30 months (average age is 18 months) with an insidious onset of clinical signs. The organisms may be seen in a synovial fluid smear stained with Wright, Leishman, or Giemsa stain; they may also be found in the cerebrospinal fluid. Mycoplasmal arthritis can be treated with tylosin, gentamicin, or erythromycin.

278.5 FUNGAL ARTHRITIS

Fungal arthritis is very rare. It usually occurs as an extension of fungal osteomyelitis but may also present as a primary granulomatous synovitis. Fungal infections of joints have involved a range of organisms, including *Coccidioides immitis, Blastomyces dermatitidis, Filobasidiella* (*Cryptococcus*) *neoformans, Sporotrichum schenckii,* and *Aspergillus terreus*. The organisms may be seen in synovial fluid smears or cultured from the joint.

278.6 RICKETTSIAL ARTHRITIS

Polyarthritis increasingly is recognized in association with rickettsial infections in dogs. *Rickettsia rickettsii,* the causative organism in Rocky Mountain spotted fever (RMSF), is transmitted by ticks of the *Dermacentor* genus and is endemic in wooded areas of the central United States and the eastern seaboard. RMSF is a severe disease associated with rapid dissemination of *R. rickettsii* from the site of the tick bite to many organs in the body, resulting in widespread vasculitis. Polyarthritis is one possible clinical sign.

Canine ehrlichiosis (*Ehrlichia canis* infection transmitted by the tick *Rhipicephalus sanguineus*) may present as a polyarthritis in certain geographically restricted areas, including Missouri and Tennessee. Cats are thought to suffer infection by rickettsiae of the *Ehrlichia* genus, but case reports are lacking.

278.7 PROTOZOAL ARTHRITIS

Leishmaniasis is a chronic systemic disease caused by the protozoan parasite *Leishmania donovani. L. donovani* is transmitted by insect vectors, mainly sandflies, and is endemic in areas such as the Mediterranean, Africa, Asia, and South America. The dog is the main reservoir host in many areas. In addition to polyarthritis, signs such as fever, malaise, weight loss, dermatopathy, lymphadenopathy, and hepatosplenomegaly may occur in the dog. The disease has a long latent period and may appear in nonendemic areas despite prolonged quarantine

procedures. The synovitis is usually associated with an infiltrate of large numbers of macrophages filled with *Leishmania* bodies. An immune-mediated polyarthritis may also be seen in association with the infection. Leishmaniasis is an important zoonosis, and there are public health implications if the disease is diagnosed in dogs, particularly outside endemic areas. Cats can become infected, but clinical disease is rare.

Toxoplasma gondii infection is well known in the cat and does occur rarely in the dog; lameness can be a feature, but joint involvement is poorly documented. *Neospora caninum* infection can cause a polymyositis as well as neurologic disease; only experimental infection in the cat has been reported.

Infection with *Hepatozoon canis* can cause polyarthritis and polymyositis in both the dog and the cat. Infection occurs by ingestion of the vector tick (*R. sanguineus*), which contains the organism in its digestive tract.

Infection with *Babesia* spp. most often causes severe anemia, although polyarthritis and polymyositis have very rarely been described. *B. canis* and *B. gibsoni* affect the dog, and *B. felis, B. cati, B. herpailuri,* and *B. pantherae* affect the cat. Babesioses are tick-borne diseases carried by ixodid ticks, and concurrent infection with other protozoal organisms can occur.

1960

1961

278.8 VIRAL ARTHRITIS

Calicivirus can produce a true infective arthritis in the cat, most often under cattery conditions, and certain strains are more likely to be involved. Experimental studies have shown that calicivirus can infect joints and cause synovitis, and that live virus can be recovered from these joints.[22,23] A field strain of calicivirus isolated from a lame cat (strain F65) was used to infect experimental cats either intra-articularly or by contact exposure. This strain was particularly trophic for the joints, although nasal, oral, and ocular tissues were also infected.

278.9 IMMUNE-MEDIATED ARTHRITIDES

The immune-based arthropathies are divided into two broad categories, erosive and nonerosive,[24–29] based on whether bony destructive changes are present on the radiographs. The diseases that cause bony destruction generally have a poorer prognosis. A radiographic survey of several joints should be made.

278.10 EROSIVE IMMUNE-BASED ARTHRITIDES

278.10.1 Rheumatoid Arthritis

Rheumatoid arthritis (Figures 278-4 and 278-5) can affect any breed or cross-breed of dog; it is very rare in the cat.[30] Animals are usually adult, although the exact age of onset varies (an average age of 5 to 6 years is reported).[24]

The classic radiologic feature of rheumatoid arthritis is the presence of subchondral bone destruction, visualized as an irregularity of the articular surface or as “punched out” erosions (Figure 278-6). Advanced cases may show extensive bone destruction with gross joint deformity. A more generalized loss of mineralization of the epiphysis can be another feature, and soft tissue swelling around or synovial effusion within the joint may be present. Calcification of the soft tissues around the joint is often seen. In some early cases, radiographic evidence of bone destruction may be absent; such evidence generally appears within 6 months if the disease persists.

Rheumatoid arthritis is commonly but not invariably associated with the presence of circulating autoantibodies against immunoglobulin G, collectively known as rheumatoid factor.[31] However, rheumatoid factor is not specific for this disease, because it occurs in the other immune-mediated arthropathies and in other disease states, particularly those of a chronic nature, in which antigen-antibody interaction ocurs.[31] Certain dogs in which rheumatoid arthritis can be diagnosed test negative for rheumatoid factor, and some dogs initially may test positive but later test negative, and vice versa.

Figure 278-4 Gross appearance of the carpus of a dog with rheumatoid arthritis. Two obvious areas of cartilage and bone loss can be seen, and the resultant ulcers have been replaced with granulation tissue. The synovium is thickened and discolored. Multiple, symmetric joint involvement was apparent in this dog.

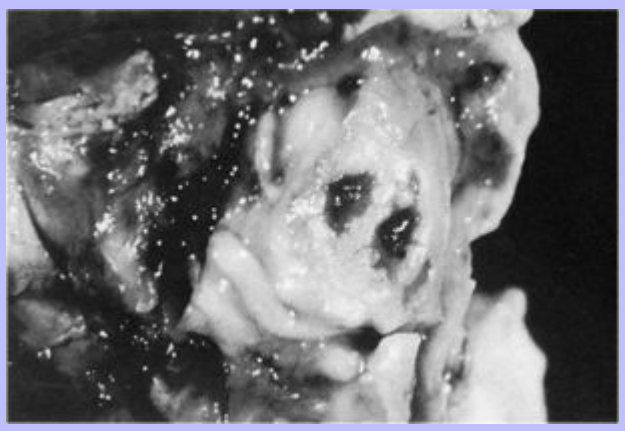

Figure 278-5 Photomicrograph of a canine rheumatoid joint. The articular cartilage has been replaced with granulation tissue in several areas, and a thin covering of the articular cartilage by granulation tissue (pannus) is seen in some areas.

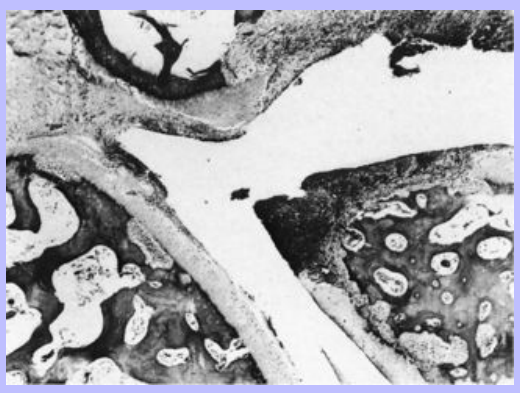


278.10.1.1 Periosteal Proliferative Polyarthritis

Periosteal proliferative polyarthritis, an erosive polyarthritis, is rare in the dog but common in the cat.[30] It affects mainly the hocks and carpi, and the characteristic feature is marked periosteal new bone formation, often extending beyond the confines of the joint (Figure 278-7). Also, one or more joints show localized bony erosions. Bony destruction and proliferation can also occur at the attachment of ligaments and tendons, lesions known as *enthesiopathies*. Cats of any age can be affected, although the disease is said to be common in young adults. Male castrated cats appear to be affected more often.

1961

1962

Figure 278-6 Craniocaudal radiograph of a carpus of a dog with rheumatoid arthritis. The obvious radiolucent areas in the carpal bones represent bony lysis. Also, the joint space is increased between some of the carpal bones. This appearance may be seen with a septic joint, but this dog had multiple joint involvement consistent with an immune-based polyarthritis.

Figure 278-7 Mediolateral radiograph of the hock joint of a cat with periosteal proliferative polyarthritis. New bone deposits are seen on the bones of the hock joint and on the distal tibia and proximal metatarsus. The periosteal reaction extends beyond the confines of the joint. Small areas of bone lysis also can be seen in most of the tarsal bones. Two small areas of bone lysis are present in the tip of the os calcis, together with periosteal new bone, a finding consistent with an erosive enthesiopathy.

278.11 NONEROSIVE IMMUNE-BASED ARTHRITIS

278.11.1 Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystemic disease characterized by simultaneous or sequential development of autoimmune hemolytic anemia, immune-mediated thrombocytopenia, leukopenia, glomerulonephritis, dermatitis, polymyositis, pleuritis, central nervous system (CNS) disease, and symmetric

polyarthritis.[26] SLE occurs in both dogs and cats, and because the clinical signs are so variable, diagnosis of the disease can be difficult.

The pathogenesis of SLE involves two main components, autoimmunity and immune complex hypersensitivity. Antibodies against red blood cells, platelets, and leukocytes are important in the development of hemolytic anemia, thrombocytopenia, and leukopenia; the deposition of immune complexes (possibly nuclear antigen and antinuclear antibody) in the kidneys (glomeruli), joints (synovial blood vessels), and skin (dermal/epidermal junction), and possibly in other organs, explains the inflammatory changes in these tissues.

Joint radiographs may show no obvious abnormalities, although occasionally soft tissue swelling or synovial effusion is present.

SLE is characterized by the presence of circulating antinuclear antibody (ANA), a group of autoantibodies targeted against nuclear material.[32] Although antinuclear antibody is found in various chronic disease states, a diagnosis of SLE cannot be justified unless the ANA test result is positive.

278.12 POLYARTHRITIS/POLYMYOSITIS SYNDROME

In polyarthritis/polymyositis syndrome, polyarthritis is complicated by polymyositis. This syndrome is most often seen in spaniel breeds.[27] The dogs test negative for antinuclear antibody, therefore the disease cannot be categorized as SLE.

These dogs present with marked stiffness and poor exercise tolerance, and they often adopt a crouched stance. Widespread muscle atrophy is usually apparent, although in the early stages, muscle swelling and pain may be seen. Muscle atrophy can be associated with fibrosis and contracture, resulting in reduced joint motion; this may be seen in the limb joints and also in the temporomandibular joints, leaving the dog unable to open its mouth.

The muscle enzymes creatine phosphokinase and aldolase are often increased, but not in all cases. Electromyography may show focal areas of spontaneous activity in affected muscles. The myositis is confirmed by multiple muscle biopsy examination (at least six muscles), although the inflammatory change can be patchy and may be absent from some muscles (myositis should be seen in at least two of the biopsy samples).

278.13 POLYARTHRITIS/MENINGITIS SYNDROME

Polyarthritis/meningitis syndrome has been seen in several breeds, including the weimaraner, Newfoundland, German short-haired pointer, boxer, corgi, and Bernese mountain dog. It also is reported in the cat. These animals present with pyrexia, stiffness, and neck pain and in some cases with nervous signs. Cerebrospinal fluid shows increased protein, white cell, and creatine phosphokinase levels, indicating an inflammatory lesion of the central nervous system.

278.14 SJÖGREN SYNDROME

In humans Sjögren syndrome was originally described as a syndrome comprising keratoconjunctivitis sicca (“dry eye”), xerostomia (“dry mouth”), and a polyarthritis, which may be an erosive (rheumatoid) arthritis or a nonerosive arthritis. Dry eye in the dog has been reported with SLE and lymphocytic thyroiditis.[1] Sialadenitis with rheumatoid arthritis has also been documented.[1]

278.15 FAMILIAL RENAL AMYLOIDOSIS IN CHINESE SHAR PEIS

Dogs with familial renal amyloidosis of Chinese Shar Peis present with episodes of fever and with swelling of one or both hock joints and occasionally other joints.[33,34] Enthesiopathies are also seen. The age of onset of signs is variable (young puppies or adult dogs), and the period between attacks can be variable but often is 4 to 6 weeks. Amyloid deposits occur in several organs, but renal amyloidosis and hepatic amyloidosis are the conditions most significant to the prognosis. Amyloidosis eventually results in renal or hepatic failure, which may occur any time between 1.5 and 6 years of age.

278.16 POLYARTHRITIS OF THE ADOLESCENT AKITA

Polyarthritis of adolescent Akitas affects dogs less than 1 year of age.[35] Meningitis may also be present, as may other organ involvement. These dogs have an unfavorable prognosis, because the response to anti-inflammatory and immunomodulatory drugs is poor.

1962
1963

278.17 POLYARTERITIS NODOSA

Polyarteritis nodosa is an inflammatory condition of the small arteries, often of a granulomatous nature, that can be diagnosed only by histologic examination of biopsy material. Polyarthritis, polymyositis, and meningitis can occur. The attacks are often cyclical, although persistent signs can occur.

278.18 DRUG-INDUCED ARTHRITIS

Drug-induced vasculitides are basically hypersensitivity reactions involving the deposition of drug antibody complexes around blood vessels in different areas of the body. The drug may act directly as an antigen or may combine with host proteins as haptens to form neoantigens.

Polyarthritis is only one feature of these disease syndromes; fever, lymphadenopathy, and macular-papular or bullous-type hemorrhagic rashes are common. Thrombocytopenia, hemolytic anemia, polymyositis, retinitis, and glomerulonephritis are also reported.

The most commonly incriminated drugs are antibiotics, particularly sulfa drugs, lincomycin, erythromycin, cephalosporins, and penicillins. The Doberman pinscher appears particularly susceptible to sulphadiazine-trimethoprim.[36] The diagnosis is made on the basis of worsening clinical signs while the animal is undergoing drug therapy and very rapid improvement (2 to 7 days) after the drug is stopped. The animal usually has had to have encountered the drug previously to become sensitized or has been undergoing long-term therapy.

278.19 VACCINATION REACTIONS

Occasionally an immune-based polyarthritis can develop after vaccine inoculations. It is most likely to occur after the first injection of a primary vaccination course, particularly in kittens.[37] The polyarthritis is generally seen 5 to 7 days after the first inoculation, and the lameness is usually only transient, lasting for 24 to 48 hours.

The calicivirus component appears to cause the condition, and calicivirus antigens have been identified in synovial macrophages of vaccinated (F9 strain) and naturally infected (A4 strain) cats.[22] The presence of these antigens has been associated with an active synovitis.

Persistent polyarthritis in the dog has been reported after recent vaccination.[38] Canine distemper antigens have been found in immune complexes from the joints of dogs with immune-mediated arthritis.[3]

278.20 IDIOPATHIC POLYARTHRITIS

Idiopathic polyarthritis includes all those cases of inflammatory arthropathy that cannot be classified into the other groups. It is still the most common type of polyarthritis in both the dog and the cat.

The idiopathic group can be divided into four subcategories[1]:

- Type I: Uncomplicated idiopathic arthritis; this is the most common subgroup.
- Type II: Idiopathic arthritis associated with infections remote from the joints (reactive arthritis). The infections commonly occur in the respiratory tract, tonsils, conjunctiva (e.g., chlamydia in the cat), urinary tract, uterine tract, skin (including anal furunculosis) and oral cavity.[28]
- Type III: Idiopathic arthritis associated with gastrointestinal disease (enteropathic arthritis). The gastroenteritis is usually characterized by vomiting and/or diarrhea. Sometimes blood is present in the feces. Cases of intestinal bacterial overgrowth and malabsorption have been complicated by polyarthritis, and very occasionally the intestinal disease is an ulcerative colitis.
- Type IV: Idiopathic arthritis associated with neoplasia remote from the joints (arthritis of malignancy). The neoplastic lesion may not be apparent by clinical assessment; some are recorded only during a *postmortem* examination. Neoplasias have included squamous cell carcinoma, heart base tumor, leiomyoma, and mammary adenocardinoma.[28] In the cat, myeloproliferative disease is the most common association,[30] and cats with a nonerosive polyarthritis that do not respond well to therapy should always have a bone marrow examination and should be tested for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV).

The age of onset can vary from a few months to 11 years; many animals are young adults (1 to 3 years) when first presented, especially in type I cases. The pathology is generally an acute/subacute synovitis (Figures 278-8 and 278-9). Soft tissue swelling and/or synovial effusion may be apparent on radiography (Figure 278-10), although often no abnormality is visible. Disease of other body systems is not uncommon.

278.21 TREATMENT

The treatment and prognosis vary with the different types of polyarthritis. Repeated synovial fluid analysis is the most sensitive method of monitoring the effectiveness of treatment. A fall in the total cell count and a reduction in the proportion of polymorphs are good prognostic signs. The erosive arthropathies and animals with multiple-system disease tend to have a poorer prognosis.

The initial treatment in most cases is to attempt immunosuppression with high doses of corticosteroids. These are given orally for 2 weeks (prednisolone, 2 to 4 mg/kg) in a daily divided dose, and the dosage then is gradually

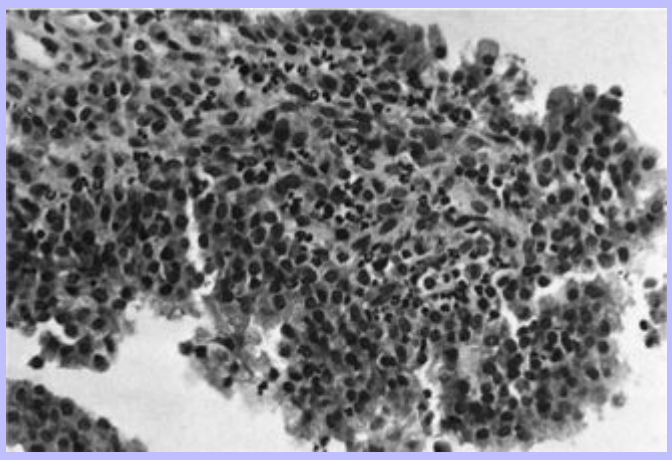
reduced over the next 4 to 8 weeks. Generally a marked response occurs within a few days, but it is important that therapy be maintained to help prevent relapses.

Figure 278-8 Photograph of the stifle joint from a dog with nonerosive polyarthritis (idiopathic type 1). The synovium is thickened and discolored, but the articular cartilage appears normal.

Figure 278-9 Mediolateral radiograph of the stifle joint of a dog with nonerosive polyarthritis (idiopathic type 1). Only soft tissue changes are seen (loss of the infrapatellar fat pad and distension of the caudal joint capsule). Although these changes are not specific for immune-mediated arthritis, this dog had multiple symmetric joint involvement, and the synovial fluid analysis was consistent with an inflammatory arthropathy.

Repeat arthrocentesis and synovial fluid analysis of a joint initially sampled for diagnostic purposes are performed at 2 weeks; if the white cell count has fallen below 4000/mm^3 and most of the cells are mononuclear, the prognosis is reasonably good. If the polymorph count is still high, high-dose steroid therapy should be continued for a longer period. Relapses are always possible, therefore the prognosis overall is guarded.

Figure 278-10 Photomicrograph of a synovial membrane biopsy sample from a dog with idiopathic type 1 polyarthritis. Hyperplasia and hypertrophy of the lining layer are present, as is an inflammatory infiltrate of mononuclear and polymorphonuclear cells in the supporting layer. This is typical of an inflammatory arthropathy, whether infective or immune based, and it could be consistent even with a degenerative arthropathy.



If relapses occur or if the response to prednisolone therapy is poor, a combination of prednisolone and cytotoxic drugs can be tried. The cytotoxic drug of choice is cyclophosphamide, given orally at a dosage of 1.5 mg/kg (for dogs over 30 kg), 2 mg/kg (for dogs 15 to 30 kg), or 2.5 mg/kg (for dogs under 15 kg). The drug is given on 4 consecutive days of each week or as close to this regimen as possible, allowing for the fact that, because of health and safety issues, tablets cannot be divided. In addition, oral prednisolone is given each day at an anti-inflammatory dosage (0.25 to 0.5 mg/kg) to help control pain by reducing the articular inflammatory load. This treatment is continued for 2 to 4 months, even though clinical remission may occur much earlier. Cyclophosphamide should not be used for longer than 4 months because of bladder toxicity problems. The urine can be tested weekly for blood, but the drug does not need to be stopped unless overt blood is visible.

Once cytotoxic therapy has been instigated, blood counts should be monitored every 7 to 14 days. If the white cell count falls below 6000/mm^3 or the platelet count below 125,000/mm^3, the dosage should be reduced by one fourth; if the white cell count falls below 4000/mm^3 or the platelet count below 1000,000/mm^3, the drug should be discontin-ued for 2 weeks and then recommenced at half the original dosage.

In dogs (but not in cats), azathioprine can be used as an alternative to cyclophosphamide, at a daily oral dosage of approximately 2 mg/kg every other day, together with low-dose prednisolone given every other day (alternating with the azathioprine). Bone marrow suppression is more likely with azathioprine.

If the response to cytotoxic drugs and prednisolone is still poor or if relapses occur, a combination of a cytotoxic drug, low-dose prednisolone, and levamisole can be tried. Levamisole may act as an immunomodulatory drug

(i.e., it may suppress helper T cells). It is administered as a liquid oral preparation at a dosage of 5 to 7 mg/kg every other day up to a maximum of 150 mg daily.

Whatever the therapeutic regimen used, the intention is to stop therapy after 3 to 6 months. Generally the cytotoxic drug and levamisole are stopped first, and the steroid is continued at an ever-decreasing dosage.

Gold injections (sodium aurothiomalate or aurothioglucose) have been used in cases of rheumatoid arthritis with some success. It is important to administer a small test dose before full treatment is begun to check for any adverse sensitivity to the drug, and the animal must be checked regularly during treatment for toxic side effects. The dose ranges from 5 to 40 mg, given by intramuscular injection at weekly intervals for 6 weeks. Generally, low-dose prednisolone also is given.

Auranofin (Ridaura), an oral preparation of gold, is also available. Auranofin, which is given at a dosage 0.05 to 2 mg/kg administered twice daily, is less toxic than the injectable gold preparation, but diarrhea is a common side effect.

A combination of oral methotrexate and leflunomide has been used in the cat to treat rheumatoid arthritis. The methotrexate dose is given once weekly; on the day it is given the dose is 7.5 mg divided into three separate and equal doses of 2.5 mg each. The leflunomide dose is 10 milograms daily and is given by oral administration. When significant improvement has occurred, the doses are reduced to 2.5 mg of methotrexate once weekly and 10 mg of leflunomide twice weekly.

Constant corticosteroid therapy sometimes is necessary to keep an animal in clinical remission, and this is perhaps acceptable if only a small dose is required. A few patients spontaneously recover within a day or two without any treatment. Nonsteroidal anti-inflammatory drugs can be used in mild cases or while laboratory results are awaited.

1964

1965

Treatment of idiopathic arthritis types II, III, and IV is directed primarily against the infective, alimentary, or neoplastic lesion, although corticosteroid therapy may be necessary. Colchicine treatment has been used in attempts to control the amyloidosis of familial renal amyloidosis of the Chinese Shar Pei, but its effectiveness has not been proved, and it does not influence the episodes of fever and arthritis.

It is important to provide supportive therapy for these animals when appropriate. Rest, avoidance of stress environments, and good nutrition are essential. Patients receiving immunosuppressive therapy should be checked regularly for secondary infections, and owners should be warned to avoid potential disease environments. Because of the possible involvement of canine distemper virus in immune-mediated arthritis, dogs that have suffered immune-mediated polyarthritis should be screened for distemper antibody levels when a booster inoculation is due; if the levels are consistent with protection, the booster should exclude the distemper component.

279 CHAPTER • 279 Skeletal Diseases

Kenneth A. Johnson

A.D.J. Watson

279.1 INTRODUCTION

Animals with bone disease may have signs of lameness, deformity, or dysfunction that could be confused with, or complicated by, joint, muscle, or neurologic disorders. Therefore a systematic approach is necessary in evaluating animals with these signs. The expertise of a radiologist and bone pathologist will often be invaluable in establishing a diagnosis. Traumatic injuries should also be considered in the differential diagnosis but are not discussed here, because excellent descriptions exist elsewhere.[1] Some bone diseases that also affect joints are described in Chapter 278.

The precise cause of many bone diseases that affect dogs and cats is unknown. Furthermore, some conditions have multiple causes, such as the congenital, heritable, and metabolic disorders. This makes logical classification difficult. A causative system is used here for want of a better alternative.

279.2 BONE PATHOPHYSIOLOGY

279.2.1 Structural Organization of Bone

Bone is a living tissue with several important functions, including storage of calcium, phosphorus, and other minerals. Bones act as a series of levers that facilitate the action of muscles and joints in movement, and they provide support and protection for other body systems. In addition, bone marrow stroma provides an inductive environment for hematopoiesis and is a source of osteogenic precursor cells.[2,3] Bones are structurally composed of compact (cortical) and cancellous (trabecular) bone (Figure 279-1).[4] The microstructural units of cortical bone are osteons that, in cross-section, have concentric layers of collagen fibers and a central canal.

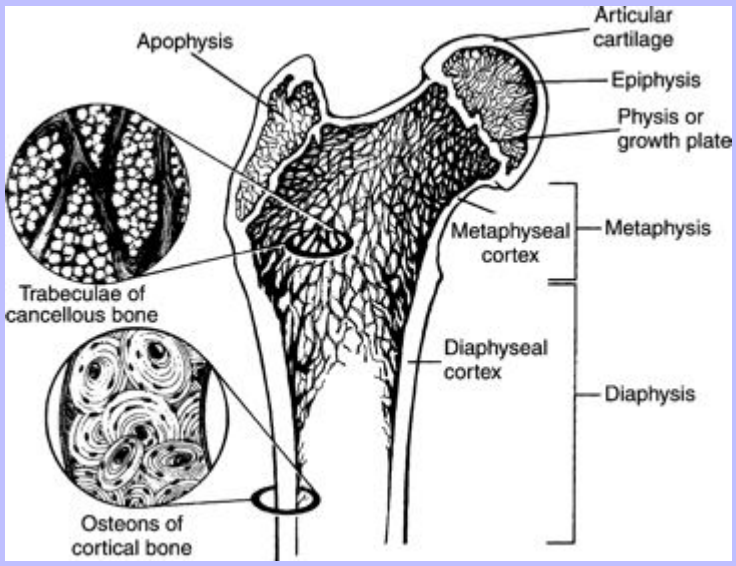
Trabeculae of cancellous bone have a three-dimensional lattice arrangement and large intertrabecular spaces containing hemopoietic or fatty marrow tissue. Long bones have several distinct regions: diaphysis, metaphysis, and epiphysis (see Figure 279-1). In growing animals, each epiphysis contains one or more ossification centers, is covered by hyaline cartilage on the articular surface, and is separated from the metaphysis by the physis or growth plate.[5,6] For reasons not well understood, many diseases have a predilection for certain regions of bone or even for particular bones.

Bone cells are derived from two separate cell systems: (1) the stromal fibroblastic (osteoblasts and osteocytes) and (2) hemopoietic (osteoclasts) systems.[2,3] During bone formation, osteoblasts synthesize collagenous matrix called *osteoid*, which is mineralized to become bone. Osteoblasts entrapped in newly forming bone become osteocytes. At sites of normal skeletal growth and remodeling, osteoblasts are derived from determined osteoblast precursor cells that reside in bone marrow stroma, endosteum, and periosteum. In injury or disease, inducible osteogenic precursor cells derived from other mesenchymal tissues, such as muscle and fibrous tissue, can be stimulated to differentiate to osteoblasts and form extraperiosteal ectopic bone. Osteoblasts can form several different types of bone.[4] Lamellar bone has collagen fibers in a parallel array and

is found in osteons and mature trabecular bone. Formation of lamellar bone requires a pre-existing matrix, such as calcified cartilage matrix (so-called endochondral ossification) or old bone that has been partially removed by osteoclastic resorption. Woven bone is characterized by random orientation of its collagen fibers. It can be deposited *de novo*, without pre-existing bone or cartilage, and is formed when new bone is laid down rapidly in growth, fracture repair, and bone disease.[7] Normally it is remodeled to lamellar bone but may persist in rapidly growing osteogenic tumors.

Osteoclasts are large, multinucleate cells formed by fusion of circulating mononuclear cells. They are found on the surface of bone trabeculae and within remodeling osteons and are responsible for bone removal during growth, modeling, and remodeling of the skeleton. Osteoclasts erode mineralized bone first by solubilizing mineral, then digesting the protein.[3] This leaves concave pits in the bone surface, called *Howship's lacunae*. Formation and resorption of bone is regulated systemically by parathyroid hormone (PTH), calcitonin, and vitamin D (Chapter 237). The principle action of PTH is to activate osteoclastic bone resorption and increase blood calcium concentration. Osteoblasts have PTH receptors, but osteoclasts do not. The increase in osteoclast number and activity induced by PTH is mediated by osteoblasts via a complex coupling mechanism involving several cytokines, including receptor activator of nuclear factor-kappa B (RANK) ligand, interleukins, and tumor necrosis factor (TNF).[2,3]

Figure 279-1 Regions and microstructure of an immature proximal femur.

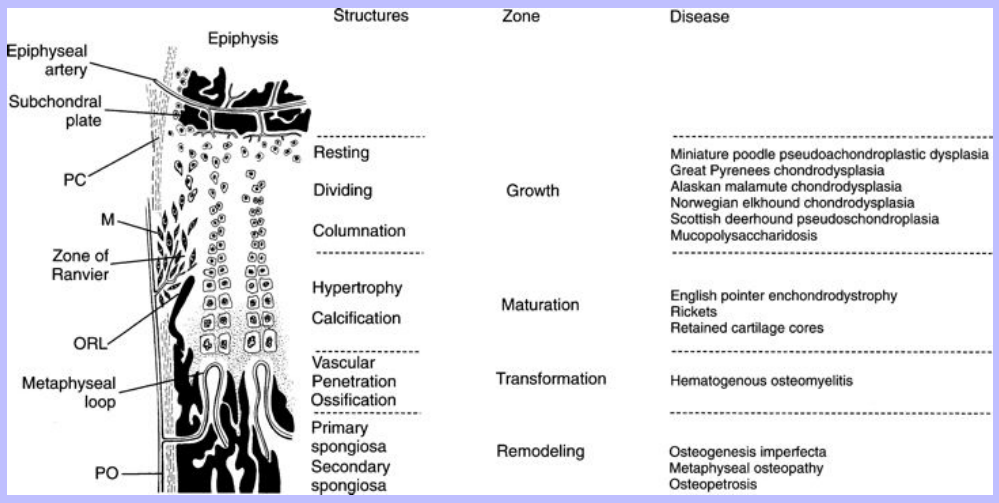


279.2.2 Bone Growth and Development

Growth of the axial and appendicular skeleton is primarily by endochondral ossification at the physes. Most physeal growth is longitudinal, but the zone of Ranvier and subperiosteal appositional growth contribute circumferential expansion as well. Physes have various zones that reflect chondrocytic structure and metabolic activity, but the transition between zones is gradual (Figure 279-2). Once formed, each chondrocyte remains in a fixed anatomic location throughout its life and there accomplishes all its functions.[8,9] The two most prominent stages involve proliferation and hypertrophy (including mineralization of matrix), prior to tissue

resorption during vascularization. Most of the longitudinal growth of a physis is due to the tenfold increase in chondrocyte volume that is maximal in the hypertrophic zone. Defects in any part of the sequence, such as incomplete chondrocyte maturation, cause dwarfism or disordered bone growth (see Figure 279-2).

Figure 279-2 The physis divided based on histologic structure and physiologic function (growth, maturation, transformation, and remodeling). Regions affected by some diseases of growth and remodeling are indicated. In the zone of Ranvier, undifferentiated mesenchymal cells *(M)* give rise to chondroblasts. The periosteum *(PO)* and perichondrium *(PC)* are continuous in this region. The metaphyseal cortex also extends into this region, becoming the osseous ring of Lacroix *(ORL)*, which acts as a peripheral restraint to the cell columns but does not impede latitudinal growth of the adjacent zone of Ranvier. (Adapted from Ogden JA: Skeletal Injury in the Child, 2nd ed. Philadelphia, WB Saunders Co, 1990, p 37.)



279.2.3 Modeling of Bone

Modeling is the process that molds and sculpts the contours of expanding bones during growth. Within the metaphysis, the primary spongiosa is modeled to secondary spongiosa, which in turn is resorbed to form the marrow cavity of the shaft. Simultaneously, bone diameter decreases rapidly in the metaphyseal *cutback zone* as redundant bone is removed by subperiosteal osteoclastic resorption. In modeling, bone formation rates are frequently unequal to resorption rates, but unlike remodeling, bone formation is not dependent on resorption to precede it.[10] Modeling can correct the shape of malunited fractures, deformities, and bone subjected to altered loading, as predicted by Wolff's law. However, because the modeling process is closely coupled to growth, it is usually less effective after maturity.[10]

279.2.4 Normal and Pathologic Bone Remodeling

Remodeling is the process in which bone renews itself throughout life.[10] It always follows the sequence of activation → resorption → formation, and the packets of cells at a remodeling site are collectively called *bone multicellular units*.[10,11] Remodeling occurs in three bone envelopes: (1) the periosteal surface, (2) the endosteal-trabecular (cancellous bone) surface, and (3) the osteonal (intracortical) surface (Figures 279-3 and 279-4). In normal remodeling, bone formation equals resorption, whereas in bone disease a pathologic imbalance of resorption and formation often results in osteopenia of cortical and cancellous bone. Bones subjected to disease, trauma, or disuse exhibit a response termed the *regional acceleratory phenomenon*, in which the number of activated bone multicellular units increases suddenly.[10] This results in increased cortical porosity and trabecular thinning that reaches a peak at approximately 2 to 3 months; it may take up to 1 year to be reversed, during which time resorption sites are refilled with new bone.[12]

1966

1967

Figure 279-3 Remodeling osteon in cortical bone shown in longitudinal section. Components of this bone multicellular unit are shown in four transverse sections on the lower level. **a,** Cutter cone with osteoclasts *(OC)* resorbing bone. **b,** Capillary loop *(CL)* with undifferentiated lining cells *(LC)* in the quiescent zone between resorption and formation. **c,** Closing cone with centripetally advancing osteoblasts *(OB)*, separated by an osteoid seam *(OS)* from radially deposited new lamellar bone *(LB)*. **d,** Completed osteon (Haversian system).

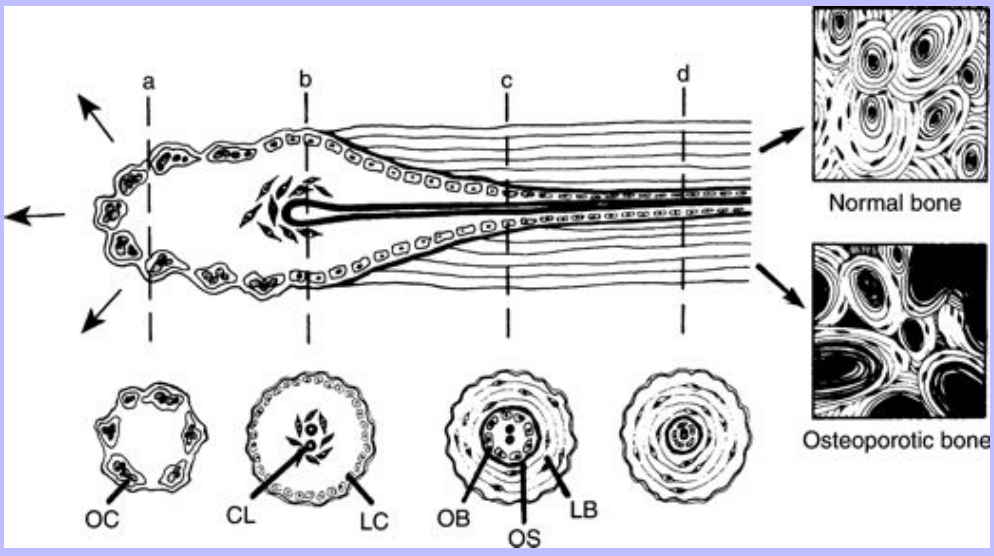


Figure 279-4 Trabecular bone remodeling with the components of bone multicellular unit: osteoclasts *(OC)*, nonmineralized matrix *(M)*, osteoblasts *(OB)*, osteoid seam *(OS)*, new lamellar bone *(LB)*, and cement line *(CL)* separating it from original bone. Normally, formation equals resorption, but in diseases causing osteoporosis, bone formation is inadequate or defective.

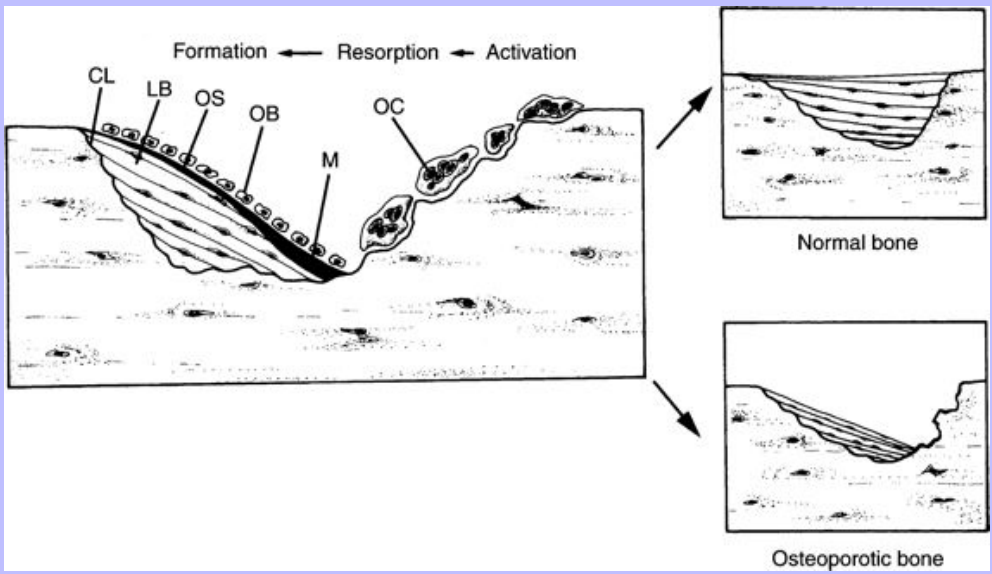

279.3 DIAGNOSIS OF BONE DISEASE

279.3.1 History and Signs

Initially, it is important to establish the age, breed, and sex of the patient because these factors may be associated with increased risk of a particular disease. Common complaints from owners are lameness, deformity, difficulty in rising, and reluctance to exercise. One must ascertain the duration and intensity (shifting, constant, intermittent, worsening) of the problem, any known trauma, and any previous illness, medication, or surgery, as well as response to therapy. The owner should be asked whether exercise or rest exacerbates the problem, and whether swelling, drainage, or apparent pain had been noticed. Recognition of similar problems in related animals may indicate heritable disease. The type and quantity of foods, vitamins, and minerals fed should be determined.

279.3.2 Physical Examination

In conjunction with the normal physical examination, special attention is paid to lameness and gait abnormalities and to the musculoskeletal system (see Chapters 194 and 195).[13,14] Visual appraisal might detect abnormalities in limb length and symmetry. The bony prominences and distal limb bones are palpated

to detect pain, swelling, dyssymmetry, or crepitus. By comparison with the contralateral limb, muscle atrophy or altered range of joint motion may be identified. Each abnormality alone is rather nonspecific but aids in region localization. Before proceeding with sedation and radiography, further testing should be considered to exclude neurologic disease as a contributing factor (see Chapters 44 and 191).

279.3.3 Radiology

Radiology is the most useful method for routine noninvasive evaluation of skeletal lesions. To appreciate subtle lesions, radiographs must be excellent. Two or more views are always needed, with the limb properly positioned. Comparison with radiographs of the contralateral limb or a radiographic atlas is useful to distinguish real bone lesions from anatomic and breed variations.[15]

Bone has a limited number of ways of responding to injury or disease. Lesions should be characterized according to changes in bone density, size, shape, or contour; the type of margination; the nature of any periosteal reaction; region of bone involved; and soft tissue changes.[16–18] The finding of a particular response, such as periosteal new bone, is not necessarily diagnostic of a specific disease (Box 279-1). Abnormalities could result from traumatic, neoplastic, infectious, idiopathic, or other processes. When considered in conjunction with signalment, history, and physical abnormalities, radiographic findings may lead to a diagnosis or a list of diagnostic alternatives. At this point it is valuable to consult descriptions of various bone diseases, to evaluate the possibilities, and to decide what further tests are indicated. Tests that are directed at confirming the most likely diagnosis, yet are least invasive and have low morbidity, are done first.

279.3.4 Nuclear Imaging

Scintigraphy is highly sensitive in detecting skeletal lesions, but it is not widely available and is generally not specific for cause.[19,20] After a radiopharmaceutical, usually ^{99m}technetium labeled methylene disphosphonate (^{99m}TcMDP), is injected intravenously, it is incorporated into sites of new bone formation and remodeling and in regions of increased blood flow. The distribution of radionuclide in bone is detected with a gamma camera and is an indication of skeletal metabolic activity, complementing the structural information from radiographs. In cases of lameness in which physical examination and radiographs are unremarkable, scintigraphy may pinpoint a region of increased uptake in bone or a joint. Further procedures such as computed tomography (CT), biopsy, culture, or surgical exploration would then be needed to determine the cause of the "hotspot."

Tumor metastases in bone have a characteristic multifocal distribution, detectable by scintigraphy before they are seen on radiographs.[20] Although scintigraphy also detects primary bone tumors, it is seldom needed for their diagnosis. Scintigraphy with ^{99m}TcMDP may help detect osteomyelitis before radiographic signs appear, but it is not specific for the disease.

279.3.5 Computed Tomography

High-resolution CT provides excellent cross-sectional images of lesions not found with radiographs. Its greatest application in the musculoskeletal system has been in evaluating the complex anatomy of skull, spine and pelvis; in delineating boundaries of tumors involving soft tissues or bone; and in detecting early bone destruction.[21] For bone tumors this information allows more precise presurgical planning for en bloc resection of cranial and pelvic lesions and for limb salvage in appendicular lesions (Figure 279-5).[22–24]

279.3.5.1 Box • 279-1 Radiologic Signs of Some Common Bone Diseases

279.3.5.1.1 Bone Loss

1. Generalized and diffuse

    Primary hyperparathyroidism

    Renal secondary hyperparathyroidism

    Nutritional secondary hyperparathyroidism

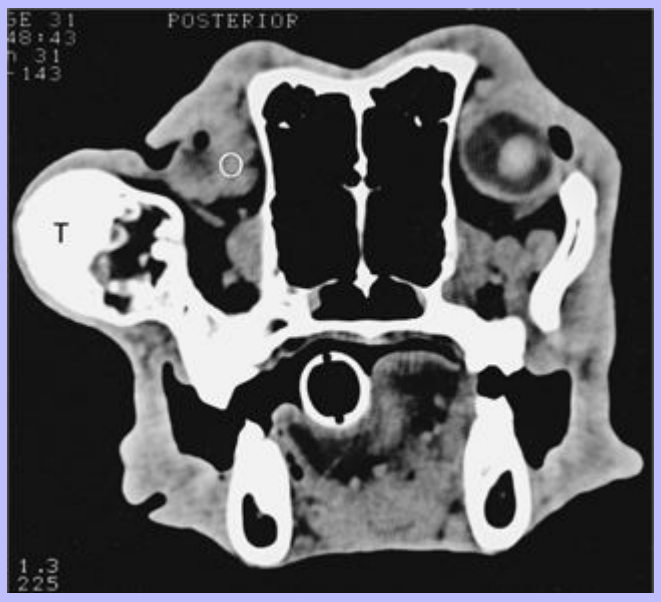
Figure 279-5 Computed tomography (CT) image of an osteoma *(T)* of the zygomatic arch that caused ocular *(O)* displacement.



279.3.6 Magnetic Resonance Imaging

Advantages of magnetic resonance imaging (MRI) are that high-resolution, serial, multiplanar images of skeletal soft tissues, such as ligament, tendon, menisci, and articular cartilage, can be obtained without the use of ionizing radiation. However, because this imaging modality relies on detection of changes in the orientation of mobile tissue protons within a strong magnetic field, the signal intensity of mineralized bone matrix is low. Adjacent soft tissues (periosteum, endosteum, fat, articular cartilage, and bone marrow) mainly define contours of bone. Subtle lesions of metaphyseal cancellous bone can be appreciated, as can displacement, compression, and invasion of soft tissue by expansile osseous lesions. However, cortical bone lesions are better visualized using CT.

279.3.7 Chemistry

Estimation of blood calcium and inorganic phosphate concentrations and of alkaline phosphatase activity will occasionally be useful in diagnosing some bone diseases, but these variables are maintained within reference ranges in many skeletal diseases. Validated assays for canine PTH, PTH-related protein, and vitamin D metabolites are useful in hypercalcemic disorders (Chapter 237).

279.3.8 Hematology

Alterations in circulating leukocyte numbers may be consistent with acute osteomyelitis, but the hemogram is usually unremarkable in chronic osteomyelitis and other bone diseases.

279.3.9 Biopsy and Histopathology

Histologic examination of a representative bone biopsy is the most reliable way to establish a diagnosis when radiographic signs are not highly characteristic of a particular disease. Biopsy may be necessary to distinguish between malignant and benign neoplasia, osteomyelitis, developmental lesions, and degenerative conditions. It also specifically identifies tumor type and grade, establishes the prognosis, and may dictate appropriate treatment. For various reasons, mistakes are frequent at this stage of the investigation. The most common pitfall is inappropriate sampling and submission of a biopsy that is reactive bone formed secondarily to the actual disease. Because processing of bone for histology can take 1 week or more, such an outcome can be frustrating and misleading.

Closed needle biopsies of medium-to-large, solid, solitary lesions of appendicular long bones are obtained using a 4-inch, 8-or 11-gauge Jamshidi bone biopsy needle (Sherwood Medical Co., St. Louis, MD) (see Chapter 77).[25] This method has less postsurgical morbidity (pain, hematoma, infection, tumor seeding, pathologic fracture) than incisional biopsy. The clinician should carefully evaluate the radiograph to ensure that the biopsy is obtained from the center of the lesion and that dense reactive bone is avoided. The skin puncture site and biopsy tract must be situated so that they can be subsequently excised if the lesion is surgically resected. Two or three cores of tissue are taken by redirecting the needle through the same skin opening. Needle orientation can be guided with image intensification or radiography. Jamshidi needle biopsy is not suitable for lesions of small bones or lesions with recent pathologic fractures, because there may be significant hematoma in the latter. For cystic and fluid-filled lesions, or those associated with extensive osteolysis and tumor necrosis, an open incisional wedge biopsy through a limited surgical approach might be necessary. Bone that appears abnormal can also be collected with a bone curette, taking care to avoid mutilating the specimen.

For investigation of diseases affecting growth and endochondral ossification, physeal biopsies can be obtained percutaneously from the greater tubercle of the humerus with a Jamshidi needle.[26] For suspected metabolic bone diseases, larger specimens of cancellous bone are collected with an 8 mm Michele trephine from the iliac crest or by excision of a segment of rib or distal ulnar diaphysis.[27]

The surgical borders of lesions excised en bloc are labeled with India ink for examination by the pathologist to ensure tumor-free margins.[28] Specimens can also be radiographed using nonscreen film or industrial film in a Faxitron cabinet system. Biopsies are fixed in neutral buffered formalin for 6 to 24 hours; they must not be frozen.[7] Large bone specimens should be cut into 5 mm slabs to ensure proper fixation.[7] If osteomyelitis is suspected, a portion of the biopsy should be separated for bacteriologic culture before the remainder is fixed in formalin. Bone specimens that cannot be cut with a scalpel are decalcified in 10% formic acid prior to embedding in paraffin. Rapid decalcification in strong acids or excessive decalcification will destroy cellular detail and render the biopsy nondiagnostic. Nondecalcified bone biopsies embedded in methylmethacrylate and sectioned with a sledge microtome are needed for diagnosis of some metabolic bone diseases.[29] Histologic evaluation of bone is rather specialized and requires the expertise of a pathologist with special interest and training. Most pathologists will want to review the clinical data and radiographs as well, before making a diagnosis.

279.3.10 Cytology

Cytologic examination of fluids and exudates obtained by sterile aspiration is valuable in early detection of acute osteomyelitis, before obvious radiographic changes occur in bone.

279.3.11 Microbiology

Isolation and identification of bacteria are helpful in confirming a diagnosis of osteomyelitis, and *in vitro* susceptibility testing aids in antimicrobial drug selection. Cultures of pus from externally draining tracts are less than 50% accurate in identifying the pathogens causing osteomyelitis, because the tracts become colonized by skin organisms and gram-negative bacteria. It is preferable to culture fluid collected by sterile aspiration, or from pus, necrotic tissue, and sequestra collected during surgical débridement. Both aerobic and anaerobic culture are advisable, because anaerobic bacteria are involved in up to 60% of bone infections in small animals.[30] Samples for aerobic culture should be collected into a sterile container, taken to the laboratory, and plated out on agar within 10 to 15 minutes. Specimens for anaerobic culture require special handling because a few minutes of exposure to air will kill sensitive anaerobes and prevent subsequent isolation. Fluid for anaerobic culture can be collected into a syringe if air is expelled and the needle capped with a rubber stopper.

1969

1970

When the anticipated delay in plating out samples exceeds 15 minutes, tissue samples and swabs are placed into a reduced Cary-Blair, solidified anaerobic holding media (Becton Dickinson, Franklin Lakes, NJ) to exclude oxygen. Both aerobes and anaerobes may be isolated from such preparations because most aerobic bacteria are facultative anaerobes.

279.4 CONGENITAL BONE DISORDERS

Embryonic and postnatal skeletal development are complex and exquisitely susceptible to errors. Skeletal growth disorders that are apparent at birth or manifest later in young animals are of two main types: (1) generalized dysplasias and (2) localized malformations of individual bones. Some are caused by inherited defects and sporadic mutations, and some are due to teratogens and unidentifiable embryopathies. In humans, more than 100 such disorders, mostly inherited, have been listed in the *Paris Nomenclature for Constitutional Disorders of Bone*.[31] This classification is based on specific clinical, genetic, radiologic, histologic, and biochemical features. Animal diseases are not sufficiently characterized to allow complete adoption of the Paris system,[32] although some general groupings are possible (Box 279-2). Generalized dysplasias are described later with developmental and genetic disorders or with joint diseases (see Chapter 278), whereas dysostoses are considered here.

Dysostoses include the malformations of individual bones either singly or in combination. They can involve the craniofacial region, the axial bones, and extremities. Embryonic limb bud development commences with a projection of mesoderm covered by ectoderm. Three signaling centers within the limb bud that control and coordinate limb development are (1) the apical ectodermal ridge, (2) the zone of polarizing activity, and (3) the Wingless-type signaling center.[33] The apical ectodermal ridge is a thickened layer of ectoderm overlying the distal tip of the limb bud that acts as a signaling center guiding proximal to distal limb development. It also causes interdigital necrosis, thereby separating webbed digits, probably by the local expression of FGF genes.[34] The zone of polarizing activity exerts control via the signaling molecule sonic hedgehog protein, and the Wingless-type signaling center controls limb alignment with respect to dorsal orientation.[33] Subsequently, the

individual bones form from cartilage anlages and the secondary centers of ossification.[5,34] Three mesodermal rays (ulnar, radial, and central) contribute to pectoral limb formation; disturbances of one or more rays or of the signaling centers will result in perturbations of the corresponding components of bone and associated soft tissue. For example, failure of the apical ectodermal ridge may produce syndactyly of the digits or result in a truncated limb similar to congenital amputation.[33] Except for a few heritable disorders that will be mentioned, most dysostoses in dogs and cats occur sporadically.

279.4.1 Hemimelia, Phocomelia, and Amelia

In these conditions the animal has a congenital absence of portions of the normal structures in an extremity. Hemimelia is either longitudinal (paraxial), with absence of the ulnar, radial, or central regions in the forelimb, or transverse, with the distal portion of the limb completely absent.

279.4.1.1 Box • 279-2 Some Congenital Skeletal Disorders of Small Animals

279.4.1.1.1 Osteochondrodysplasias (Abnormalities of Cartilage, Bone Growth, and Development)

A. Defects of growth of tubular bone or spine

Multiple epiphyseal dysplasia: beagle

Pseudoachondrodysplasia: miniature poodle

Scottish deerhound

Chondrodysplasia: Alaskan Malamute

Cocker spaniel

English pointer

Great Pyrenees

Norwegian elkhound

Ocular-skeletal dysplasia: Labrador retriever

Samoyed

Pelger-Huët anomaly: cats

Scottish fold osteochondrodysplasia: cats

B. Disorganized development of cartilage and fibrous components

Multiple cartilaginous exostoses (osteochondromatosis)

Enchondroma

Fibrous dysplasia

C. Abnormalities of density, of cortical diaphyseal structure, or metaphyseal molding

Osteogenesis imperfecta

Osteopetrosis

279.4.1.1.2 Primary Metabolic Abnormalities

Vitamin D–dependent rickets

Mucopolysaccharidosis (MPS)

Fucosidosis

GM gangliosidosis

Gaucher's disease

279.4.1.1.3 Dysostoses with Malformation of Individual Bones, Singly or in Combination

Hemimelia

Phocomelia

Amelia

Syndactyly

Polydactyly

Ectrodactyly

Segmental hemiatrophy

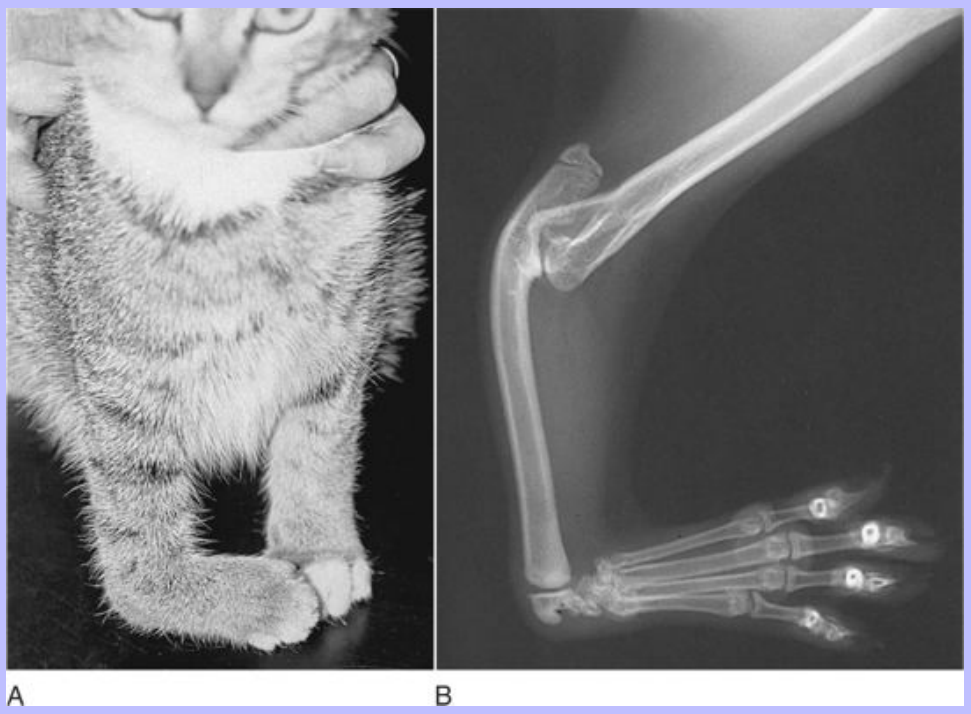
Adapted from Sharrard WJW: Pediatric Orthopaedics and Fractures, 3rd ed. London, Blackwell Scientific Publications, 1993.

Radial agenesis is the most common paraxial hemimelia in cats and dogs. It is usually unilateral and sporadic. Bilateral radial agenesis might be an inherited autosomal recessive trait in Chihuahua dogs.[32] In radial agenesis, the radius is partially or completely absent, and the ulna is shorter, thickened, and curved (Figure 279-6). The radial carpal bone and first digit are often absent as well. Lack of a radial head support allows humeroulnar subluxation, and the range of elbow motion is reduced. The metacarpus deviates into varus, severely impairing limb function. One hypothesis is that radial agenesis and other hemimelias are a consequence of neural crest injury because limb bud embryopathies often have a segmental pattern that corresponds to the distribution of the segmental sensory nerves.[35] Treatment of radial agenesis by reconstructive surgery has not been very successful, and amputation may be necessary. Another, less common paraxial hemimelia is tibial agenesis.[32]

1970

1971

Figure 279-6 Kitten with radial agenesis. **A,** Radial agenesis and a 90-degree varus angulation of the metacarpus. **B,** The radius and radial carpal bone are absent. The proximal ulna is misshapen, the distal ulna thicker than normal, and the carpus malarticulated. (From Winterbotham EJ et al: Radial agenesis in a cat. J Small Anim Pract 26:393, 1985.)



Complete absence of a distal portion of a limb (congenital amputation) can be caused by transverse hemimelia, strangulation by constrictive bands, or *in utero* accidents.[36] The cause may be impossible to determine in young animals, because postnatal trauma can also cause amputations.

In phocomelia, an intercalary segment of limb is missing. In severe cases the paw with rudimentary digits is attached to the trunk like a seal flipper. Proximal femoral focal deficiency is a phocomelia with a missing segment of femur. In man, this is usually a unilateral defect that is not inherited.[37] A young dalmatian with proximal femoral focal deficiency had unilateral hindlimb shortening and muscle atrophy that became accentuated with further growth.[38] Radiographically, bone in the intertrochanteric, neck and head regions of the femur was absent, and there was marked femoral shortening.

Amelia is complete absence of one or more limbs. Two kittens with bilateral hindlimb amelia have been reported.[32] Most animals affected by amelia probably die or are euthanized at birth.

279.4.2 Syndactyly

Two or more digits are fused in a bony or soft tissue union in syndactyly.[7,32] This is not clinically important in pets, and surgery is generally unwarranted unless the deformity causes lameness. Congenital synostosis of adjacent metatarsal bones is a variation on digital fusion (Figure 279-7).

279.4.3 Polydactyly

Polydactyly is the presence of extra digits, usually on the medial side of the paw in dogs and cats. An inherited syndrome of skeletal defects exists, including polydactyly and syndactyly in Australian shepherd dogs.[7] An X-linked gene was suspected. Polydactyly is an inherited autosomal dominant trait in cats.[32] Multiple hindlimb dewclaws in Great Pyrenees have similar inheritance.

Figure 279-7 Congenital metatarsal bone synostosis.

1971

Figure 279-8 Vestigial first metatarsal bone *(M)* and an anomalous tarsal bone *(T)* extending medially from the central tarsal bone in a Saint Bernard.

In Saint Bernard dogs, dewclaws may be associated with anomalous tarsal bones. Some have a large curved bone that seems to be an extension of the central tarsal bone on the medial side of the proximal row of tarsal bones (Figure 279-8). These tarsal anomalies occur bilaterally, are not associated with clinical signs, and are probably inherited.

279.4.4 Ectrodactyly

Often called split hand or lobster claw deformity, ectrodactyly is caused by incomplete fusion of the three rays or absence of the central ray.[37] Classically, the third metacarpal bone and digit are absent, producing a deep cleft that divides the paw into radial and ulnar parts, but many variations occur. The third metacarpal bone may be present and hypoplastic, and neighboring digits and metacarpal bones may be absent or hypoplastic.[39–41] The cleft between metacarpal bones may terminate just below the carpus, or extend proximally through the carpus, separating radius and ulna entirely (Figure 279-9).[39–41] Asynchronous radial

and ulnar growth can contribute to the structural disorder at the carpus. Half of the affected dogs have concomitant congenital elbow luxation. It is usually an isolated deformity without breed predilection in dogs, but may be inherited in cats.[7,32] Function can be improved by reconstructive surgery or arthrodesis.[39,42]

279.4.5 Segmental Hemiatrophy

Hemiatrophy is a misnomer because the condition is actually limb hypoplasia rather than atrophy of a normal structure. The affected forelimb is noticeably shorter and slimmer, especially in the antebrachium and paw.[43] An affected golden retriever also had darker pigmentation of skin and hair of the abnormal limb and horny keratinization of pads and nails, but it has no pain or discomfort.[44] Radiographically the carpal bones were smaller, and the numbered carpal bones were misshapen. The metacarpal bones were 3 cm shorter than contralateral bones and half normal diameter. This is a sporadic deformity and probably not inherited. It must be distinguished from atrophy that follows long-term limb immobilization.[12] A similar type of distal hypoplasia of metacarpus and digits is seen in immature dogs, subsequent to accidental trauma or surgery to the antebrachium.[44] Ilizarov limb lengthening may be indicated if shortening impairs function.

Figure 279-9 Forelimb of 12-week-old mixed breed dog with ectrodactyly, including distal radial and ulnar separation.

279.5 DEVELOPMENTAL AND GENETIC BONE DISORDERS

279.5.1 Osteopetrosis

Defective osteoclastic resorption of bone is the principal feature of osteopetrosis. In growing bones, failure of normal bone modeling results in accumulation of primary spongiosa, so the diaphysis remains filled with bone and a marrow cavity does not form. Affected bones have a *marbled* densely homogeneous radiographic appearance, but they are actually quite fragile. Many forms of osteopetrosis exist. Osteoclasts may be absent, be present in reduced numbers, or be defective in their ability to resorb bone.[7] The disorder is rare and not very well characterized in dogs and cats.[7,45] Idiopathic acquired osteopetrosis of adult cats was characterized by thickening of diaphyseal cortices and vertebral bodies.[45] Feline leukemia virus (FeLV) also produces medullary sclerosis and nonregenerative anemia in growing cats, probably through infection of hemopoietic precursor cells from which osteoclasts arise.[7]

279.5.2 Osteogenesis Imperfecta

Osteogenesis imperfecta comprises a group of heritable diseases characterized by osteopenia, excessive bone fragility, and increased susceptibility to fracture. Fractured bones form callus and heal, but unless stabilized adequately, malunion and deformities occur.[46,47] Radiographically there can be generalized osteopenia, thinning of diaphyseal cortices, and multiple fractures in various stages of union. The fundamental defect in humans is abnormal type I collagen production, mostly due to mutations of genes that normally code for procollagen synthesis.[46] The resulting type I collagen fibrils are thin and fail to mineralize. Osteogenesis imperfecta is rare in dogs and cats, and the mode of heritability and exact biochemical defects are unknown.[32,47,48] Animals may have multiple fractures, with minimal or no trauma. Some may also have dentinogenesis imperfecta (seen as pink teeth), stunted growth, and apparent weakness.[48] The diagnosis is made by analysis of type I collagen from cultured skin fibroblasts,[48] but the more common causes of osteopenia, including renal and nutrition secondary hyperparathyroidism, should be eliminated first.

1972
1973

279.5.3 Mucopolysaccharidosis

The mucopolysaccharidosis (MPS) disorders are rare genetic lysosomal storage diseases caused by specific defects in lysosomal enzymes that are involved in metabolism of glycosaminoglycans. Compounds normally degraded by these enzymes accumulate intracellularly, interfering with cellular function and producing characteristic clinical signs. Several MPS disorders have been recognized in cats (MPS I, VI, and VII) and dogs (MPS I, II, IIIA, IIIB, VI, and VII),[49] but the presence and severity of skeletal abnormalities produced by them are different.

MPS VI is caused by decreased arylsulfatase B activity and leads to intracellular accumulation and increased urinary excretion of dermatan sulfate. Feline MPS VI has been recognized mainly in Siamese cats, as an autosomal recessive disorder, but has also been described in domestic shorthaired (DSH) and long-haired cats, and a Siamese and DSH cross.[49–51] MPS VI has also been reported in dogs of several breeds.[49] Skeletal disease is the predominant abnormality. Clinical features become evident in affected cats from age 6 to 8 weeks and include small head and ears, flattened face, corneal clouding, pectus excavatum, growth retardation, skeletal deformity, and hindlimb paresis or paralysis from spinal cord compression by bone

lesions. They have a crouching gait, and manipulation of joints and cervical spine causes pain. Radiographic features include epiphyseal dysplasia, thinning of long-bone cortices, generalized osteopenia, bilateral coxofemoral subluxation, secondary osteoarthritis, and vertebral fusion.[52] Diagnostic confirmation is provided by demonstration of excess dermatan sulfate in urine with the toluidine-blue (Berry) spot test, metachromatic granules in neutrophils, and reduced arylsulfatase B activity in leukocytes.[49] A PCR-based screening method allows detection of carrier cats.[50]

MPS I in DSH cats is an autosomal recessive disease due to decreased activity of alpha-L-iduronidase.[49,53] Clinical features are similar to MPS VI, but facial dysmorphism may not be as striking as in Siamese, and metachromatic granules are usually less distinct in leukocytes than in MPS VI and MPS VII.[54] Radiographic features are similar to MPS VI, except that epiphyseal dysplasia and dwarfism are absent. Neurologic abnormalities due to spinal cord compression by bone proliferation occur relatively later, after 2 years of age. Excretion of dermatan sulfate and heparin sulfate in urine is detectable using the toluidine-blue spot test.[53] MPS I has also been reported in dogs. Affected animals are dwarfed and have swollen painful joints, glossoptosis, corneal clouding, and progressive motor and visual deficits. Radiographic features include epiphyseal dysgenesis, periarticular bone proliferation, and enlargement of femoral diaphyses.[55]

MPS II was diagnosed in a 5-year-old male Labrador retriever with coarse facial features, macrodactylia, generalized osteopenia, progressive neurologic deterioration and a positive urine test for glycosaminoglycan.[56] Iduronate sulfatase activity was deficient in cultured dermal fibroblasts.

Canine MPS VII (beta-glucuronidase deficiency) has been described in dogs and cats.[50] Affected dogs appear normal at birth, but by age 2 to 3 months develop hindlimb paresis and have a disproportionately large head, flattened face, swollen lax joints, bowed limbs, dorsoventrally flattened rib cage, and corneal clouding.[57] Radiographic features include bilateral coxofemoral luxation, abnormally shaped carpal and tarsal bones, generalized epiphyseal dysplasia, cervical vertebral dysplasia, and platyspondylisis. Feline MPS VII is characterized by growth retardation, delayed dental eruption, corneal clouding, abdominal distension, and multiple skeletal abnormalities.[58–60] In both species, peripheral leukocytes contain metachromatic inclusions, and urinary excretion of chondroitin sulfate is increased.[58,61] Genetic tests can distinguish phenotypically normal MPS VII carrier dogs and cats from homozygous normal animals.[58,62]

Several therapeutic strategies for MPS have been trialed with some success, including enzyme replacement therapy, heterologous bone marrow transplantation, and somatic cell gene transfer, but all require further development.[49]

279.5.4 Dwarfism

Various disorders causing small stature in dogs and cats listed in Table 279-1 are reviewed in other chapters. Considered here are skeletal dysplasias and some endocrinopathies (hyposomatotropism and hypothyroidism) that are more commonly associated with dwarfism in small animals.

279.5.4.1 Skeletal Dysplasias (Osteochondrodysplasias)

Osteochondrodysplasias are disorders characterized by abnormalities in growth and development of cartilage, bone, or both (see Box 279-2). Disorders of this type have been reported in several breeds of

dogs. Box 279-3 summarizes the better-characterized entities. Most have known or suspected genetic basis and autosomal recessive inheritance is common. They frequently cause disproportionate dwarfism, with discrepant development of axial and appendicular skeleton producing reduced limb length relative to the trunk (Figure 279-10).

Another type of genetic dwarfism occurs in achondroplastic dog breeds, such as bulldog, Boston terrier, Pekinese, pug, and Shih Tzu. These animals have been bred selectively for achondroplasia and thus have shortened maxilla, depressed nasal bridge, flared metaphyses, and short bowed limbs as part of accepted breed standards.[32] Hypochondroplastic breeds, such as Basset hound, beagle, dachshund, Dandie Dinmont terrier, Scottish terrier, Skye terrier, and Welsh corgi have similarly shaped legs as a breed characteristic, although their skulls are normal.[32] These forms of dwarfism differ from the nonpathologic, mutant, proportionate reduction in stature in dogs that has led to the establishment through selective breeding of many miniature and toy breeds.

279.5.4.1.1

Box • 279-3 Canine Osteochondrodysplasias: Clinical and Radiologic Signs, and Inheritance Pattern

279.5.4.1.1.1

Alaskan Malamute Chondrodysplasia[7,63]

Short limbs, bowed forelegs, carpal joints enlarged, paws deviated laterally; ulna growth plate thickened, irregular and flared; associated hemolytic anemia; autosomal recessive trait, complete penetrance, variable expression

279.5.4.1.1.2

Beagle Multiple Epiphyseal Dysplasia[7,63]

Short limbs, enlarged joints, kyphosis; stippled mineralization of epiphyses, especially femur and humerus, disappeared by 5 months; vertebrae short; dysplastic hips; osteoarthropathy in adults; autosomal recessive trait

279.5.4.1.1.3

Bull Terrier Osteochondrodysplasia[64]

Abnormal hind leg gait, femoral neck fractures; nonossified foci in femoral necks and metaphyses of long bones; some long bones distorted; dwarfing not noted; littermates affected but inheritance not known

279.5.4.1.1.4

English Pointer Enchondrodystrophy[7,65,66]

Short limbs, bowed forelegs, abnormal locomotion; wide irregular growth plates; possibly inferior prognathism; probable autosomal recessive trait

279.5.4.1.1.5

Great Pyrenees Chondrodysplasia[7,63,67]

Very short limbs, forelegs bowed with valgus deformity; body length reduced slightly; flared, flattened metaphyses; poorly developed epiphyses and cuboidal bones; vertebrae poorly ossified and irregular; autosomal recessive trait

279.5.4.1.1.6

Irish Setter Hypochondroplasia[68]

Mildly short limbs and spine, variable radius and ulna bowing and carpal valgus; growth plates, epiphyses and metaphyses radiographically normal; autosomal recessive trait

279.5.4.1.1.7

Labrador Retriever Ocular-Skeletal Dysplasia[7,69]

Short limbs, prominent elbows and carpi, paws deviated laterally, hind legs hyperextended; tubular bones short and wide, cortices thin, metaphyses flattened and flared, increased metaphyseal opacity; epiphyses and cuboidal bones large and misshapen; hip dysplasia, abnormal elbows; cataracts, retinal dysplasia and detachment; autosomal trait, recessive effect on skeleton, incompletely dominant on eye

279.5.4.1.1.8

Miniature Poodle Multiple Enchondromatosis[70,71]

Short bowed limbs, femoral neck fractures; lucent areas extending from growth plates into metaphyses and some diaphysis; diaphyses distended and distorted; ribs and vertebrae also affected; sternum lacked bone; autosomal nondominant trait

279.5.4.1.1.9

Miniature Poodle Multiple Epiphyseal Dysplasia[63]

Similar to disorder in beagle; inheritance unknown, but two of three affected were littermates

279.5.4.1.1.10

Miniature Poodle Pseudoachondroplasia[7,63]

Poor growth, abnormal gait; short, bent legs, enlarged joints; possible inferior prognathism; vertebrae short, limb bones short and thick with bulbous ends; stippled densities in epiphyses; ossification complete by 2 years of age, but limbs remained short and deformed; probable autosomal recessive trait

279.5.4.1.1.11 Norwegian Elkhound Chondrodysplasia[7,63]

Shortened body, disproportionally short limbs, especially forelegs, which may be bowed; metaphyses flared and flattened, with denser band; ventral vertebral bodies irregular, delayed union of vertebral end plates; may have glucosuria; autosomal recessive trait

279.5.4.1.1.12 Samoyed Ocular-Skeletal Dysplasia[7,72,73]

Short forelegs, varus deformity of elbows, valgus of carpi, premature closure of ulnar growth plates, bowed radii; domed forehead; cataracts, retinal detachment, hyaloid artery remnants eosinophilia; autosomal recessive trait

279.5.4.1.1.13 Scottish Deerhound Pseudoachondroplasia (Osteochondrodysplasia)[74,75]

Retarded growth, short bowed limbs, exercise intolerance, small head, short trunk, lax joints, kyphosis; vertebrae and long bones short, epiphyseal ossification irregular and delayed; later osteopenia, severe deformity; single autosomal recessive inheritance suspected

Figure 279-10 **A,** Radiograph of a 5-week-old Alaskan Malamute with chondrodysplasia. Physeal cartilage is widened, and adjacent metaphyseal bone roughened and irregular. **B,** Radiograph of a normal littermate of same age for comparison.

Figure 279-11 Osteochondro-dysplasia of Scottish fold cats. **A,** Exostoses around the carpus. **B,** Exostoses and ankylosis of the tarsal joints. (Courtesy of Veterinary Imaging Associates, Sydney, Australia.)

An osteochondrodysplasia with autosomal dominant inheritance has been described in Scottish fold cats.[76] Along with the folded ears typical of this breed, affected individuals show signs of lameness, reluctance to jump, stiff and stilted gait, short mis-shapen distal limbs, and short thick inflexible tail. Radiographic features include irregular size and shape of bones of tarsus, carpus, metatarsus, metacarpus, phalanges, and caudal vertebrae. In addition, these animals have narrowing of apparent joint spaces, new bone production around distal limbs joints, diffuse osteopenia, and formation of a plantar exostosis caudal to the calcaneus in advanced cases (Figure 279-11). However, the severity and rate of progression of changes are quite variable. Treatment is noncurative, but pentosan polysulfate, glycosaminoglycans, nonsteroidal anti-inflammatory drugs (NSAIDs), or a combination of these treatments might be palliative.[76]

A chondrodysplasia in two unrelated kittens with shortened, bowed forelimbs was described.[77] Radiographic signs included long bone bowing, metaphyseal flaring, and a gross enlargement of physeal

cartilage that resembled rickets. Serum calcium, phosphorus, and 1,25-dihydroxyvitamin D_3 concentrations were normal, but PTH concentrations were below the reference range. Furthermore, treatment of the kittens with oral 1,25-dihydroxyvitamin D_3 for 3 months did not resolve the radiographic abnormalities or correct the stunted statue. The disorder is considered to be a (osteo)chondrodysplasia of unknown heritability rather than rickets.[77]

1975

1976

279.5.4.2 Pituitary Dwarfism

Hypopituitarism and consequent dwarfism, inherited in autosomal recessive fashion in German shepherd dogs and Karelian bear dogs, has also been described in other dog breeds (Weimaraner, Spitz, toy pinscher) and cats.[78] A cystic, vestigial adenohypophysis is present in many affected German shepherds, but some have a hypoplastic or a normal-appearing pituitary gland. The syndrome is dominated by effects of hyposomatotropism, but deficiency of other adenohypophyseal hormones can lead to degrees of accompanying secondary hypothyroidism, hypoadrenocorticism, and hypogonadism. Affected animals are usually recognizable by the age of 2 or 3 months. They grow slowly but retain near-normal body proportions. The soft puppy-hair coat is retained initially, but symmetric alopecia and hyperpigmentation develop with age. Accompanying abnormalities include abnormal behavior (aggression, fear biting), delayed dental eruption, short mandible, cardiac disorders, cryptorchidism, megaesophagus, and testicular atrophy or estral abnormalities.

Radiographically, limb bones are shortened, with delayed closure of growth plates in some cases. Epiphyses may show disordered and incomplete calcification, suggesting hypothyroidism. Hormonal testing can be undertaken to confirm the diagnosis if necessary. Most pituitary dwarf animals can be expected to remain small for life. However, two unusual cases with typical clinical features at 10 weeks of age grew steadily and appeared normal when 1 year old.[79] Both had normal hormonal test results, indicating that growth hormone secretion ideally should be evaluated in suspected cases to clarify prognosis.

Replacement therapy with growth hormone (if available and economical), and thyroxine or glucocorticoid if indicated, could be considered, but long-term prognosis is poor.[78] Another promising approach involves chronic progestin administration to induce growth hormone production from mammary ductular cells of affected dogs of either sex.[80]

279.5.4.3 Congenital Hypothyroidism

Skeletal development is abnormal in congenital hypothyroidism, which is rare in dogs and cats. Although cases are usually encountered sporadically in various breeds, some familial occurrences are known: secondary hypothyroidism with autosomal recessive inheritance in giant schnauzers,[81] primary dyshormonogenesis with autosomal recessive inheritance in Abyssinian cats,[82] thyroid unresponsiveness to thyroid-stimulating hormone (TSH) with autosomal recessive inheritance in Japanese cats,[83] and thyroid unresponsiveness to TSH in related Scottish deerhounds.[84]

Abnormalities may be detectable by the age of 1 or 2 months. Affected animals are disproportionate dwarfs, with short limbs and spine, blocklike trunks, and broad short skulls. The radiographic features are epiphyseal dysgenesis and delayed skeletal maturation (Figure 279-12). Nonskeletal findings include delayed dental eruption, macroglossia, lethargy, mental dullness, persistent puppy haircoat progressing to thinning and alopecia, mild nonregenerative anemia, and hypercholesterolemia. Thyroid gland enlargement

can accompany congenital dyshormonogenesis[85] but is absent if a hypothalamic-pituitary defect is causing thyroid understimulation[86] or thyroids are unresponsive to TSH.

A low blood plasma thyroxine concentration is expected, but results of other thyroid tests will differ, depending on whether the defect is of thyroidal, pituitary, or hypothalamic origin. The plasma growth hormone response to provocative stimuli may be suppressed (Chapter 235).[80,86] Treatment with thyroxine can reverse many of the abnormalities but should commence early and continue for life.

279.5.5 Retained Cartilage Cores

In young large and giant breed dogs, cartilage cores sometimes form in the metaphysis of the distal ulna. Physeal hypertrophic chondrocytes fail to mature and mineralize adjacent matrix, and they accumulate in long columns in the primary spongiosa.[87] The cause of the disorder is unclear. In Great Dane pups, formation of cartilage cores in the distal ulnar and tibial metaphyses was associated with feeding diets containing three-times the recommended content of calcium.[88]

Figure 279-12 **A,** Forelimb of 15-week-old Great Dane with features of congenital hypothyroidism. Reader should note the disordered and irregular ossification of epiphyses (epiphyseal dysgenesis) in humerus, radius, and ulna; the absence of an olecranon apophysis; and delayed skeletal maturation. **B,** Normal Great Dane of similar age for comparison. (Courtesy of R.B. Lavelle.)

Radiographically a central, radiolucent core of cartilage exists that is 5 to 10 mm wide and 2 to 6 cm long, extending from distal ulnar physis into metaphyseal bone (Figure 279-13). Lesions are usually bilateral. They may be a subclinical radiographic finding or be associated with varying degrees of growth retardation after 5 months of age. Retarded ulnar growth causes relative shortening of the ulna, valgus, and rotation of the paw, cranial bowing of the radius, and carpal and elbow subluxation (see Figure 279-13).

279.5.6 Craniomandibular Osteopathy

Craniomandibular osteopathy occurs mainly in young West Highland white, Scottish, Cairn, Boston, and other terriers, and occasionally in nonterrier breeds.[89] Autosomal recessive inheritance is known in West Highland white terriers,[90] and a hereditary predisposition may exist in Scottish terriers. However, the sporadic occurrence in unrelated breeds suggests other causative factors are also involved. Canine distemper virus (CDV) infection of bone has been mentioned as a possible cause,[89] although an epidemiologic study did not indicate a direct relationship.[91] The condition is usually recognized at age of 3 to 8 months, when affected pups develop mandibular swelling, drooling of saliva, prehension difficulties, pain on opening the mouth, or some combination of these signs. The clinical course may fluctuate, with periods of remission and exacerbation. Abnormal physical findings comprise firm, often painful, swelling of mandible, temporomandibular region, or both areas. Periods of pyrexia occur in some cases. Restricted jaw movements and atrophy of masticatory muscles may be obvious in severely affected dogs. Mandibular swelling without pain or eating difficulties occurs in some dogs, especially of larger breeds.

1976

1977

Figure 279-13 **A,** Seven-month-old Great Dane with bilateral forelimb deformities caused by retained cartilage cores in the distal ulnar physes. **B,** Radiograph demonstrating retained cartilage core *(arrows)* extending from distal ulnar physis into the metaphysis. (From Johnson KA: Retardation of endochondral ossification at the distal ulnar growth plate in dogs. Aust Vet J 57:474, 1987.)

Radiographic changes are generally bilateral but often asymmetric, with irregular bony proliferation involving the mandible and tympanic bulla-petrous temporal bone areas in about 50% of cases. However, changes can be confined to the mandible (33% of cases) (Figure 279-14) or the tympanic bulla-petrous temporal region (13%). The calvarium and tentorium ossium are often thickened (Figure 279-15), and other skull bones are sometimes affected. Concurrent long bone lesions resembling later stages of metaphyseal osteopathy have been observed in a few terriers with craniomandibular osteopathy.

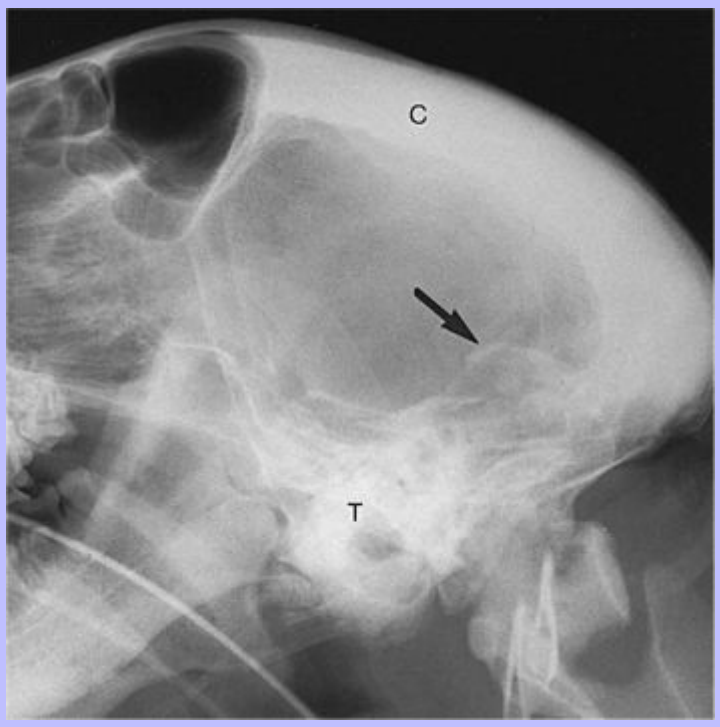
Figure 279-14 Macerated skull of a Doberman pinscher with craniomandibular osteopathy. Reader should note extensive bone changes involving mandible. Tympanic bullae, petrous temporal bones, and temporomandibular joint (TMJ) regions were unaffected in this dog. (From Watson ADJ et al: Craniomandibular osteopathy in Doberman pinschers. J Small Anim Pract 16:11, 1975.)

The diagnosis is straightforward in cases with typical clinical and radiographic features. Routine laboratory tests are unlikely to be helpful. Bone biopsy may be useful in atypical cases, such as dogs of rarely affected breeds with lesions confined to the mandible, especially if unilateral. The histopathology involves resorption of existing lamellae, proliferation of coarse trabecular bone beyond normal periosteal boundaries, replacement of marrow spaces by vascular fibrous stroma, and infiltration at the periphery of new bone by inflammatory cells. A mosaic pattern of irregular cement lines is present in the new primitive bone.[92]

1977

1978

Figure 279-15 Skull of Scottish terrier with craniomandibular osteopathy. The tympanic bulla-petrous bone area *(T)* shows dense sclerotic bone changes. Reader should note thickened calvarium *(C)* and tentorium osseum *(arrow)*.



Craniomandibular osteopathy is self-limiting. Abnormal bone proliferation eventually slows and becomes static at about 1 year of age. Lesions then tend to regress, although radiographic abnormalities or impaired prehension sometimes persist. Anti-inflammatory drug treatment can reduce pain and discomfort, but the effect on lesions is unknown. The prognosis is guarded when extensive changes affect the tympanic-petrous temporal areas and adjacent mandible. Ankylosis and adhesions may then develop, permanently restricting jaw movements and eating. Rostral hemimandibulectomy can be a useful salvage procedure in these cases.[44]

279.5.7 Multiple Cartilaginous Exostoses

In rare instances these benign lesions (osteochondromatosis, multiple hereditary osteochondromata) occur in dogs and cats, as single or multiple exostoses. The disorder may be inherited as an autosomal dominant trait in humans, horses, and dogs.[93,94] Protuberances consist of cancellous bone covered by a cap of hyaline cartilage and arise in the metaphyseal region of bones formed by endochondral ossification. With continued physeal growth and elongation of long bones, exostoses may be finally located in the diaphysis. Lesions develop and grow most rapidly in immature animals, becoming senescent at maturity. Malignant transformation of exostoses to chondrosarcoma occurs rarely in aged animals.[95,96]

The cause is unknown. One hypothesis is that congenital or acquired defects in the perichondrial ring allow an island of physeal cartilage to be pinched off and trapped in metaphyseal bone. This physeal cartilage continues to grow radially, giving rise to exostoses. However, this does not explain the similar lesions found occasionally in nonskeletal sites, such as tracheal cartilages.

Superficially located exostoses may be palpable. Signs may include paresis due to progressive spinal cord compression in young animals (see Chapter 193) or pain due to impingement of exostoses on adjacent tissues.[97] Radiographically, lesions are rounded to cauliflower-like in outline, with a smooth thin shell of cortical bone (Figure 279-16). They protrude above the bone contour and may extend into the medullary cavity. Internally, exostoses have well-defined bone trabeculae that are continuous with the medullary cavity, and diaphyseal cortex in the region is interrupted by the lesion. Adjacent bones such as ulna and metacarpals may be deformed by expanding exostoses (see Figure 269-16). Solitary exostoses are biopsied to allow differentiation from neoplastic lesions. Surgical excision of exostoses that are causing spinal cord compression or lameness is recommended (see Chapter 193).[97] All exostoses should be monitored for malignant transformation.

279.6 IDIOPATHIC BONE DISORDERS

279.6.1 Enostosis

Enostosis (panosteitis, eosinophilic panosteitis) is a relatively common disease causing lameness in medium, large, and giant breed dogs.[98] Amongst breeds at greatest risk are Great Pyrenees, Basset hound, Shar Pei, mastiff, giant schnauzer, and German shepherd dog.[99] Two thirds of affected dogs are male. The age of onset is 6 to 18 months; older dogs are rarely affected. Lameness is acute in onset, not associated with trauma, and intermittent in one or more limbs. Each episode of lameness lasts 2 to 3 weeks but, with recurrent bouts, enostosis may persist for 2 to 9 months. Other signs in early stages include anorexia, lethargy, pyrexia, and weight loss. On physical examination, pain is detected on deep palpation of affected bones. Bones commonly affected are the ulna, humerus, radius, femur, and tibia. Ilium, metatarsal, and other bones are rarely affected. The disease begins in the medullary bone marrow, in the region of a nutrient foramen.

Figure 279-16 Radiograph demonstrating a solitary multiple cartilaginous exostosis-type lesion in the forelimb of a young dog. Reader should note the expansile lesion of the proximal radius, causing malalignment of the radius and attenuation of adjacent ulna. (Courtesy of R.B. Lavelle.)

The cause is unknown: genetic predisposition, hemophilia, bacterial infection, vascular abnormality, metabolic disease, allergy, hyperestrogenism, and endoparasitism have been proposed, but the evidence for most of these is scant.[98] Viral infection is considered a possible cause, based on clinical features of the disease, transmission experiments, and *in situ* hybridization demonstration of virus in bone cells of dogs infected with CDV.[98,100] A relationship between enostosis and ingestion of protein-and-energy-rich foods was suggested recently, and changes in protein or amino acid metabolism were reported in affected dogs.[101]

Three radiographic stages are recognizable.[98] The first stage, with medullary radiolucency due to bone marrow degeneration, is infrequently seen. Most often detected is the second stage (Figure 279-17). A granular, hazy increased radiopacity that begins in the region of the nutrient foramen may extend to fill the entire medullary cavity. Formation of new endosteal bone and a thin layer of smooth periosteal bone are

secondary changes. In the final stage, most bones return to normal appearance, but some have residual thickening of medullary trabeculae and cortical deformity.

Histopathologically, lesions are characterized initially by replacement of normal marrow by fibrous tissue, followed by excessive remodeling of cortical and medullary bone in the affected areas, with endosteal new bone formation generally more prominent.[98] Basenjis and West Highland white terrier dogs with inherited pyruvate kinase (PK) deficiency can develop intramedullary osteosclerosis but, unlike enostosis, new trabecular bone formation is uniform throughout the medullary cavity.[102]

1978

1979

Figure 279-17 Radiograph of a forelimb of a young dog with enostosis, showing patchy intramedullary densities in the humeral diaphysis. (Courtesy of Veterinary Imaging Associates, Sydney, Australia.)

Enostosis can occur concurrently with developmental diseases such as ununited anconeal process and osteochondritis dissecans, and it may be difficult to determine which disease is causing lameness. Leukocytosis and eosinophilia occur inconsistently in affected dogs; serum chemistry is unremarkable. Enostosis is self-limiting, usually by age 18 months, but analgesic NSAIDS may help alleviate pain and lameness.

279.6.2 Metaphyseal Osteopathy

Metaphyseal osteopathy (hypertrophic osteodystrophy) is a disease of young rapidly growing dogs of larger breeds. Breeds at particular risk include Great Dane, Weimaraner, boxer, Irish setter, German shepherd, and Labrador and golden retrievers.[99] Signs usually begin at 3 to 4 months of age (range 2 to 8 months), with metaphyseal swelling and pain, accompanied by depression, inappetence, and variable pyrexia. Some cases recover within a few days, but others have one or more relapses during the following weeks before they finally recover. In a few instances, repeated relapses and consequent pain, cachexia, and debility, necessitate euthanasia. Unexplained deaths have been observed rarely.

Radiographic changes occur especially in metaphyses of limb bones and are usually bilateral. Scapulae and ribs may also be affected. In the early stage, an irregular radiolucent zone is present in the metaphysis, separated from the normal-appearing growth plate by an opaque band (Figure 279-18, *A*). Surrounding soft tissue may be swollen. Later radiographs may show metaphyseal enlargement with irregular periosteal new bone formation, although not all affected dogs develop these changes (Figure 279-18, *B*). Once the disease is no longer active, bone changes undergo repair and remodeling, but some diaphyseal distortion and exostoses may remain (Figures 279-18, *C*, and 279-19).

Hematologic and biochemical tests contribute little to the diagnosis, although neutrophilia, monocytosis and lymphocytopenia can occur during active disease, reflecting stress and inflammation. The principal histologic changes involve the primary spongiosa of metaphyses, with acute suppurative osteomyelitis, necrosis, trabecular microfractures, and defective bone formation. Trabecular resorption produces the radiolucent metaphyseal zone. The opaque band near the growth plate results from trabecular collapse and secondary bone formation. Periosteal thickening, with subperiosteal fibrosis and inflammation, periosteal new bone formation, extraperiosteal dystrophic calcification, or a combination of these abnormalities may be seen.[103]

The cause of metaphyseal osteopathy is unknown. Prior suggestions implicating hypovitaminosis C, overnutrition, or copper deficiency have not been substantiated. Attempts to identify a causative infectious agent or to transmit the disease have not been successful. However, CDV RNA has been detected within bone cells of dogs with metaphyseal osteopathy, suggesting a role for this virus in the etiopathogenesis.[104] Other circumstantial evidence supports this[103–105]: Metaphyseal osteopathy may be accompanied or preceded by respiratory or gastrointestinal (GI) signs; dental enamel hypoplasia, a sequel to distemper infection, was found in two dogs with metaphyseal osteopathy; three of seven dogs inoculated with blood from dogs with metaphyseal osteopathy developed distemper; and typical bone changes have developed in some pups 4 to 21 days after inoculation with live distemper virus vaccine. However, the osteosclerotic metaphyseal lesions found in a series of dogs clinically affected with distemper differed macroscopically, radiographically, and histologically from metaphyseal osteopathy.[106] Any relationship between distemper virus, metaphyseal osteopathy, and other hyperostotic bone diseases (craniomandibular osteopathy and enostosis) remains uncertain. An epidemiologic study concluded that, apart from the obvious age effect, risk factors for metaphyseal osteopathy, craniomandibular osteopathy, and CDV infection were dissimilar.[91] Metaphyseal

osteopathy has been reported in related dogs of several breeds, including Weimaraner littermates.[105–107] However, most cases are sporadic, affecting isolated pups in a litter.

No specific treatment exists for metaphyseal osteopathy. Dietary imbalances or excesses should be avoided and an anti-inflammatory analgesic given as needed to reduce pain. Good nursing care may be required to avoid dehydration, undernutrition and pressure sores.

279.6.3 Calvarial Hyperostosis

An unusual hyperostosis affecting frontal and parietal bones was reported in two unrelated bull mastiffs.[103] From age 6 months there was progressive outward thickening of the calvarium (the cranial cavity was unaffected) with pyrexia, lymphadenopathy, and eosinophilia. The swelling stabilized at maturity, then regressed. The lesion was a subperiosteal hyperostosis with initial deposition of new woven bone followed by secondary osteonal remodeling. Similarities were noted with cases of craniomandibular osteopathy, inherited PK deficiency, and human infantile cortical hyperostosis.[102,108,109]

1979
1980

Figure 279-19 Humerus, ulna, and radius of a young giant-breed dog that suffered metaphyseal osteopathy. Reader should note the severe deformities and periosteal new bone.

279.6.4 Multifocal Osteopathy

An idiopathic multifocal osteopathy was described in four young adult Scottish terriers, of which at least three were genetically related (fourth pedigree unavailable).[110] The condition was characterized by multifocal absence of bone in skull, cervical spine, radius, ulna, and femur (Figure 279-20). Histopathologic findings in one case indicated osteoclastic osteolysis and replacement of bone by fibrous tissue. Associated clinical signs included reluctance to move, stiff and stilted gait, carpal valgus and laxity, drooling and dysphagia.

279.6.5 Avascular Necrosis of the Femoral Head

Avascular (or aseptic) necrosis of the femoral head (Legg-Calve-Perthes disease) occurs in adolescent dogs. Miniature and small dog breeds are mostly affected, but Australian shepherd dogs also have increased risk of developing this disorder.[99] Within the predisposed small breeds, about 2% of individuals are affected, without apparent sex predilection. Clinically affected individuals are commonly presented at 4 to 11 months of age with hind leg lameness, usually unilateral but sometimes bilateral (12% to 20% of cases). The onset of lameness is usually gradual, though there may sometimes be a history of trauma. The severity varies from a slight limp to complete nonweight-bearing lameness. Pain and reduced range of movement are found on palpating the affected joint. Crepitus, shortening (up to 2 cm) of the affected limb (largely due to muscle spasm), and muscle atrophy may be evident at initial presentation.

The cause of this condition is unknown, but autosomal recessive inheritance has been suggested for West highland white and Yorkshire terriers, toy and miniature poodles, and pug dogs.[111] Early exposure to sex hormones, a consequence of precocious sexual maturity in small breeds, may be a factor. Another suggestion is that injury or infection and increased synovial fluid in the hip joint disrupt the blood supply to the femoral epiphysis while the growth plate is present. Continued weight bearing could then lead to collapse and remodeling of the femoral neck and head.

Figure 279-20 Radiograph of the antebrachium of a Scottish terrier with multifocal osteopathy. Reader should note the marked attenuation in diameter of the radial diaphysis. (Courtesy of C.W. Hay.)

One of the earliest radiographic changes in this disorder is increased radio-opacity of the affected femoral head. Later changes include an apparent increase in joint space width, shortening and widening of the femoral neck, irregular opacity of femoral epiphyseal and metaphyseal regions, and flattening and irregularity of femoral articular cartilage (Figure 279-21). Secondary osteoarthrosis and acetabular osteophytes may also be evident.

Conservative treatment (short walks on a leash several times daily, swimming, analgesic drug as needed) produces satisfactory outcomes in 25% to 30% of affected dogs, whereas femoral head and neck excision, when performed correctly, gives good to excellent results in 67% to 85% of cases, though slight intermittent lameness may remain.[94,112] Excision arthroplasty is advisable if conservative treatment does not produce clinical improvement within 4 weeks.[112]

Figure 279-21 Later stage Legg-Calve-Perthes disease. Reader should note the multifocal osteolysis of the femoral head, thickened femoral neck, and increase in width of joint space. (Courtesy of Veterinary Imaging Associates, Sydney, Australia.)

279.6.6 Secondary Hypertrophic Osteopathy

In secondary hypertrophic osteopathy (pulmonary hypertrophic osteoarthropathy), firm nonedematous swelling develops in all four limbs, usually in response to intrathoracic disease, most often neoplasia. Of 180

canine cases, 98% had intrathoracic disease, and 92% of these had either metastatic lung neoplasia or primary tumors of lung or thoracic esophagus.[113] A few dogs had pneumonitis, endocarditis, or dirofilariasis. Of four cases lacking intrathoracic disease, three had urinary rhabdomyosarcoma and one had hepatic carcinoma. Because of the association with neoplasia, secondary hypertrophic osteopathy occurs mostly in older animals. No breed or gender predilection exists in dogs. The disorder is rare in cats.

Signs related to limb changes often precede signs of thoracic disease, but they can begin simultaneously with or after thoracic signs. Affected animals are stiff and reluctant to move. Swelling of all limbs occurs, which are warm, firm, and may be painful. Thoracic disease may be manifested by cough, dyspnea, abnormal lung sounds, or cardiac displacement. Abnormal laboratory findings, if any, are related to the underlying intrathoracic disease.

Radiographic changes are characteristic: soft tissue swelling of distal extremities initially, then periosteal new bone formation as irregular nodules perpendicular to the cortex or smoother parallel deposits (Figure 279-22). Bone changes begin distally and may spread proximally to involve humerus and scapula, femur, and pelvis. Ribs and vertebrae are sometimes affected.

On histologic examination, the bones are surrounded by highly vascular, dense connective tissue containing numerous thick-walled arteries. The osteogenic layer of the periosteum is hyperplastic, and overlies maturing and remodeling trabecular bone. The pathogenesis of secondary hypertrophic osteopathy involves increased blood flow to the distal extremities, then overgrowth of connective tissue and subsequent osteoneogenesis. 1981
This seems to involve a neural reflex originating in the thorax and affecting connective tissue and periosteum 1982
of the limbs. The efferent pathway apparently involves nerve fibers that leave the lung near the bronchi and join the vagus in the mediastinum. The nature of the efferent connection, whether neural or hormonal, is unknown. Regression of secondary hypertrophic osteopathy may follow removal of the source of afferent impulses by excision of the lung lesion, or interruption of the afferent fibers by peribronchial dissection or vagotomy. There may be an alternate afferent pathway from parietal pleura along intercostal nerves, because regression has sometimes followed thoracotomy and section of intercostal nerves or extensive resection of a neoplasm of the thoracic wall. The rare association with intra-abdominal lesions is more obscure.

Figure 279-22 Radiograph of distal forelimb of a dog with secondary hypertrophic osteopathy. Periosteal new bone growth occurs, with nodular appearance affecting the metacarpals and digits. Adjacent soft tissues are thickened. (Courtesy of Veterinary Imaging Associates, Sydney, Australia.)

Treatment should be directed against the underlying thoracic disease, using appropriate medical or surgical methods. Successful resection of lung lesions by lobectomy or pneumonectomy can quickly remove pain, soft tissue swelling, and lameness. The bone abnormalities usually regress gradually over several months. Where complete removal of lung lesions is not possible, the skeletal signs may be ameliorated by removal of larger lesions even if multiple small lesions remain. Relief may also follow intrathoracic vagotomy on the same side as the lesion, or on the worse affected side if metastases are bilateral.

279.6.7 Medullary Bone Infarction

Medullary bone infarcts do not cause clinical signs in dogs. They affect older dogs and are usually found in conjunction with osteosarcoma and, occasionally, skeletal fibrosarcoma or renal adenocarcinoma.[114,115] Bone infarcts are characterized radiographically by numerous, irregularly demarcated areas of increased radiopacity in the medullary cavities of one or more bones (Figure 279-23). The densities obliterate medullary cavities to varying degrees. Any bone may be affected, but infarcts are mainly found distal to elbow and stifle.[114]

Figure 279-23 Radiograph demonstrating medullary bone infarction in an aged dog with osteosarcoma *(O)* of the olecranon. The multiple areas of medullary sclerosis in the radius and ulna are infarcts.

The pathogenesis of the disorder is unknown and does not seem to be due to metastatic tumor cell dissemination. However, intramural collagen deposition causes occlusion of nutrient arteries, hypoxia and widespread necrosis of medullary soft tissues and bone, and new bone proliferation on endosteum and

medullary trabeculae.[114] Common causes in humans are dysbaric conditions, fat embolization, hyperadrenocorticism, hyperviscosity, hemoglobinopathy, and anemia. Medullary bone infarcts should be differentiated from enostosis, bacterial and fungal osteomyelitis, and metastatic neoplasia.

279.6.8 Bone Cyst

Benign cystic bone lesions, either monostotic or polyostotic, are uncommon in dogs and cats. Young dogs of larger breeds are affected most often, with Doberman pinschers and German shepherds over-represented.[94,116] Males are affected twice as often as females. The cause is unknown, but may involve intramedullary metaphyseal hemorrhage, local disturbance of bone growth, or other factors.[113] Heritable factors might also be implicated, because lesions occurred in three Doberman pinscher littermates and in three Old English sheepdogs littermates and both parents.[94]

Bone cysts may be subclinical until they are large or fracture with trauma. Pain, lameness, and local swelling may ensue. The lesions occur in metaphyses and adjacent diaphyses of long bones, sparing growth plates and epiphyses. The distal radius or ulna (or both) are affected most often. The cysts are lined by a thin membrane and contain fluid that may be blood tinged. Radiographically, the lesions are lytic and expansible, with thinned cortex and little or no periosteal reaction. There may be one or several chambers, partially divided by bony ridges or partitions (Figure 279-24). 1982 1983

Figure 279-24 Bone cyst in distal femur of a young Doberman pinscher. The lesion has expansile, lytic appearance, with thinning of overlying cortex. Bony ridges or partitions are evident internally.

Alternative diagnoses are atypical bone neoplasia, aneurysmal bone cyst, and fibrous dysplasia of bone. Fine needle aspiration biopsy and cytologic examination may be useful: only a benign bone cyst is likely to be fluid filled, although the other lesions may contain areas of cystic degeneration or hemorrhage. If uncertainty persists, surgical biopsy and histopathologic study are indicated. To stimulate healing of bone cysts, surgery has been advocated, using drainage, curettage, bone grafting, and external support to prevent fractures. Some untreated cysts heal spontaneously without surgery, although pathologic fracture of cystic bone is a risk.[117]

279.6.9 Aneurysmal Bone Cyst

Aneurysmal bone cyst is a non-neoplastic lesion that results in considerable local bone destruction. Although common in man, it is rare in dogs and cats. Lesions arise in ribs, pelvis, scapula, spine, and metaphyses of long bones in young adults and geriatric animals.[118,119] The cause is unknown, but tumors, developmental abnormalities, and trauma-induced hemorrhage causing venous obstruction or arteriovenous shunts in bone marrow have been suggested as initiating factors.[7] Localized partial disruption of medullary blood flow results in endosteal bone resorption and outward displacement of the periosteum. The periosteum forms successive layers of woven bone that are resorbed as the lesion expands, producing the appearance of a ballooning aortic aneurysm.[7] Blood-tinged fluid and fibrovascular tissue fill the lesion which has a honeycomb appearance with huge vascular channels. Radiographically, it appears as a large expansile cyst, with minimal internal trabecular septation, surrounded by thin rim of mineralized soft tissue or bone (Figure 279-25). A triangle of laminated periosteal new bone (Codman's triangle) forms at the junction between cyst and adjacent normal diaphyseal bone. Some have an underlying tumor (osteosarcoma, giant cell tumor) that complicates diagnosis. Signs may be suddenly exacerbated by neoplastic erosion of vessels and intralesional hemorrhage or by fracture.[119] Uncomplicated lesions have a good prognosis when treated by en bloc resection, amputation, or curettage.[120] Nonresectable lesions in man are irradiated to stop bleeding and lesional growth, but postirradiation sarcoma can ensue.

279.6.10 Subchondral Bone Cyst

Subchondral bone cysts are benign lesions in subchondral bone between growth plate and articular cartilage.[121] They are usually lined with synovium and occasionally communicate with the articular synovial membrane. Radiographs show a single or multilocular radiolucent defect with well-circumscribed borders. They are common in horses and pigs and usually a manifestation of osteochondrosis.[7] This association was also noted in a dog.[121]

279.6.11 Fibrous Dysplasia

Fibrous dysplasia is a rare fibro-osseous lesion of bone believed to be of developmental origin.[7] It affects mainly young or newborn animals and may be monostotic or polyostotic. The lesions are expansile and may cause problems of disfigurement or compression of adjacent structures or bone weakness and fracture (Figure 279-26). Monostotic lesions have been reported in the jaw or infraorbital bone of dog, and in mandible, maxilla, or distal ulna of cats.[122,123] Fibrous dysplasia, aneurysmal bone cysts, and benign bone cysts are distinct entities but have been confused in the veterinary literature.[124]

The lesions have marked homogenous radiopacity and are composed of firm, gray fibrous tissue that is gritty when cut. Histologically, they consist of fibrous connective tissue stroma containing spicules of woven bone replacing normal osseous tissue. Cavities of various size containing clear or bloody fluid may be scattered throughout.[7] Two feline lesions were resected, and both patients were free of recurrence 4 years later.[122]

279.6.12 Central Giant Cell Granuloma

This rare, non-neoplastic lesion affects the tooth-bearing regions of maxilla and mandible of young dogs.[125] Trauma-associated intraosseous hemorrhage seems to be an initiating factor. Radiographically the lesion is a rounded to ovoid, expansile, uniloculated radiolucency that is well demarcated from surrounding tissue by a thin rim of smooth nonreactive bone. Adjacent teeth may lose their laminae dura and be displaced, but tooth root resorption is rare. The center of the lesion consists of tan-colored soft tissue composed mainly of loose fibrovascular stroma containing pleomorphic mesenchymal cells and numerous large, irregular multinucleated giant cells. These cells arise from mesenchymal tissue and are neither osteoclasts nor involved in bone resorption. The lesions resemble giant cell tumors histologically. The latter are potentially malignant tumors that cause extensive destruction at the ends of long bones. Because central giant cell granuloma is rare, diagnosis should be confirmed by biopsy. Treatment is by curettage or en bloc resection.[125]

279.7 METABOLIC, NUTRITIONAL, AND ENDOCRINE BONE DISORDERS

The term *metabolic bone disease* is used here to encompass various conditions that cause generalized reduction in bone mass, or *osteopenia*. Osteopenia can be categorized into excessive bone resorption, or *osteolysis*, as occurs in hyperparathyroid states, and defective bone formation. The latter is further subdivided into insufficient formation of osteoid, or *osteoporosis*, and defective mineralization of osteoid, or *rickets-osteomalacia*. 1983 1984

Figure 279-25 Aneurysmal bone cyst of the tibia in a 2-year-old boxer dog that had sustained a tibial fracture as a puppy. **A,** Reader should note the angular deformity of the diaphyses of the tibia and fibular due to fracture malunion. A large cystic cavity in the proximal tibia is associated with a soft tissue mass cranial to the tibia. **B,** Arteriogram showing a dilated, tortuous arteriovenous fistula extending from the tibia into adjacent soft tissue. (Courtesy of J.H. Marti.)

Major causes of metabolic bone disease involve nutritional or hormonal processes (or both). The more important causes discussed here are nutritional secondary hyperparathyroidism, rickets, renal osteodystrophy, and hypervitaminosis A. Other metabolic bone diseases that rarely produce bone-related clinical signs are mentioned briefly.

279.7.1 Nutritional Secondary Hyperparathyroidism

Nutritional secondary hyperparathyroidism is a metabolic disorder in which bone production is normal but osteopenia results from excessive bone resorption. It is caused by diets providing excess phosphate,

insufficient calcium, or both.[94] Affected animals have usually been fed mainly meat, organ tissue, or both. This provides adequate phosphate but insufficient calcium, and Ca/P ratios of about 1:16 to 1:35,[126] which contrast with the recommended 1.2:1 for dogs and 1:1 for cats. Added cow's milk provides insufficient calcium to correct the imbalance. The imbalance induces hypocalcemia, which increases secretion of PTH. Increased parathyroid activity tends to normalize blood calcium and inorganic phosphate concentrations by promoting mineral resorption from bone, enhancing intestinal calcium absorption, and facilitating renal phosphate excretion and calcium retention. However, continued ingestion of the defective diet sustains the hyperparathyroid state and causes progressive skeletal demineralization and consequent clinical signs.

Nutritional secondary hyperparathyroidism causes clinical disease in pups and kittens of all breeds, but it also occurs occasionally in adults. Signs in young animals are lameness, reluctance to stand or walk, and skeletal pain. Costochondral junctions and metaphyses may appear swollen, and pyrexia is sometimes present. Bone fractures can follow relatively mild trauma. Limb deformity may be evident. Paresis or paralysis may result from vertebral compression, and constipation may follow pelvic collapse. Effects are less dramatic in adults, but generalized osteopenia and skeletal pain are sometimes seen, and resorption of alveolar bone may cause loosening and loss of teeth.

Radiographically, decreased bone density and thin cortices are seen, with or without fracturing (Figure 279-27). Growth plates are normal, but metaphyses may be mushroom shaped. An area of relative radio-opacity occurs in the metaphyses adjacent to growth plates, representing the area of primary mineralization, and may be best appreciated in the distal radius and ulna (Figure 279-28).

1984

1985

Figure 279-26 Fibrous dysplasia in the ulnar diaphysis, with secondary lysis and new bone formation in adjacent radial cortex. (Courtesy of P.A. Manley.)

Blood biochemical tests are of little value in confirming nutritional secondary hyperparathyroidism. The calcium concentration is usually within the reference range because of compensatory changes. Concentrations of inorganic phosphate and alkaline phosphatase may appear high but should be interpreted carefully because growing animals often have higher values than adults.

Affected animals should be confined for the first few weeks of treatment to reduce the risk of fractures and deformity. A good quality, nutritionally complete commercial ration should be fed. For all but mildly affected cases, sufficient calcium carbonate should be added to produce a calcium/phosphorus ratio of 2:1. This is maintained for 2 to 3 months, after which the supplement is withdrawn. Oversupplementation with calcium should be avoided. For severely affected cases parenteral administration of calcium (e.g., 10 to 30 mL of 10% calcium gluconate solution by slow intravenous infusion daily for 3 days) may help reduce pain and lameness initially, but it does little to correct the calcium deficiency. An NSAID might be useful for short-term analgesia. The prognosis is generally good, unless skeletal deformity and disability are marked.

Figure 279-27 Abdomen of kitten with nutritional secondary hyperparathyroidism. Reader should note poor contrast in radio-opacity between bones and soft tissues such as liver and kidneys. The cortices of long bones are thin, vertebrae are lucent, and the vertebral column is deformed in the thoracolumbar area.

279.7.2 Rickets

Clinical cases of rickets are rare in dogs and cats. Rickets and its adult equivalent, osteomalacia, occur when insufficient calcium, phosphorus, or both is available for mineralization of newly formed osteoid. The more likely causes of rickets in dogs and cats are hypovitaminosis D (dietary deficiency),[127] inborn error in vitamin D metabolism,[128] or low availability of minerals from the diet (inadequate concentration, impaired

absorption). Dogs and cats do not synthesize cholecalciferol (previtamin D_3) in skin exposed to ultraviolet (UV) light, and are mainly dependent on dietary intake.[129–131]

Affected animals may be lame and reluctant or unable to walk. Fractures or bending of long bones can occur. Enlargement of costochondral junctions and metaphyses may be evident. Other possible abnormalities are delayed dental eruption, weakness, listlessness, and neurologic signs (excitability, tremor, convulsion, and coma) from hypocalcemia. Potential blood test abnormalities include low calcium, low inorganic phosphate, increased alkaline phosphatase, increased PTH, and low 25-hydroxycholecalciferol (the storage form of vitamin D).[127,128,132]

Characteristic radiographic findings are axial and radial thickening of growth plates and cupping of adjacent metaphyses (Figures 279-29 and 279-30). The distal ulnar growth plates are consistently the most severely affected, and this finding reflects a failure of mineralization of cartilage that is being produced at the normal rate. Additional findings are osteopenia, thin cortices, and bowed diaphyses.

When dietary deficiency is suspected, therapy requires a regular diet with adequate and not excessive amounts of calcium, phosphorus, and vitamin D.[127,132] The regimen described for nutritional secondary hyperparathyroidism would be appropriate. Treatment with dihydrotachysterol was effective in a dog in which an inborn error in vitamin D metabolism was suspected.[128]

279.7.3 Renal Osteodystrophy

Renal osteodystrophy is an osteopenic disorder that results from chronic renal failure (CRF). This complex abnormality involves both hyperparathyroidism (excessive bone resorption) and rickets-osteomalacia (impaired osteoid mineralization). Hyperparathyroidism results from impaired renal excretion of phosphate and consequent hyperphosphatemia. This lowers blood calcium concentration, increases parathyroid gland activity, and induces bone resorption. Although this tends to normalize blood calcium concentrations, the hyperparathyroid state is maintained by persisting hyperphosphatemia. Concurrently, synthesis of 1,25 dihydroxyvitamin D declines because of reduced functional renal mass. This and other metabolic derangements lead to severe depression of enteric calcium absorption, impaired mineralization of osteoid, and thus rickets-osteomalacia.

Figure 279-28 Foreleg of a pup with nutritional secondary hyperparathyroidism. Bone is abnormally radiolucent and cortices are thin. Growth plates are normal, but relatively radio-opaque zones are present in the adjacent metaphyses (representing areas of primary mineralization of osteoid).

The syndrome is dominated by signs of renal failure and uremia. Bone disease is more likely to be recognized clinically in growing dogs or, rarely, cats with early onset renal failure. Changes may be most evident in the head. The mandible and maxilla may be pliable and swollen, owing to bone resorption and fibrosis, and teeth may be malaligned, loose, or lost. Skeletal pain, fractures, and bowing of long bones can also occur. Osteopenia of the mandible and maxilla leads to enhanced radiographic contrast between teeth and bone, and teeth may appear almost unsupported by bony tissue.[133]

Treatment is directed against the underlying disease, if possible. Reduced phosphate intake, coupled with oral phosphate binder (aluminum hydroxide or carbonate) as necessary, can help to control hyperphosphatemia. Once this is achieved, consideration can be given to administering calcium to improve calcium balance or administering calcitriol to control hyperparathyroidism (see Chapters 258 and 260).

Figure 279-29 Foreleg of a 12-week-old Saint Bernard with rickets due to an inborn error in vitamin D metabolism. Enlarged physes and cupping of adjacent metaphyseal bone are features of rickets. (From Johnson KA et al: Vitamin D–dependent rickets in a Saint Bernard dog. J Small Anim Pract 29:657, 1988.)

279.7.4 Hypervitaminosis A

Prolonged intake of excessive vitamin A supplements or ingestion of mainly liver diets can cause osteopathy. The major finding in older cats is extensive, even confluent, exostoses and enthesophytes involving cervical and cranial thoracic vertebrae (Figure 279-31). Enthesophytes may also form around limb joints, especially

shoulder or elbow, which may reflect increased sensitivity of tendon, ligament, and joint capsule attachments to the effects of tension.[113,134]

The lesions are painful in the early stages and may ankylose, causing neck stiffness and abnormal posture. Associated clinical signs are lethargy, depression, irritability, poor grooming, lameness, and gingivitis.[113] Experimental vitamin A toxicosis in young animals depressed chondrocyte and osteoblast activities, which produced thin bone cortices, retarded long bone growth, and produced loose or lost teeth in kittens.[134,135] Puppies had joint pain, thin bone cortices, and retarded bone growth.[136]

Treatment necessitates avoiding the source of vitamin A. Mature cats will improve clinically, but rigidity from ankylosis will probably remain despite bone remodeling. Bone growth may be retarded permanently in young animals.[134]

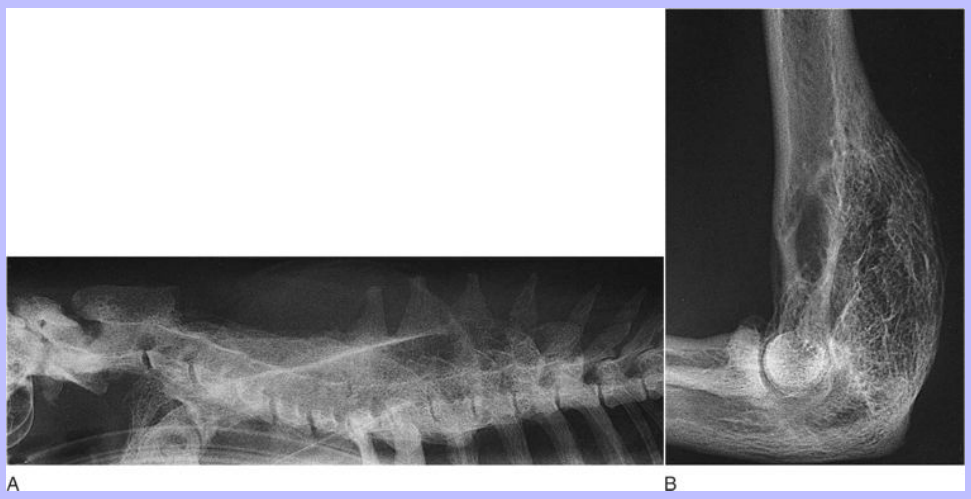
279.7.5 Other Endocrine and Nutritional Bone Disorders

279.7.5.1 Primary Hyperparathyroidism

With uncontrolled hyperplastic or neoplastic proliferation of parathyroid tissue, excessive secretion of PTH may cause increased bone remodeling and skeletal demineralization. This could lead to lameness, pain, fractures, vertebral collapse, loose or lost teeth, and pliable, possibly swollen jaw bones (Figure 279-32). However, the predominant findings usually relate to hypercalcemia[137] and include polydipsia (PD), polyuria (PU), listlessness, incontinence, weakness, inappetence, and urocystolithiasis (see Chapter 237).

Figure 279-30 Foreleg of a greyhound puppy with rickets due to dietary deficiency of vitamin D. Reader should note the axial and radial enlargement of the physes and cupping of the adjacent metaphyseal bone. (Courtesy of R. Malik and Veterinary Imaging Associates, Sydney, Australia.)

Figure 279-31 Cat with hypervitaminosis A. **A,** Confluent exostoses affect the dorsum of the spine from the second cervical to the fifth thoracic vertebrae. **B,** Exuberant exostoses of distal humerus and proximal ulna are ankylosing the elbow.



279.7.5.2 Humoral Hypercalcemia of Malignancy

With certain neoplasms, especially lymphosarcoma or adenocarcinoma of the anal sacs in dogs, widespread skeletal demineralization ensues through the humoral action of PTH-related protein.[137,138] Although skeletal dysfunction can occur as with primary hyperparathyroidism, findings are usually dominated by changes related to the underlying tumor and the effects of hypercalcemia (see Chapter 237).

279.7.5.3 Hyperadrenocorticism

Chronic glucocorticosteroid excess due to iatrogenic excess or naturally occurring hyperadrenocorticism causes osteopenia. Retarded growth and delayed growth plate closure may occur in young dogs,[139] and spontaneous fractures and increased prevalence of intervertebral disk disease have been suggested.[140] Osteopenia in spontaneous canine hyperadrenocorticism is attributable primarily to decreased bone formation; bone resorption is apparently normal, although parathyroid hyperplasia is present in some cases (see Chapter 136).[140]

279.7.5.4 Hypogonadism

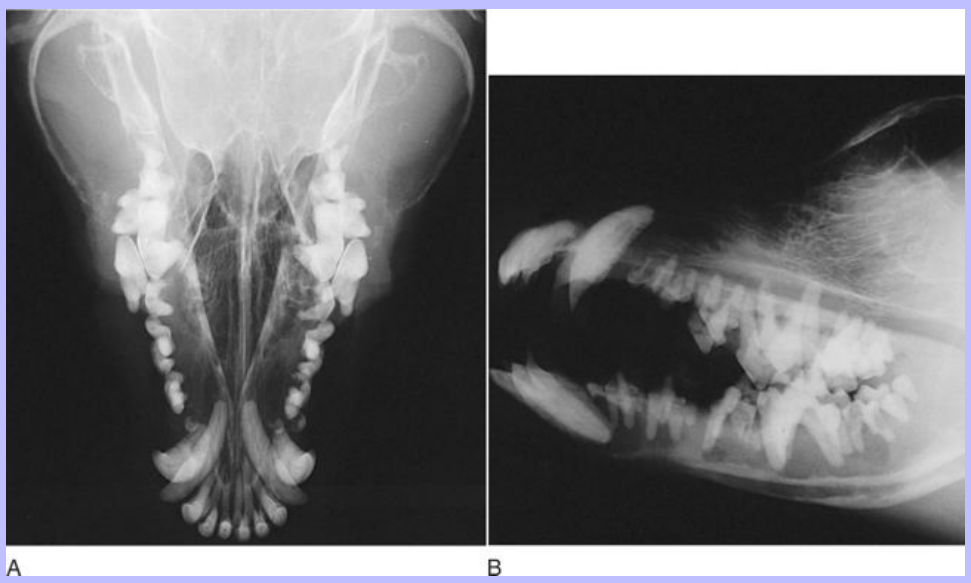
Hypogonadism, whether a developmental defect or produced surgically, can delay growth plate closure.[7] In dogs, closure was delayed by neutering in both sexes, and the extended growth period resulted in longer radius and ulna in all males, as well as in bitches neutered at 7 weeks.[141] Gonadectomy in cats delayed distal radial physeal closure but did not affect bone length.[142] However, neutered male cats are predisposed

to spontaneous, nontraumatic fractures of the femoral capital physis between the ages of 5 to 24 months.[143–145] Fractures are often bilateral. Radiographic signs include physeal fracture displacement and lysis of the metaphyseal bone, producing an "apple core" appearance. Histological examination of specimens resected at surgery revealed that the articular cartilage and epiphyseal bone of the capital epiphysis had normal structure and viability, but the physeal cartilage was thickened and necrotic.[144] Normally this physis closes at 7 to 9 months of age in sexually intact cats. Delayed physeal closure after early gonadectomy apparently allows the persistence of cartilage that is unable to support normal weight-bearing activities.

1987

1988

Figure 279-32 Radiograph of an aged Keeshond with parathyroid adenoma and hyperparathyroidism, with profound osteopenia of the skull and mandible. **A,** In the ventrodorsal view, osteolysis of the zygomatic arch, maxilla, facial bones, and mandible occurs. **B,** In the lateral view, loss of the lamina dura and mandibular cortex occurs, except for the thin ventral cortex.



279.7.5.5

Hepatic Osteodystrophy

Severe hepatic disease can produce rickets—osteomalacia due to malassimilation of fat and vitamin D (and secondarily of calcium) and impaired production of 25-hydroxyvitamin D.[146] Osteoporosis may also occur due to diminished hepatic protein synthesis.[146] Although well-recognized in human patients, hepatic osteodystrophy has yet to be characterized in dogs and cats.

279.7.5.6 Anticonvulsant Osteodystrophy

Prolonged high-dose anticonvulsant therapy with primidone, phenytoin, or phenobarbitone can cause osteodystrophy in human epileptics.[146] These drugs induce hepatic enzymes that enhance catabolism and excretion of vitamin D, resulting in calcium malabsorption, hypocalcemia, secondary hyperparathyroidism, and osteomalacia. Phenytoin also directly inhibits intestinal calcium transport and bone resorptive responses to PTH and vitamin D metabolites.[146] The significance of these changes to veterinary patients is unknown.

279.7.5.7 Hypovitaminosis A

Vitamin A is important for growth, maturation, and remodeling of bone. Hypovitaminosis A decreases osteoclastic activity and impedes bone remodeling, causing long bones to be deformed. Affected animals are usually lame. The condition is probably rare.[113,147]

279.7.5.8 Hypervitaminosis D

Skeletal demineralization follows massive intake of vitamin D, its active metabolites or analogs. Although osteopenia, bone deformation, and retarded growth are possible, the major clinical effects are related to hypercalcemia and soft tissue mineralization.[136] Correcting intakes of vitamin D, calcium, and phosphate should resolve the bone problems, but soft tissue damage may persist.

279.7.5.9 Zinc-Responsive Chondrodysplasia

This form of dwarfism occurs in Alaskan malamutes and possibly other northern breeds.[147] Affected dogs have short, bowed legs; flared, irregular, thickened growth plates; and coarse, disorganized metaphyseal trabeculae. Hemolytic anemia with macrocytosis, hypochromia, and stomatocytosis are also present. Life-long supplementation with zinc sulfate or gluconate was suggested.[147]

279.7.6 Copper Deficiency

Lameness and bone fragility can occur in dogs on copper-deficient diets.[7] Radiographic features are thickened growth plates and flared metaphyses, with osteopenia and epiphyseal slipping in severe cases. Histologically the animal has thickening of the zone of hypertrophic chondrocytes plus disorganization and collapse of the primary spongiosa.[148] The condition is rare.

279.7.6.1 Lead Poisoning

Although skeletal signs are absent in plumbism, lead lines are seen radiographically in bones of some affected immature dogs. The lines are radio-opaque bands in metaphyses adjacent to growth plates of long bones (Figure 279-33). They result from accumulation of thick mineralized trabeculae at these sites because of impaired osteoclastic activity. The presence of lead itself adds little to the radio-opacity.

279.7.6.2 Overnutrition in Growing Dogs

Provision of balanced diets in quantities in excess of recommended daily intake or feeding diets that contain greater than the recommended content of protein, energy, minerals, or vitamins, have been referred to as *overnutrition* or *overfeeding*. Experimental studies of young growing Great Danes found that feeding of an excessively supplemented diet was associated with development of wobbler syndrome, enostosis, osteochondrosis, and metaphyseal osteopathy.[149] Subsequently, it was found that diets with excessive protein content have no adverse effects on skeletal development.[150] However, Great Dane puppies fed a diet containing triple the recommended calcium requirement had elevated absorption and retention of calcium and disturbed endochondral ossification, and they developed osteochondrosis, retained cartilage cores, radius curvus syndrome, and had stunted growth.[88,151,152] Another study of Great Dane puppies fed diets with calcium/phosphorus ratios of 1.2:1, but with lower than recommended concentrations of calcium, found that bones had lower bone mineral content throughout the growth period.[153] Long bone growth was also delayed until 6 months of age, but after this time bone growth caught up and was normal by 12 months of age, despite dietary deficiency in calcium.

1988
1989

Figure 279-33 Radiograph of distal forelimb of a puppy with lead poisoning. Radiopaque bands are present in metaphyses adjacent to growth plates.

Young Great Danes fed *ad libitum* with a balanced commercial diet initially had greater increases in body weight and height than littermates fed a restricted (two thirds of the caloric intake) diet.[132] The restricted puppies later had a period of catch-up growth, and by age 7 months long bones were of identical length.[132] Restricted feeding (25% reduction in total intake) of a balanced diet limited the incidence and severity of osteoarthritis secondary to hip dysplasia in Labrador retriever dogs.[154] Accordingly, overfeeding and oversupplemented diets should be avoided in growing pups. *Ad libitum* feeding is not recommended because it does not result in larger adult dogs, and it increases risk of orthopedic problems such as hip dysplasia.[132,154]

279.8 NEOPLASTIC BONE DISEASE[155]

Neoplasia of the skeletal system can be categorized into primary bone tumors, metastatic bone tumors, tumors of soft tissues extending into adjacent bone, and benign bone tumors.[155] These conditions are discussed elsewhere in this text. Non-neoplastic conditions of bone, such as cystic lesions and fibrous dysplasia, that may be confused with primary bone cancer, are important differentials. Bone cysts and fibrous dysplasia of bone are discussed earlier in this chapter.

279.9 BONE INFECTION

Bone infection (osteomyelitis) may be bacterial, fungal, or possibly viral (see Metaphyseal Osteopathy) in origin. Beta lactamase–producing *Staphylococcus* cause approximately 50% of cases of bacterial osteomyelitis, often as monomicrobial infections.[30] Polymicrobial infections may have mixtures of *Streptococcus* and gram-negative bacteria (*Escherichia coli, Pseudomonas, Proteus,* and *Klebsiella*), and sometimes anaerobic bacteria. More common anaerobic isolates are *Actinomyces, Peptostreptococcus, Bacteroides,* and *Fusobacterium*.[156] Anaerobes are especially common in bite wound infections. *Nocardia*, *Brucella canis,* and tuberculosis cause osteomyelitis in rare instances.[155] Mycotic genera that cause osteomyelitis include *Coccidioides, Blastomyces, Histoplasma, Cryptococcus*, and *Aspergillus*. Fungal osteomyelitis is often a component of disseminated mycotic infections that occur in certain specific regions of the world. Diagnosis and treatment of deep mycoses are discussed in Chapter 174.

279.9.1 Pathophysiology

Bacterial contamination of bone can occur with open fractures, surgery, bite wounds, foreign-body penetration, gunshot injury, extension from soft tissue, and hematogenous spread. However, bone is relatively resistant to infection unless the animal has concurrent soft tissue injury, bone necrosis, sequestration, fracture instability, implanted foreign material, altered host defenses, or some combination of these problems.[157] In chronic infections, avascular fragments of cortical bone (sequestra) are colonized by bacteria, surrounded by exudate, and may persist for long periods. New bone formed by periosteum (involucrum) incompletely encapsulates the focus of infection and sequestrum. Exudate draining from the bone follows sinus tracts that discharge through skin openings, generally in a more dependent location. Osteomyelitis is exacerbated by fracture and instability. Cortical bone at the fracture site is resorbed because of infection and interfragmentary motion, and this causes further widening of the fracture gap and additional instability.

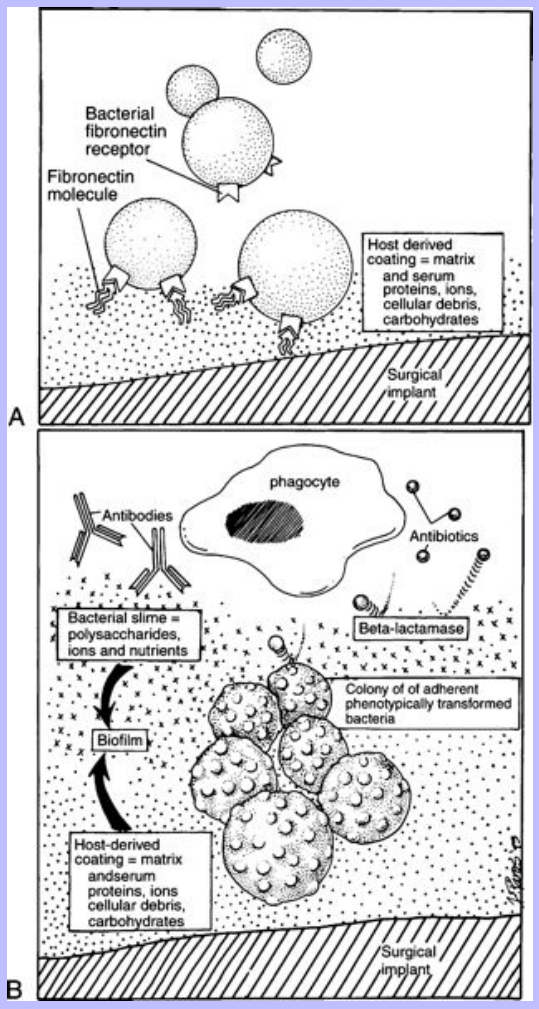
Extraneous material (wood, soil, asphalt, and surgical implants) may incite a foreign-body response, interfere with local host defense mechanisms, and provide a nidus for infection.[157,158] Bacteria have unique mechanisms for bonding to surfaces of implanted foreign material. Initially the surfaces of implants become coated with matrix and serum proteins, ions, cellular debris, and carbohydrates (Figure 279-34).[159] Fibronectin, collagen, and fibrinogen are especially important in bacterial binding to biomaterial. Staphylococci and other gram-positive bacteria possess numerous cell membrane receptors for binding to fibronectin on implant surfaces.[159] Gram-negative bacteria are less effective at binding and have pili and fimbriae that specifically bind cellular proteins, matrix proteins, and glycolipids.[159] Bacteria also bind to exposed collagen matrix proteins (sialoprotein) and hydroxyapatite crystals of damaged bone.[159–161]

1989

Once adherent, bacteria have two important mechanisms that ensure their persistence: (1) slime production and (2) phenotypic transformation.[159,162] Adherent staphylococci and some other bacteria produce a slime composed of extracellular polysaccharide, ions, and nutrients. Slime, together with host-derived material (matrix and serum proteins, ions, cellular debris, and carbohydrate), envelopes bacterial colonies and is called *biofilm* or *glycocalyx* (see Figure 279-34). Biofilm is a virulence factor, because it increases bacterial adhesion, shields bacteria from phagocytes and antibodies, and modifies drug susceptibility.[159] Most antimicrobial drugs diffuse through biofilm, but biofilm may contain high concentrations of beta-lactamase, which protects some bacteria. In addition to providing physical protection, biofilm causes adherent bacteria to transform phenotypically to more virulent strains that are more resistant to antimicrobial drugs than when they are tested *in vitro*.[159]

1990

Figure 279-34 Mechanisms of bacterial persistence in chronic osteomyelitis. **A,** Foreign material such as surgical implants become coated with host-derived material containing fibronectin that binds with membrane receptors of contaminating bacteria. **B,** Adherent staphylococci and some other bacteria produce a slime that together with the host-derived material is called *biofilm*. Biofilm increases bacterial adhesion, protects bacteria from phagocytes and antibodies, and may also contain beta-lactamase. In addition, some adherent bacteria are phenotypically transformed to more virulent strains. (From Johnson KA: Osteomyelitis in dogs and cats. J Am Vet Med Assoc 205:1882, 1994.)



The metaphyses of long bones are commonly affected in young animals with acute hematogenous osteomyelitis.[163] These regions may be especially vulnerable because capillary endothelium therein is discontinuous, allowing extravasation of erythrocytes and possibly bacteria.[157] When local defenses are compromised, osteomyelitis may ensue. This probably accounts for the development of metaphyseal osteomyelitis in Irish setter pups with leukocyte adhesion protein deficiency and border collies with neutropenia due to impaired release of neutrophils from bone marrow (Figure 279-35).[164,165]

279.9.2 Diagnosis

Acute osteomyelitis may produce signs of systemic illness including pyrexia, inappetence, dullness, and weight loss, together with neutrophilia and left shift. Heat, pain, and swelling in muscle and periosteum surrounding the infected bone may be evident. In chronic osteomyelitis, abscessation with single or multiple sinus tracts is a prominent sign. Lymphadenopathy, muscle atrophy, fibrosis, and contracture accompany chronic disease, but hematologic alterations are uncommon.

Radiographs are usually necessary for diagnosis (see Radiology). In acute osteomyelitis, soft tissue swelling (but no osseous changes) occurs, except perhaps in young animals with acute metaphyseal osteomyelitis. In chronic osteomyelitis, periosteal new bone forms early and tends to be extensive, spiculated, and radially orientated (Figure 279-36). Bone resorption produces cortical thinning, medullary lysis, and rounding of fractured bone ends. In young animals, the diaphyseal cortex may be entirely resorbed and replaced by a shell of involucrum. The finding of sequestra is virtually diagnostic for osteomyelitis. Sequestra may be small and obscured by surrounding bone, but it should always be suspected in cases of persistent bone infection. Contrast radiography may help delineate sinuses and foreign bodies. A water-soluble contrast media (10 to 20 mL of Urografin, 76%) is injected slowly through a Foley catheter into each sinus.

Figure 279-35 Polyostotic metaphyseal osteomyelitis in a border collie pup that had persistent neutropenia. **A,** Disruption of metaphyseal architecture of distal femur and proximal tibia, with irregular areas of radiolucency and sclerosis and some periosteal new bone adjacent. **B,** Similar changes are evident in distal humerus and proximal radius.

Figure 279-36 Pelvis of a cat with chronic osteomyelitis probably due to a bite wound from another cat. The hemipelvis is thickened by the formation of irregular, speculated new periosteal bone. (Courtesy of Veterinary Imaging Associates, Sydney, Australia.)

1990

1991

Incomplete delineation of sinuses is a problem. Isolation of bacteria from the site of suspected bone infections should be attempted to confirm the diagnosis and determine *in vitro* drug susceptibility. The diagnosis can usually be made from the history, physical examination, radiology, microbiology, or some combination of these factors.

279.9.3 Treatment

Contrary to long-held beliefs, most antimicrobial drugs penetrate bone well. However, osteomyelitis can be difficult to treat because of factors discussed under pathophysiology. Beta-lactam agents (penicillins, cephalosporins), tetracyclines, and aminoglycosides readily traverse the capillary membrane in normal and infected bone, and they are widely distributed in interstitial fluid.[166] Peak tissue concentrations of these drugs

are reached 25 to 45 minutes after intravenous administration in normal and infected bone, and concentrations in bone closely reflect those in blood.[166] Therefore factors other than drug penetration (such as toxicity, administration routes, *in vitro* susceptibility, and cost) should dictate drug selection. Acute bacterial osteomyelitis may be cured by 4 to 6 weeks of antimicrobial drug therapy, provided bone necrosis is limited and no fracture occurs. However, in chronic osteomyelitis, drug treatment is futile without surgical intervention to remove sequestra and débride necrotic tissue.[157] Débrided wounds are left open to heal by secondary intention, protected with sterile dressings, and irrigated daily with sterile physiologic saline. Fractures must be stabilized and bone defects grafted with autologous cancellous bone. Treatment of chronic osteomyelitis is invariably prolonged and expensive, and may be frustrated by episodes of recurrence. Treatment of recurrent osteomyelitis may necessitate a further search for sequestra, repeated débridement and drainage, reassessment of fracture stability, and re-evaluation of microbiology and antimicrobial drug therapy.

280 APPENDIX

280.1 Drug Index to the Sixth Edition of the Textbook of Veterinary Medicine

Stephen Ettinger, DVM

Etienne Côté, DVM

Note: Drugs listed represent a compilation of the more commonly used therapeutic agents. Not all drugs are included. Some listed may be infrequently or never used by clinicians. This listing represents the more commonly used drugs in small animal practice, without implying endorsement (or lack thereof) of specific medications. Appendix I provides a listing of the trade names for many of these agents for easy cross-reference purposes. Appendix II lists the veterinary and human products within this listing by indication in veterinary medicine.

Drugs are listed by their generic names. Trade names are in parentheses under the generic title. A brief description of the drug's actions or indications follows. Canine and feline dosage levels are given individually. Abbreviations include QID (every 6 hours), TID (every 8 hours), BID (every 12 hours), SID (every 24 hours), and EOD (every 48 hours); IV (intravenous), IC (intracardiac), IM (intramuscular), SC or SQ (subcutaneous), and PO (oral); and PRN (as needed) and CRI (constant rate infusion). “Total dose” is the amount given to a patient in each single dose (in contrast to “dose per kilogram body weight”) and not the total amount of drug given for the full course of treatment. The comments column lists commonly expected side effects, specific comments, or other characteristics that are particularly important to the clinician. A sixth column includes commonly available sizes and formulations. Those with HM are human-labeled items; those with VM are veterinary-labeled; and some are available either way. Abbreviations used in this column are: T = tablets; C = capsules; S = oral solution; I = injectable; P = powder; ER = extended release product; O = topical ointment; OS = ophthalmic solution; OO = ophthalmic ointment; OTC = over the counter, nonprescription item.

The clinician should recheck drug dosages for accuracy as well as for specific indications, contraindications, and warnings. Drugs are listed not only by their licensed uses but also by commonly practiced uses. Again, the clinician needs to identify the specific and recommended indications for each drug by reviewing relevant information (e.g. product insert, primary sources) before prescribing or using a drug.

Drugs dosages, comments, and side effects are taken from the parent textbook. There have been new and additional drugs and dosages included since publication of the 6th edition of the parent textbook. Other sources have been used, including the editors' clinical experience; the *Formulary* from the Animal Medical Center, New York, NY; the *Veterinary Drug Handbook*, 4th edition, by D.C. Plumb, University of Minnesota, Iowa State Press, Ames, IA; *Current Veterinary Therapy*, R.W. Kirk and J. D. Bonagura, editors, WB Saunders Co., Philadelphia, PA; *Infectious Diseases of the Dog and Cat,* 2nd edition, CE Greene, editor, WB Saunders, Philadelphia, PA; and *Small Animal Medicine*, Dana Allen, editor, J. B. Lippincott Co., Philadelphia, PA, 1991. Although ranges for drug dosages are given, at times a specific dosage identified represents the recommendations of the redactors.

Table • App-1 A

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Acepromazine (acetylpromazine, PromAce, AtraVet, "ace")	Sedation Preanesthetic Central antiemetic	Premedication or as part of sedative protocol: 0.03-0.15-mg/kg SQ, IM, IV As oral sedative (e.g. prior to travel): 0.5 -1mg/kg PO	Same	Over sedation causes CNS depression; in old or systemically ill patients, use at fraction of low dose (e.g. ¼) or not at all Do not use in patients with seizures or hypotension Has no anxiolytic properties on its own (travel)	5, 10, 25 mg T 10 mg/ml I VM
Acetaminophen (Tylenol, most "aspirin free" preparations)	Antipyretic Analgesic	10-20 mg/kg BID; PO	Do not use	Hypotensive agent Toxic to cats Gastric irritation	Many sizes T OTC
Acetazolamide (Diamox)	Glaucoma C.A. Inhibitor	2-10 mg/kg PO TID	2-10 mg/kg PO TID	Hypokalemia Panting	125, 250 mg T, C HM
Acetylcysteine (Mucomyst)	1. Acetaminophen toxicosis in cats 2. Decrease bronchial secretion viscosity 3. Collagenase complicated corneal ulcers	1. Same as for cats 2. Nebulize as 2% soln BID 3. 1 drop 10% soln q 2-4 in eye	first dose 140 mg/kg, then 70 mg/kg PO q 6 h for 3-7 treatments; may be given as slow bolus IV	Tastes bad Bronchospasm possible, Conjunctivitis if prolonged topical use	100, 200 mg/ml I HM
Acetylsalicylic acid (ASA, aspirin)	Analgesia Anti-inflammatory Antipyretic Post H.W. therapy DIC Antithrom-botic via decreased platelet aggregation	10-25 mg/kg PO, SID-TID 0.5 mg/kg PO BID as antithrombotic	Per cat: 40.5-81 mg q 48-72 h (this is aspirin for Aspirin Regimen Users)	Anorexia-nausea G-I irritation Gastric ulcer-bleeding Platelet dysfunction Doses higher than mini-dose are *less* anticoagulant	81, 300, 600 mg T HM
Acitretin (Soriatane)	Synthetic retinoid for keratinization disorders in specific breeds (e.g. cocker spaniels)	0.5-1.32 mg/kg PO SID		Teratogenic; excreted in milk; adverse effects similar to etretinate?	10, 25 mg T HM

ACTH Gel	Provocative agent for diagnosis of hyper- or hypoadreno-corticism	2 U/kg IM; obtain blood pre- and 2-hour post-injection for cortisol levels. Maximum dosage is 20 units per dog.	Per cat: 10 U; obtain blood pre- and 1- and 2-hour post-inj.	Rare allergic reaction	40, 80 IU/ml I HM
ACTH-like solution, aqueous (tetracosactrin, cosyntropin, Cortrosyn)	Provocative agent for diagnosis of hyper- or hypoadreno-corticism; appears superior to ACTH gel but more costly	5 microg/kg (0.005 mg/kg) IV once; obtain blood pre- and 1-hour post-injection for cortisol levels	Per cat: 0.125 mg IM or IV total dose; obtain blood pre- and 30- and 60 minutes post-inj.	Costly; remains effective if diluted, fractionated, and frozen for use at low dose (dogs)	250 microg (0.25 mg) per ampule I HM
Activated charcoal	Gastrointestinal adsorbent	1 g/5 ml water: give 10 ml of slurry/kg	1 g/5 ml water: give 10 ml of slurry/kg	1. Do not induce vomiting 2. Inhalation pneumonia 3. Follow with cathartic	VM, HM (various)
Albendazole (Valbazen)	Giardia Other endoparasites	25 mg/kg PO BID for 48 h	Same but for 5 days 10-21 days for *Paragonimus*	May cause bone marrow suppression at rec'd dosages	300 mg/ml (paste) S VM
Albuterol (Ventolin, Proventil, Volmax)	Immediate but short-acting beta-2 adrenergic agonist bronchodilator	0.02- 0.05 mg/kg (20 - 50 microg/kg) PO BID-TID Inhalant: 1 puff as needed up to BID	1 puff as needed	Beneficial effect lasts < 4 hrs Restlessness, muscle tremors Use with caution in patients where sympathetic drive could be harmful (heart disease, hypertension, hyperthyroidism, etc.)	2, 4, 5 mg T 2.5 mg/ml S 6.8, 17 g inhalation canisters (0.1 mg [100 microg] per puff) HM
Allopurinol (Zyloprim)	Urate urolithiasis	10 mg/kg PO TID, then reduce to 10 mg/kg PO SID after 1 month	9 mg/kg/day PO	TID Rx for 30 days then SID	100, 300 mg T HM
Aluminum hydroxide (Amphojel, AlternaGEL)	Phosphate binder Antacid	Initially, 10-30 mg/kg PO BID-TID. Titrate based on PO4 to 10-90 mg/kg PO BID-QID 5-10 ml/dog	Same. Per cat: approx. 1-3 ml BID-TID	May cause metabolic alkalosis Amphojel= 64 mg Al(OH)3/ml; AlternaGel= 120 mg Al(OH)3/ml	OTC S HM
Amikacin (Amikin) (Amiglyde-V)	1. Aminoglycoside 2. GM + and – agent	5-10 mg/kg BID, IV, IM, SQ	Same	Nephrotoxic Ototoxic Neuromuscular blockade Poor G-I absorption	50 mg/ml I VM

Amino acids 3% and glycerin injection with electrolytes (ProcalAmine)	Partial parenteral nutrition	Maintenance rate	Maintenance rate	Essential and nonessential amino acids, carbohydrates, and electrolytes for IV infusion	IV soln bags S
Aminocaproic acid (Amicar)	Antiprotease activity for degenerative myelopathy	15 mg/kg PO TID		Limited information on side effects or benefits	200 mg T 250 mg/ml S 250 mg/ml I HM
Aminopentamide (Centrine)	Antispasmodic, cholinergic blocking agent Similar to atropine	0.02 mg/kg PO, IM, SQ, BID-TID	0.02 mg/kg PO, IM, SQ BID-TID	Dryness of the mouth Atropine-like side effects Contraindicated in GI obstruction, GI infection/toxin, glaucoma, heart disease, tachycardia	0.2 mg T 0.5 mg/ml I VM
Aminophylline	Bronchodilator Diuretic (very mild)	5-10 mg/kg PO, IV, SID-TID	2-6 mg/kg PO, SID-BID	Hyperexcitability Tachycardia Gastric irritation Anorexia Administer IV slowly	100, 200 mg T 25 mg/ml I VM
Aminopropa-zine (Jenotone)	Used in urethral obstructions Smooth muscle relaxant	2.2-4.4 mg/kg SID-BID IM	Per cat: 6.25-12.5 mg IM, SID-BID 48 h	Do not use with cystic atony Contraindicated in hypotension	25 mg T 25 mg/ml I VM
Amiodarone (Cordarone)	Type III antiarrhythmic agent for serious ventricular tachyarrhyth-mias that are life threatening	10 mg/kg PO BID × 1 week (loading), then 8 mg/kg PO SID		Photosensitivity Liver necrosis Keratopathy Coombs' test positive May be proarrhythmic	200 mg T HM
Amitraz (Mitaban)	Demodicosis	5-10 ml/gallon H_2O, dip dog; air dry; = 0.025 to 0.05% soln; use 3×/week on feet with a fresh solution of 0.5 ml in 30 ml propylene glycol or mineral oil		Wear gloves when applying Requires multiple dips Transient pruritus noted Use in ventilated areas	19.9% soln for dilution and topical skin application VM

Amitriptyline HCl (Elavil)	Separation, anxiety-related disorders; destructive disorders; feline inappropriate elimination Tricyclic antidepressant	1.1-4.4 mg/kg PO SID-BID	5-12.5 mg/cat PO SID-BID	Sedation; psychosis; Anticholinergic side effects Caution if seizure history	10, 25, 50, 75, 100, 150 mg T HM
Amlodipine (Norvasc)	Long acting Ca channel blocking agent for hypertension	0.0625-0.25 mg/kg PO SID	0.125-0.25 mg/kg PO SID	Somnolence Hypotension	2.5, 5, 10 mg T HM
Ammonium chloride (Uroeze)	Urinary acidifier	100 mg/kg PO BID	20-40 mg/kg PO BID	Poor palatability G-I signs Contraindicated in liver disease and in renal failure Granules = 200 or 400 mg/ ¼ teaspoon	500 mg T HM 400 mg T 200, 400 mg per ¼ teaspoon P VM
Amoxicillin (Amoxi-tabs) (Amoxi-drops) (Robamox-V)	Penicillin class antibiotic GM + and anaerobic antibacterial agent	10-20 mg/kg BID-TID PO, SQ, IM, IV	Same	Penicillin contraindications	50, 100, 150, 200, 400mg T VM, HM
Amoxicillin/Clavulanic acid (Clavamox) (Augmentin)	See *Amoxicillin* No penicillinase inactivation	10-20 mg/kg PO BID	Same	Penicillin sensitivity Vomiting in cats Tablets must remain in foil until used	62.5, 125, 250, 375 mg T 50 mg/ml S VM, HM
Amphotericin B (Fungizone)	Systemic mycoses	Test dose = 0.25 mg/kg IV; if OK, then 0.5 mg/kg in D5W given IV CRI 3 times weekly for 2 to 4 months; do not exceed 5-10 mg/kg	Test dose = 0.1 mg/kg IV; if OK, then 0.1–0.25 mg/kg in 5 to 20 ml of 5% dextrose in water given slowly IV 3 times weekly for up to 6 weeks	Nephrotoxic; monitor BUN. Pretreat with antiemetics Anaphylaxis possible May administer at lower dosage SQ in 0.45% saline plus 2.5% dextrose	50 mg/vial I HM
Amphotericin B, liposomal encapsulated (AmBisome)	Blastomycosis, histoplasmosis, cryptococcosis, coccidioidomycosis	0.5 mg/kg IV test dose; then 1-2.5 mg/kg IV every 48 h; recommended cumulative dose = 12 mg/kg		Anaphylaxis possible; less nephrotoxic than aqueous amphotericin B (above)	50 mg/vial I HM
Ampicillin	Penicillin class antibiotic Routine G+ and anaerobic infections	10-20 mg/kg TID PO, SQ, IM, IV	Same	Penicillin contraindications Phlebitis	125, 250, 500 mg C 125 mg/5 ml S 1, 3, 6 mg vials I VM, HM

Amprolium (Corid)	Enteric coccidiostat	Per pup: 100 mg total dose SID in food or water (not both) for 10 days Per adults dog: 300 mg total dose SID in food or water (not both) for 10 days		Overdosage causes CNS disturbances	9.6% S VM
Amrinone (Inocor)	Low-output systolic heart failure Phosphodiesterase inhibitor	1-3 mg bolus IV, then 0.01–0.1 mg/kg/min (10-100 microg/kg/min) IV		Tachycardia Anxiety Monitor pulse and BP	5 mg/ml I HM
Apomorphine	Induction of vomiting	¼-½ tab in conjunctival sac. Flush out after emesis	Same	Do not use if decreased consciousness Periocular irritation	6 mg T HM
Artificial tears/oint. (Adapt) (Lacrilube)	Used for insufficient tear production or with decreased blinking	1 drop in affected eye PRN	Same	Hypersensitivity	OTC HM
Ascorbic acid (vitamin C)	Acetominophen-induced methemoglobin toxicity Copper hepatotoxicity	Per dog: 100-500 mg PO total dose TID	30 mg/kg QID, PO, SQ, IM, IV for acetamino-phen toxicity		500 mg/ml I 50, 100, 250, 500 mg, 1 g T HM
L-Asparaginase (Elspar)	Induction therapy for lymphoreticular neoplasms Immune thrombocytopenia	400 IU/kg IM, IP once or as part of a protocol; or 10,000-20,000 U/m2 IM, IP, SQ	Same	Allergic symptoms Anaphylaxis Pancreatitis Coagulopathies	10,000 U/vial I HM
Atenolol (Tenormin)	β1 Adrenergic blockade Supraventricular tachyarrhythmias Systemic hypertension	0.25 - 1 mg/kg PO SID-BID	Per cat: 1/8-1/4 of 25 mg tab PO total dose SID-BID	Hypotension Depression Beta blockade induced CHF Inappetence, bradycardia Generally start at low dose and titrate up as necessary	25, 50, 100 mg T HM
Atipamezole (Antisedan)	α2 synthetic alpha adrenergic antagonist Used for reversing analgesic-sedative effects of medetomidine	Administer an equal volume of medetomidine used. Use IV or IM. Give less if over 1 hour since medetomidine		The return to normal state may not be immediate	5 mg/ml I VM

Atropine SO4	Parasymp-atholytic Anticholinergic Preanesthetic agent Organophosphate toxicity Supraventricular bradyarrhyth-mia Atropine response test	0.0.01-0.03 mg/kg IM, SQ, IV Atropine response test: Give 0.04 mg/kg IV only, and recheck ECG after 2-15 minutes. 0.2 - 2 mg/kg IV, IM, SQ for organophos-phate poisoning. For OPO4 poisoning, give ¼ dose IV—remainder IM or SQ	Same	Tachycardia Mydriasis Ileus Photophobia Do not use in CHF unless bradycardia present	0.54 mg/ml I VM Various HM
Atropine sulfate ophthalmic soln./oint.	Used when pupillary dilation is desired (e.g. uveitis)	1 drop in affected eye SID-BID	Same 1 drop in affected eye SID-BID	Atropine side effects Contraindicated in the presence of glaucoma Cats may salivate	0.5, 1% OO 0.5, 1, 2 and 3% OS HM
Aurothioglucose (Solganal)	Pemphigus complex Autoimmune diseases Rheumatoid arthritis	1st week: 0.1 mg/kg IM single dose 2nd week: 0.2 mg/kg single dose. Then 1 mg/kg once a week IM decreasing to once a month for maintenance immuno-suppression	Per cat: 1st week: 1 mg IM 2nd week: 2 mg IM Then 1 mg/kg once a week IM decreasing to once a month	Blood dyscrasias Renal and hepatotoxicity Neuritis-encephalitis Cutaneous toxicity Pain at injection site Many others	50 mg/ml I HM
Azathioprine (Imuran)	Immuno-suppressive agent (SLE, RA, immune-mediated hepatopathies, pemphigus, polymyositis, ITP, IHA, enteritis, etc)	1-2 mg/kg PO EOD-SID		Monitor CBC Bone marrow suppression (leukopenia, thrombocyto-penia), Rarely hepatotoxic Use chemo precautions when handling or administering	50 mg T HM
Azidothymidine (AZT, zidovudine, Retrovir)	Antiretroviral agent		5-15 mg/kg PO BID for 21 days	Monitor for anemia	100 mg C 300 mg T 10 mg/ml S HM

Azithromycin (Zithromax)	Broad-spectrum static macrolide antibiotic Refractory respiratory infections; other infections	5-10 mg/kg PO SID × 1-5 days	5 mg/kg PO SID × 1-5 days; pulse therapy or long-term treatment possible (weeks)	Resistant infections; GI effects; costly and perishable (expires after 1 week despite refrigerations)	250, 600 mg T 20, 40 mg/ml S HM

Table • App-2 B

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Benazepril (Fortekor) (Lotensin)	ACE inhibitor Vasodilator CHF therapy Glomerulopathy	0.25- 0.33 mg/kg PO SID	0.25 mg/kg PO SID	Dual renal-hepatic elimination Sedation, anorexia Monitor potassium Veterinary formulation not available nor approved in USA	5, 20 mg VM (Canada, Europe, others) 5, 10, 20, 40 mg T HM
Benzoyl peroxide (Oxydex) (Pyoben)	Acne, seborrhea, pyoderma, pruritus	Shampoo p.r.n.; leave on skin for 10 minutes and rinse Gel: apply topically BID-TID	Shampoo p.r.n.; leave on skin for 10 minutes and rinse Gel: apply topically BID-TID	Bleaches fabric May be skin irritant	OTC VM, HM
Betamethasone (Betasone)	Injectable or topical long acting steroid	0.1-0.4 mg/kg IM Topically apply as needed up to TID	Topically apply as needed up to TID	Glucocorticoid adverse effects 7-10 × potency of prednisone	2, 5 mg/ml I VM 0.6 mg T 3 mg/ml I HM
Bethanechol (Urecholine)	Bladder atony (nonobstructive) Cholinergic agent	Per dog: 5-25 mg PO total dose TID or 2.5-15 mg TID SQ	Per cat: 2.5-5.0 mg PO total dose BID	Do not use with obstruction or areflexic bladder GI adverse effects possible	5, 10, 25, 50 mg T HM
Bismuth subsalicylate (Pepto-Bismol)	GI tract protectant	1 ml/4 kg body weight PO up to QID	Same with caution due to salicylate composition	Side effects (uncommon): Vomiting, cramping, salivation, miosis May be treated with atropine Causes stool to develop dark or black discoloration	OTC, HM 17, 47 mg/ml S 262 mg T

Blood products	From typed donors Whole: If fresh: RBC, WBCs, platelets, plasma proteins, and coag. factors; If > 8h, RBCs and plasma proteins only. Packed RBCs for anemia Fresh frozen plasma: For protein (to ↑ albumin 1 g/dl) For coagulation factors Cryoprecipitate for VWF, hemophilia A, and fibrinogen deficiencies	5-22 ml/kg slowly IV; rapid if active hemorrhage is present 10-45 ml/kg IV45 ml/kg IV 6-10 ml/kg IV 1 unit (225 ml)/10 kg BW IV	Same	See Ch. 127	VM I

Bromide (KBr-generic)	Anticonvulsant	30-40 mg/kg PO SID or divided BID (if GI signs a problem) May require an initial loading dose of 400-600 mg/kg given in divided doses with food over 24 hrs Dose in conjunction with phenobarbital may be lower; adjust based on serum bromide levels and clinical response	20 mg/kg/day PO This product may exacerbate or induce feline lower airway disease	Used with phenobarbital or alone May potentiate side effects of sedation, incoordination, and pelvic limb weakness Effective range 500-1000 µg/ml Use ACS grade We use 14 oz KBr powder + 1 liter NaCl. 60 ml of this mixture in 8 oz Karo syrup = 400 mg KBr/ml Also available as Na+ salt May be administered per rectum to achieve more rapid blood levels May trigger severe airway disease (asthma-like) in cats In dogs for mono therapy wish to attain 300 mg/dl; for cats 100-200 mg/dl	400 mg/ml S VM
Budesonide (Entocort)	Glucocorticoid with minimal systemic effects due to topical GI distribution and rapid first-pass hepatic metabolism Inflammatory bowel disease	Per dog: 1-6 mg PO total dose SID- EOD For noninfectious colitis: ½ to 1 enema (based on body size) per rectum SID after defecation		Dosing limited by formulation (1 size unbreakable capsule); capsule dissolution designed for human ileum, unproven in vet med	1, 3 mg C 2 mg enema HM
Bunamidine (Scolaban)	*Taenia, Dipylidium, Echinococcus*	25 to 50 mg/kg PO once; fast 3 h before and after administration	Same	V/D rarely observed	100, 200, 400 mg T VM

Buprenorphine HCl (Buprenex)	Opiate agonist 1. Analgesia 2. Sedative for medical procedures	1. 0.01-0.02 mg/kg (10 – 20 microg/kg) IV, IM 2. 0.0075-0.01 mg/kg (7.5–10 microg/kg) IV, IM	0.005-0.03 mg/kg (5–20 microg/kg) IV, IM	Respiratory depression Use cautiously in aged or debilitated patients Neuroleptan-algesia when used with diazepam or acepromazine	0.3 mg/ml I HM
Busiprone (BuSpar)	Anxiolytic agent Urine spraying Aggression Repetitive behaviors	2.5-10 mg PO total dose BID-TID	2.5-5 mg PO total dose SID-BID	Caution when used with hepatic or renal disease	5, 10, 15 mg T HM
Butorphanol tartrate (Torbutrol) (Torbugesic) (Stadol)	Cough suppressant Narcotic agonist/antagonist Analgesia Sedative	Analgesia, sedation: 0.2-1 mg/kg BID-QID PO, IM, SQ 0.1-0.2 mg/kg IV Antitussive: 0.5-1 mg/kg BID-QID PO	Analgesia, sedation: 0.1-0.4 mg/kg BID-QID SQ, IM, IV	Vomiting, sedation Possible overexcitement in cats	1, 5, 10 mg T 10 mg/ml I VM, HM

Table • App-3 C

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Calcitonin (Calcimar) (Micalcin)	Reduces serum calcium in hypercalcemic states, especially cholecalciferol toxicity	4-8 IU/kg BID IV, IM, SQ	4-8 IU/kg BID IV, IM, SQ	Injections are irritating G-I upset possible	200 IU/ml I HM
Calcitriol	Vitamin D analog Hypocalcemia	0.25–0.5 microg PO total dose SID; titrate according to response	0.01–0.04 microg/kg PO SID; titrate according to response	Rapid onset of action and short activity (days), vs. others e.g. DHT	0.25, 0.5 microg C 1 microg/ml S
Calcium carbonate (Titralac, Tums)	Hypocalcemia adjunct treatment	1-4 g/day PO	Same	Could cause alkalosis; many dogs eat these as a treat	OTC, HM
Calcium chloride (or gluconate) (10% solution)	Ventricular asystole	0.1 ml/kg IV slowly, IC	Same		100 mg/ml I HM
Calcium EDTA (Versenate)	Lead, zinc, and other metal poisoning	25 mg/kg SC QID × 5 days maximum. Dilute in 5% D5W or PSS	Same	May be painful despite dilution Potentially nephrotoxic	200 mg/ml I HM
Calcium gluconate (Calcet)	Critical hypocalcemia Ventricular asystole	10% infusion: 50-200 mg/kg IV slowly over 15-30 minutes, up to QID 50-150 mg Ca++/kg/day in continuous IV infusion Oral: 150-250 mg/kg PO TID	Same	Arrhythmias; monitor ECG and overt response to treatment during infusion; V/D; Dystrophic calcification	100 mg/ml I HM
Captan powder 50% (Orthocide)	Dermatomy-coses	Mix 2 tbsp per gallon of water, apply topically every 3-7 days. Do not rinse after applying	Same	May induce contact sensitization in humans	VM
Captopril (Capoten)	Vasodilator, congestive heart failure Hypertension ACE inhibitor	0.5-1.5 mg/kg BID-TID PO	Per cat: 3.12-6.25 mg BID total dose PO	Hypotension-depression Anorexia; V/D Could exacerbate renal failure Less effective than most other “prils”	12.5, 25, 50, 100 mg T HM

Carbamate	Cholinesterase inhibitor for fleas, ticks, cheyletiellic mange	Use as a dip every 7-14 days; do not rinse off Spray EOD	Same	Do not use under 4 wks old Cholinesterase toxicity treat with atropine and bathing May stain hair yellow	0.5–2% topical solution VM
Carbenicillin (Geopen) (Pyopen)	Bacterial infections Penicillin derivative	15-100 mg/kg TID, IV, IM, SQ, PO	15-40 mg/kg TID IV, IM, SQ, Po	See *Penicillin*	382 mg T 1,2,5,10,20,30 g I HM
Carbimazole (Carbazole)	Hyperthyroidism Is metabolized to methimazole		Per cat: 5 mg PO total dose BID-TID; titrate after 1-3 weeks based on response	Adverse effects similar to methimazole; Not available nor approved in USA	5, 20 mg T HM
Carboplatin (Paraplatin)	Antineoplastic for many carcinoma and sarcoma therapies	300 mg/m^2 IV in D5W over 15 minutes every 3 weeks for 4 treatments	200 mg/m^2 IV in D5W over 15 minutes every 4 weeks	Myelosuppression Expensive Advantageous to *cis*-platinum (renal) Use chemo precautions when handling or administering	50, 150, 450 mg I HM
L-Carnitine	AA transports fatty acids into mitochondria for energy metabolism Some cardiomyo-pathies	50-100 mg/kg TID PO	50-100 mg/kg PO SID for hepatic lipidosis	Expensive in big dogs To be used with other Rx Effects uncertain	250, 500 mg T/C 100 mg/ml S HM
Carprofen (Rimadyl)	NSAID with analgesic and antipyretic effects	2-4mg/kg BID PO 4 mg/kg IV, IM, SQ for one time use as an injectable for pain relief	4 mg/kg IV, IM, SQ as a single dose for pain relief	Hepatotoxicity Do not use with bleeding disorders, inflammatory bowel disease, or GI ulcers Monitor liver values Do not use with corticosteroids or ASA May decrease ACE inhibition	25, 75, 100 mg T 50 mg/ml I VM
Carvedilol (Coreg)	α_1 Blocking and nonselective beta blockade; used in CHF and primary tachycardias	0.1 - 0.2 mg/kg PO SID starting dose; may increase to 0.4 mg/kg PO SID	Unknown	Lethargy Gastrointestinal Iatrogenic relapse of CHF; if prior CHF, begin at low dose and increase slowly over several weeks	3.125, 6.25, 12.5, 25 mg T HM

Castor Oil	Irritant cathartic	8-30 ml PO	4-10 ml PO	Gripping catharsis may develop Do not use if obstructed or atonic	OTC, HM
Cefotaxime (Claforan)	3rd generation cephalosporin; Gram + and – organisms and many anaerobes	20-40 mg/kg slow IV TID × 7 days	Same	Pain if injected IM; BM toxicity uncommon	500 mg, 1, 2, 10 g I HM
Cefoxitin (Mefoxin)	Cephamycin grouped with 2nd generation cephalosporins Some G+, G-, and anaerobic bactericidal activity	30 mg/kg IV TID-QID	Same	Pain if injected IM; BM toxicity uncommon	1, 2, 10 g vials I
Cefpodoxime (Simplicef)	Extended spectrum semisynthetic cephalosporin	5-10 mg/kg PO SID	5-10 mg/kg PO SID	Once daily dosaging	100,200mg T VM
Ceftiofur (Naxcel)	3rd generation cephalosporin	2.2- 4.4 mg/kg SQ SID- BID	Same		1, 4 g vials I
Cephalosporin antibiotics	Broad-spectrum bactericidal Less effective against gram + bacteria than penicillins Penicillinase inactivation	10-30 mg/kg BID-QID PO, SQ, IM, IV Review each product for specific dosage, handling, and administration	Same	G-I side effects Penicillin contraindications Possibly nephrotoxic at high dosages or if used with aminoglycoside antibiotics	250, 500 mg C 25, 50, 100 mg/cc S 1, 2, 20 g vials I VM, HM
Chlorambucil (Leukeran)	Lymphoreticu-lar neoplasia Chronic lymphocytic leukemia Macroglobuli-nemia Feline-IBD	2 mg/m^2 PO SID × 3 wk beyond remission, then 1.5 mg/m^2 PO SIDx15 days, then q 3rd day; or 0.1-0.2 mg/kg q 24-72 h PO	1.5 mg/m^2 PO SID as for dog or 0.1 mg/kg q 48-72 h PO or total dose per cat 2 mg/cat EOD PO	Bone marrow suppression Usually a second line agent often used with prednisone and/or other agents Use chemo precautions when handling or administering Do not break or split tablets	2 mg T HM

Chloramphe-nicol (Chloromyce-tin)	Broad spectrum bacteriostatic agent *Mycoplasma, Rickettsia, Chlamydia*, and anaerobic bacteria Excellent lipid solubility 1% oph. Oint.: Corneal ulcers and infections 0.5% oph. Soln.: Corneal ulcers and infections	30-50 mg/kg TID, PO, IV, IM, SQ Apply to eye q 6 h	15-20 mg/kg BID, PO, IV, IM, SQ Apply to eye q 4-8 h	Hepatic microsomal enzyme inhibitor May potentiate some Rx-use caution Do not use with "cidal" agents Monitor CBC and chemistries Possible teratogen	100 mg/ml I 100, 250, 500 mg, 1 g T VM, HM
Chlorhexidine 0.5% (Novasen)	1. Topical antiseptic shampoo 2. Topical antiseptic solution	Shampoo every 3-7 days or dilute the solution 1:10 with water and apply to lesions SID-TID	Same		OTC, HM
Chlorothiazide (Diuril)	Diuretic Nonhormonal Rx for CDI and NDI	20-40mg/kg BID PO	Same	Hyponatremia-hypokalemia Use cautiously with digitalis	250, 500 mg T 50 mg/ml S HM
Chlorphenira-mine (Chlor-Trimeton, ChlorTripolon)	Decongestant; antihistamine	Per dog: 2-8 mg PO total dose BID-TID	Per cat: 1-2 mg PO total dose BID-TID	May cause drowsiness or restlessness	10 mg/ml I 2 mg/ml S 2, 4, 8, 12 mg T OTC HM
Chlorpromazine (Thorazine)	Tranquilization Sedation Antiemetic	Oral tranquilization: 1-3 mg/kg PO up to QID Sedation: 0.1-1 mg/kg SQ, IM 0.01-0.03 mg/kg IV	Same	Severe CNS depression with overdosage May potentiate seizures Use sparingly or not at all in older or systemically ill patients	10, 25, 50, 100, 200 mg T 2 mg/ml S 25 mg suppository 25 mg/ml I HM
Cimetidine (Tagamet)	H2 receptor antagonist Esophagitis, gastric reflux Chronic gastritis, GI tract ulceration Hypergastri-nemia Effects of mast cell tumors	5 - 10 mg/kg BID-QID PO 5 mg/kg TID IV	2.5 - 5 mg/kg BID-TID PO	Hepatic microsomal enzyme inhibitor Administer slowly IV	200, 300, 400, 800 mg T 60 mg/ml S 150 mg/ml I HM

Ciprofloxacin (Cipro)	Fluoroquino-lone antibiotic Broad-spectrum "cidal" Mycoplasma	5-15 mg/kg BID PO		See *Enrofloxacin*	250, 500, 750 mg T HM
Cisapride (Propulsid) (Prepulsid) No longer FDA approved agent for human beings	Prokinetic serotonergic for feline megacolon; gastroesophageal reflux; 1 and 2 GI motility disorders	0.1-1mg/kg PO BID-TID	Per cat: 2.5-5 mg total dose BID-TID PO	Requires adjunctive Rx as stool softener Does not ↑ gastric secretions Increases esophageal peristalsis Reported to be associated with ventricular arrhythmias in HM	10, 20 mg T 1 mg/ml S HM
Cisplatin (Platinol)	Solid carcinomas Osteosarcoma	50-70 mg/m2 IV every 3-5 weeks; pretreat with IV fluids 12 h before and after Rx	None-do not use	Use antiemetic agent; BM suppression; renal toxicity; fatal pulmonary edema in cats; anaphylaxis; use chemo precautions when handling or administering	10 and 50 mg vials I HM
Clarithromycin (Biaxin)	Broad-spectrum macrolide antibacterial; Resistant respiratory or skin infections	5-10 mg/kg PO BID	Same	G-I, liver disturbances; bone marrow toxicity rarely	250, 500 mg T 25, 50 mg/ml S HM
Clemastine fumarate (Tavist products, Contac products, many others)	Antihistamine Allergic skin disease, other allergies	0.05–0.1 mg/kg PO BID		Lethargy/drowsiness, or restlessness Caution re other active ingredients in OTC combo formulations	1.34, 2.68 mg T HM OTC
Clindamycin (Cleocin) (Antirobe)	Lincosamide antibiotic GM +; staphylococcus; anaerobes; Bacteroides; toxoplasmosis; babesiosis; osteomyelitis	5-10 mg/kg BID PO Toxo: 5–20 mg/kg PO BID	Same Toxo: 12.5–25 mg/kg PO BID	May cause V/D and hepatotoxicity Do not use with erythromycin or chloramphenicol	150 mg/ml I 25, 75, 150 mg C 25 mg/ml S VM, HM
Clomipramine (Clomicalm) (Anafranil)	Separation anxiety in the dog-a tricyclic agent	1-2 mg/kg PO BID	5-12.5 mg PO SID-BID per cat	Do not use in breeding dogs or if dog is or has received MAO inhibitors Vomiting, lethargy, diarrhea, and polydipsia are acute adverse reactions Chronic adverse reactions are urine retention, urolith formation and sedation	5, 20, 80 mg VM T
Clonazepam (Klonopin)	Seizure disorders Panic disorders Sedation	0.5 mg/kg PO BID–TID; titrate as required to effect		2nd line seizure Rx Sedation Duration of action in dogs may be short (few hours)	0.5, 1, 2 mg T HM

Cloprostenol	Abortifacient for mismating (early, prior to ossification of fetal bones)	1-2.5 microg/kg SQ SID-EOD × 5 days	Same	Dilute 1:10 with sterile 0.9% NaCl for accurate dosing	250 microg/ml I VM
Clotrimazole (Veltrim) (Lotrimin) (Mycelex)	Used topically for nasal aspergillosis; also externally for Malassezia and other fungi	As needed to fill nasal cavity for nasal aspergillosis (follow precautions and protocol)		Intranasal administration requires preplacing catheters surgically or via endoscope. Use propylene glycol preparation for this indication	10 mg/ml topical solution OTC HM
Coal tar (0.5% to 8%)	Shampoo-seborrhea, dermatitis; eczema; keratolytic	Bathe every 3 to 14 days; leave in contact with skin for 10 minutes and rinse thoroughly	Same	May irritate skin	VM
Cobalamin (Vitamin B12) (cyanocobal-amin)	Used for treating vitamin B12 deficiency from exocrine pancreatic disease, SIBO, and in giant schnauzers	Total dose: 250-500 microg (0.25–0.5 mg) per dog IM, SQ once weekly or less, based on serum levels	Total dose: 125-250 microg (0.125–0.25 mg) per cat IM, SQ		1000 microg/ml (=1 mg/ml) I HM, VM
Colchicine	Hepatic fibrosis	0.03 mg/kg/day PO SID	No reported use	Not well described GI effects, bone marrow toxicity, teratogenicity possible	0.5, 0.6 mg T HM
Cyclophos-phamide (Cytoxan, Neosar)	Lymphoreticu-lar tumors Solid carcinomas Immune-mediated disease	50 mg/m2 (or 2 mg/kg) PO 4 days on, 3 days off, or use EOD 200-300 mg/m2 IV weekly	Same	G-I signs BM suppression Hemorrhagic cystis, especially with higher (weekly) dose Alopecia Use with caution See Chemotherapy Use chemo precautions when handling or administering Do not split or break tablets Caution cyclosporine brand name almost identical (Neosar vs. Neoral)	25, 50 mg T 100, 200, 500 mg and 1 and 2 g vials I HM
Cyclosporine ophthalmic (Optimune) (Sandimmune)	T lymphocyte inhibitor KCS in dogs	0.2% oph. oint. or soln in oil base. Use 1 drop/short strip BID in affected eye(s) until improvement occurs, then SID	Do not use	May be ophthalmic irritant Monitor for infections	HM; VM OO OS 4 ml olive oil and 1 ml cyclosporine

Cyclosporine systemic (Sandimmune) (Atopica) (Neoral)	IMHA; ITP Perianal fistula; Atopic dermatitis; eosinophilic granuloma in cats and other immunosuppressive purposes	Emulsion forms (Neoral, Atopica): 2–5 mg/kg BID PO (2–5 mg/kg SID PO if concurrent ketoconazole administration) Nonemulsion form poorly absorbed (Sandimmune): 5–10 mg/kg BID PO (5–10 mg/kg SID PO if concurrent ketoconazole administration) 2–3 mg/kg slow IV over 4 hours BID; dilute to 1 mg/ml in D5W or 0.9% NaCl before administration	Same	Adjust dose to attain good clinical response and 200-500 ng/ml blood level Oral doses based on greater absorption of emulsion forms vs. nonemulsion form Can cause nephrotoxicity (protein-losing nephropathy) Anaphylaxis possible with IV; little clinical experience with IV to date	25, 50, 100 mg T 100 mg/ml S 50 mg/ml I HM 10, 25, 50, 100 mg T VM
Cyproheptadine (Periactin)	Serotonin and H1 antagonist 1. Appetite stimulant via hypothalamic stimulation 2. Feline pica 3. Antihistamine 4. Spraying	1. 5-20 mg PO BID 2. 1 mg/kg PO BID-TID	1. Total dose = 1-4 mg/cat PO SID-BID 2. 0.22 mg/kg PO SID	Can cause excitability or depression, especially at higher doses; vomiting; aggressiveness	4 mg T 2 mg/5 ml S HM
Cytosine arabinoside (cytarabine) (Cytosar) (ARA-C)	Antineoplastic Lymphoma protocol	100 mg/m2 SID for 2-4 days SQ or slow IV	Same	Leukopenia-BM suppression GI toxicity Reconstituted vial good for 48 h Use along with cancer protocol Use chemo precautions when handling or administering	100, 500 mg 1 and 2 g vials I HM

Table • App-4 D

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Dacarbazine (DTIC)	Melanoma Sarcoma	800-1000 mg/m2 IV CRI (8 hours) q 3-4 weeks	Not recommended	G-I toxicity BM suppression Extravasation injury	100, 200 mg vials I HM
Danazol (Danocrine)	Modified androgen Used for ITP, IMHA	5-10 mg/kg PO BID	Same	Adjunctive Rx for ITP and IHA; hepatotoxicity, bone marrow toxicity possible; response may take weeks–months	50, 100, 200 mg C HM
Dapsone (Avlosulfon)	1. Antibacterial-anti-inflammatory agent used for some skin disorders 2. Antiprotozoal/ anti-mycobacterial effects	1. 1 mg/kg PO TID 2. 1 mg/kg PO TID initially until remission, then 0.3 mg/kg maintenance	Total dose: 25-50 mg per cat BID PO	Hepatotoxicity and BM suppression may occur early in therapy; hemolysis, GI signs, skin eruptions possible	25 and 100 mg T HM
Deferoxamine (Desferal, DFO)	Iron chelator; iron toxicity	10-15 mg/kg/hour IV CRI, then titrate based on serum iron levels. Alternatively, if CRI not possible, give 10-40 mg/kg TID IM for 24-72h, based on serum iron levels		Arrhythmia, hypotension, wheezing if CRI too rapid Hypocalcemia, thrombocyto-penia possible Do not use if renal failure Potential teratogen	500 mg vials I HM
Dehydrocholic acid (Decholin)	Used to stimulate bile flow	10 to 15 mg/kg TID PO for 7-10 days	Same	Do not use with biliary obstruction	HM
Deracoxib (Deramaxx)	COX-2-inhibiting nonsteroidal anti-inflammatory (NSAID) drug. For treatment of osteoarthritis, perioperative pain management	1-2 mg/kg PO SID (long-term use) 3-4 mg/kg PO SID (max. 7 days)		Gastrointestinal signs (vomiting, anorexia)	25, 100 mg chewable T VM
Desmopressin acetate (DDAVP)	1. Vasopressin analog to manage central diabetes insipidus 2. vW disease	1-4 drops intranasally or in subconjunctival sac SID-QID (diabetes insipidus); or 1-2 microg/kg SQ SID-BID Oral dose not yet determined	Same (intranasal or subconjunctival)	Rhinorrhea Hypersensitivity rkns Use nasal spray form (1.5–4 microg/drop)–40 × stronger than parenteral (4 microg/ml)	10 microg/spray (=0.1 ml) in 2.5 or 5 ml bottles 4 microg/ml I 0.1 and 0.2 mg T HM

Desoxycorticosterone pivalate (DOCP) (Percorten-V)	Replacement therapy for mineralocorticoid deficiency (hypoadrenocorticism) Each 25 mg releases 1 mg DOCA/day for 21-26 days	1 cc/12 kg q 25 days; i.e., 2 mg/kg IM or SQ		Titrate dosage to effect No glucocorticoid activity; may require oral prednisolone 0.2-0.4 mg/kg/day as adjunctive therapy	25 mg/ml I VM
Dexamethasone (Azium, Dexate) (Decadron),	Potent glucocorticoid for anti-inflammatory, immune suppression, hypoadrenocorticism, and CNS	0.1-1 mg/kg/day PO, Divide dosage. Dosage variable from	Same	HPA axis suppression Multiorgan steroid effects	0.25, 0.5, 0.75, 1, 1.5, 2, 4, 6 mg T
Dexamethasone sodium phosphate (SP)	edema; adrenal axis testing.	anti-inflammatory to that required for immune suppression. Long-term oral: EOD best LDDST = 0.01 mg/kg IV HDDST = 0.1 mg/kg IV		Very high CNS doses (e.g. 4–8 mg/kg) of unproven clinical benefit and almost always associated with short-term adverse effects (e.g. severe GI bleeding)	2, 8, 16 g/ml I (dexamethasone) 4, 10, 20, 24 mg/ml I (dexamethasone SP) VM, HM
Dexasporin oph. Soln./oint. (Maxitrol)	Neomycin, polymyxin, and dexamethasone combination used for steroid responsive ophthalmic inflammation where a combined antibiotic is desirable	1 drop in affected eye BID-QID	1 drop in affected eye BID-QID	Steroids are contraindicated in some specific eye diseases Systemic side effects are possible	0.05% ointment 0.1% soln. HM
Dexrazoxane (Zinecard, Cardioxane)	EDTA derivative that protects against doxorubicin-induced cardiomyopathy; may also be used for doxorubicin extravasation lesions	10:1 ratio to doxorubicin dose; i.e. administer 10× more dexrazoxane than doxorubicin; IV CRI over 30 minutes, begun 45 minutes prior to doxorubicin		Myelosuppression possible	250 mg and 500 mg vials I HM
Dextran (Rheomacro-dex)	Hypovolemia Plasma volume expander	20 ml/kg IV	Same	Thrombocyt-opathy	10% dextran in PSS or D5W I HM
Dextroampheta-mine (Dexedrine)	Amphetamine Narcolepsy Hyperkinesis	5-10 mg/kg PO TID 0.2-1.3 mg/kg PO PRN			5 mg T 5, 10, 15 mg ER HM
Dextromethor-phan	Antitussive	0.5-2 mg/kg PO TID	Same	Usually in association with other drugs, i.e. OTC cough syrup viz. Robitussin® Efficacy questioned	Many OTC HM

Diazepam (Valium)	1. Tranquilizer, component of anesthetic induction protocol 2. Anticonvulsant 3. Muscle relaxant 4. Appetite stimulant (cats) 5. Urine marking/spraying (cats) 6. Sedative/anxiolytic	1. With ketamine for sedation/anesthetic induction: 0.5 mg/kg IV or to effect, max 20 mg/dose 2. 0.5–1 mg/kg IV to effect. Enema: 1–2 mg/kg made up as 4 mg/ml enema solution CRI: 0.5 mg/kg/h, titrated PRN 3. 0.25–1 mg/kg PO BID-TID 6. 0.05-0.2 mg/kg IV or 0.25–1 mg/kg PO PRN up to BID	1, 2. total dose: 0.25-2 mg IV per cat, to effect 3, 5. Total dose: 1-2 mg per cat BID PO 4. 0.2 mg/kg IV prior to feeding 6. Same as for dog	Sedation; ataxia Paradoxical excitement/aggression Hepatopathy in some cats within days/weeks of starting PO use CRI: diazepam is inactivated by light and adsorbs onto plastic; use glass syringe and short tubing if possible Class IV controlled substance	2, 5, 10 mg T 5 mg/ml I HM
Diazoxide (Proglycem)	Hypoglycemia associated with insulinoma	5–20 mg/kg PO BID	None	Vomiting Anorexia	50 mg C 50 mg/ml S HM
Dichlorphenamide (Daranide)	Glaucoma Carbonic anhydrase inhibitor	2-4 mg/kg PO TID	Same	Weakness, lethargy, diarrhea Hypokalemia Hyperchloremic metabolic acidosis	50 mg T HM
Dichlorvos (Task) (Vapona) (DDVP)	Hook-, whip-, roundworms Flea collars and tags	27 to 33 mg/kg PO once 11 mg/kg PO once (puppies) Change collar every 4 months	11 mg/kg PO once Change collar every 4 months	Organophos-phate toxicity Do not use with constipation; intestinal obstruction; hepatic, cardiac, or heartworm disease	10, 20 mg T 68, 136, 204 mg C 136, 204, 544 mg paste VM
Dicyclomine (Bentyl)	Irritable bowel syndrome Detrusor hyperspasticity causing urge incontinence	0.15 mg/kg BID-TID PO			10 mg C 20 mg T HM
Diethylcarbamazine (DEC) (Caricide, Cypip, Filaribits)	1. Heartworm (HW) prophylaxis 2. Crenosoma lungworm treatment	1. 6-7 mg/kg SID PO, from start of HW season to 2 months after end of HW season 2. 70 mg/kg PO BID for 3 days	55-110 mg/kg PO once for ascarids	Vomiting May decrease sperm count Anaphylaxis if microfilaria positive dog	50, 60, 100, 120, 180, 200, 300, 400 mg T 60 mg/ml S Other sizes VM, HM

Diethylstilbesterol (DES)	1. Estrogen-responsive incontinence 2. Perianal gland adenoma, benign prostatic hyperplasia	1. Total dose: 0.1-1 mg per dog PO SID 2. Total dose: 0.25 - 1 mg per dog PO q 24–48 h × 2–7 days	0.05-0.1 mg/day PO	May induce signs of estrus; decrease to lowest effective dosage. High dosages may cause anemia, leukopenia, thrombocytopenia Ineffective for pregnancy termination Limited availability on US market	1, 5 mg T 50 mg/ml I Other sizes HM
Difloxacin (Dicural)	Fluoroquino-lone antibacterial	5-10 mg/kg PO SID; maximum = 30 days		GI effects, cartilage damage possible in pups Avoid in seizure patients	11, 45 mg T VM
Digoxin (Cardoxin) (Lanoxin)	Positive inotrope Negative chronotrope Negative dromotrope Baroreceptor upregulator	0.01 mg/kg PO BID; maximum dose for largest dog= 0.25 mg PO BID Can double doses for 1st 24h only	Total dose: ¼ of a 0.125 mg tablet per cat PO q 48h.	Serum levels of questionable clinical value Injectable form not recommended	0.125, 0.25 mg T 0.05 mg/ml S
Dihydrotachysterol (DHT, Hytakerol)	Hypocalcemia	0.03-0.06 mg/kg SID PO initially × 2–3 days, then 0.01-0.02 mg/kg every 24-48 h PO titrated to response	Same	Hypercalcemia Monitor serum and patient until well stabilized When stable, monitor long-term use to avoid osteopetrosis	0.125, 0.2, 0.4 mg T 0.125 mg C 0.2 mg/ml S HM
Diltiazem hydrochloride (Cardizem) (Sustained release forms: Dilacor, Cardizem CD)	Calcium channel blocking agent HCM-feline Acute supraventric-ular tachyarrhyth-mias (SVT)	0.5-1.5 mg/kg TID PO For acute SVT: 0.01–0.02 mg/kg IV initial dose; repeat as needed. Max cumulative IV dose = 1 mg/kg. May start at 0.1–0.2 mg/kg IV if heart is structurally normal.	0.7 mg/kg BID-TID PO 10 mg/kg SID PO in extended release form (ER)	Bradycardia Hypotension Anorexia ER form often causes adverse reactions (hepatic, GI) in cats	30, 60, 90, 120 mg T 120, 180, 240, 320 mg C 60, 90, 120, 240, 360, 420 mg ER HM
Dimenhydrinate (Dramamine) (Gravol)	Motion sickness	4–8 mg/kg PO up to TID	Total dose: 12.5 mg per cat PO up to TID	Lethargy-drowsiness Administer 1 hour prior to travel for best antinausea effect	80 mg T 12.5 mg/4 ml S 50 mg/ml I HM

Dimercaprol (BAL, British Anit-Lewisite)	Chelating agent Heavy metal toxicosis such as mercury and arsenic	2.5-5 mg/kg. IM. (Dose of 5 mg/kg used only in acute cases and only on first day.) Then q 4 h on days 1 and 2; q 8 h on day 3; BID for next 10 days	Same	Injections sting Caution: renal insufficiency	100 mg/ml I HM
Dimethyl sulfoxide (DoMoSo, DMSO)	1. Topical anti-inflammatory 2. Renal amyloidosis 3. CNS trauma	1. Apply solution topically BID-TID. Use 60% otic soln. BID 2. 80 mg/kg SQ EOD (dilute solution 1:4 with sterile water) 3.1 g/kg of 10% soln over 45 min IV	None	Erythema, pruritus Investigational except as otic soln. Wear gloves. Readily absorbed	90% gel T 90% soln. Topical VM, HM HM
Dioctyl sulfosuccinate (docusate, DSS, Colace, Surfak)	Stool softener	One or two 50-mg capsules q 12-24 h PO	One 50-mg capsule q 12-24 h PO	Also available as enema preparation for cats and small dogs	25, 50, 100 mg hard caplets OTC HM VM
Diphenhydra-mine HCl (Benadryl Allergy)	H1 receptor antihistamine	2-4 mg/kg BID, TID, PO 1-2 mg/kg BID IM, SC	Same Do not use IV	Sedative Anticholinergic Antiemetic Use with caution in seizure patients	25, 50 mg C, T 2.5 mg/ml S 10 mg/ml I HM
Diphenoxylate HCl with atropine (Lomotil)	Antidiarrheal Nonanalgesic opiate	0.1-0.2 mg/kg PO up to TID Total dose: 0.625 - 2.5 mg PO per dog, up to TID	0.6-1.2 mg PO BID	Sedation Constipation Ileus Use with caution in cats (opiate adverse effects)	2.5 mg T 2.5 mg/5 ml S HM
Dipyrone (Novin)	Antipyretic	25 mg/kg SQ, IM, IV up to TID	Same	Hypothermia BM suppression Do not use if hyperthermia is not true fever (contraindicated in heat stroke, brachycephalic crisis, etc)	300 mg T 500 mg/ml I HM
Disopyramide (Norpace)	Ventricular dysrhythmias Type IA agent	6–22 mg/kg TID PO	None	Rarely used May be used with quinidine or procainamide	100, 150 mg C 100, 150 mg ER HM

Dithiazanine iodide (Dizan)	Microfilaricide	6.6-11 mg/kg SID PO for 7-10 days	None	Stains stool purple V/D, anorexia	10, 50, 100, 200 mg T VM
Dobutamine HCl (Dobutrex)	Inotropic agent for cardiomyo-pathy, heart failure. Short term usage Beta1-agonist	0.0025–0.02 mg/kg/min (2.5-20 microg/kg/min) IV constant rate infusion	0.004–0.005 mg/kg/min (4-5 microg/kg/min) IV constant rate infusion	Use 48 h maximum May increase heart rate Monitor for arrhythmias Continue usual cardiac therapy Cats are very sensitive to Rx and may have seizures Doses above 0.01 mg/kg/min (10 microg/kg/min) in dogs = more likely to be arrhythmogenic	12.5 mg/ml I HM
Dolasetron (Anzemet)	Serotonin-inhibiting central antiemetic	0.6-1 mg/kg/day IV	Same	Dose extrapolated from human medicine; little supportive evidence, negative effects poorly established at this time	100 mg T HM
Dopamine HCl (Intropin)	Alpha, beta1, and dopaminergic agent Inotropic agent for heart failure Pressor agent-hypotension	0.002 – 0.008 mg/kg/min (2-8 microg/kg/min) IV CRI in LRS, 0.9% saline, or D5W	Same	Tachycardia Vaso-constriction Requires ICU monitoring Acute renal failure application no longer considered valid	40, 80, 160 mg/ml I HM
Doxapram (Dopram)	1. Respiratory stimulant 2. Diagnostic aid for laryngeal paralysis suspects	1. 5-10 mg/kg once IV Repeat if needed 2. 2.2 mg/kg IV	Same	For puppy/kitten respiratory stimulation use 1-5 drops under tongue or via umbilical vein	20 mg/ml I HM
Doxorubicin (Adriamycin)	Lymphomas Carcinomas Solid tumors	According to chemo protocol either 30 mg/m2 IV CRI once every 3 weeks (for dogs > 10 kg) or 1 mg/kg IV once every 3 weeks (for dogs <= 10 kg) Not to exceed total dose of 250 mg/m2	According to chemo protocol 20-25 mg/m2 once every 3 weeks IV CRI to max. total dose of 90 mg/m2	Anaphylaxis BM suppression Cardiotoxic Severe vesicant (extravasation injury) Use chemo precautions when handling or administering	2 mg/ml I HM

Doxycycline HCl (Vibramycin)	Tetracycline antibiotic Rickettsia, Ehrlichia, Hemo-bartonella/Ana-plasma, and Chlamydia infections Brucellosis	5 mg/kg (loading dose) PO then 2.5-5 mg/kg in 12 h, then 2.5-5 mg/kg 2 – 5 mg/kg IV CRI BID	5 mg/kg (loading dose) PO, 2.5 mg/kg in 12 h, then 2.5 mg/kg q 24 h	Do not use in puppies, kittens, or pregnant state May cause anorexia, vomiting, depression	20, 50, 100 mg T/C 5, 10 mg/ml S HM

Table • App-5 E

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Edrophonium Cl (Tensilon)	Diagnostic agent for cholinergic stimulation. Myasthenia gravis May slow some supraventricu-lar tachycardias	0.1–0.2 mg/kg IV; max = 5 mg total dose	Total dose = 0.25-1 mg IV per cat	Muscarinic signs	10 mg/ml I HM
Enalapril maleate (Vasotec) (ENA card)	ACE inhibitor Vasodilator CHF Hypertension Glomerulo-pathy	0.5 mg/kg SID PO initially, then to BID if necessary	0.25 mg/kg SID PO	Hypotension, weakness, anorexia Avoid with renal failure Avoid increasing furosemide dosage when initiating or increasing enalapril dosage	1, 2.5, 5, 10, 20 mg T 1.25 mg/ml I VM, HM
Enilconazole (Imaverol)	Nasal aspergillosis	10 mg/kg diluted with equal amount sterile water and administered intranasally via tubes placed in frontal sinuses		Not approved Possible allergic reactions	Use poultry grade product 10% emulsion
Enrofloxacin (Baytril)	Broad spectrum fluoroquinolone class antibiotic	2.5-10 mg/kg BID PO, IM Double dosage single administration per day may be equally effective	2.5–5 mg/kg PO SID (=maximum in cats)	Do not use in puppies or kittens. Causes cartilage pathology. Avoid high doses and/or long courses of treatment (risk of irreversible retinopathy).	5.7, 22.7, 68 mg T 22.7 mg/ml I VM
Ephedrine	Bronchodilator Urinary incontinence	1-2 mg/kg PO BID-TID	2-5 mg BID-TID PO	For bronchospasm: usually used in combination with sedatives and/or bronchodilators Use with caution if sympathetic drive could be harmful (heart disease, hypertension, hyperthyroidism etc.). Narrow therapeutic-toxic range	25, 50 mg C 25 mg/ml I HM

Epinephrine (adrenaline)	Alpha and beta adrenergic agent used for inotropic and chronotropic support 1. cardiac arrest 2. bronchodilation 3. anaphylaxis	1. 0.0025 mg/kg IV, repeated to effect (= 1 ml of 1:10 000 per 40 kg body weight). Triple if administering intratracheally 2, 3. 0.025 mg/kg IV, IM, SC	Same	Arrhythmogenic Increases MVO2 (avoid high doses [tachycardia]) Vasoconstric-tion Avoid direct sunlight exposure Note 1:1000 and 1:10,000 solution both commonly available	1:1000 (1 mg/ml) I 1:10,000 (0.1 mg/ml) I Epipen: 1:1000. 0.15 mg (0.15 ml) or 0.3 mg (0.3 ml) one-time dose HM
Epirubicin (Ellence) (Pharmorubicin) (4′-epi-doxorubicin)	Anthracycline antineoplastic	As for doxorubicin according to chemo protocol. e.g. 30 mg/m2 IV CRI q 21d		As for doxorubicin but with generally fewer adverse effects (esp. lesser incidence and extent of cardiotoxicity)	10, 50, 200 mg I (2 mg/ml) HM
Epsiprantel (Cestex)	Tapeworms (cesticide)	5.5 mg/kg PO once	2.75 mg/kg PO once	GI signs possible	12.5, 25, 50, 100 mg T VM
Erythromycin	1. Macrolide antibiotic GM positive drug Campylobacter, Mycoplasma, Rickettsia, Chlamydia 2. GI prokinetic	1. 10-20 mg/kg TID PO 2. 0.5–1 mg/kg TID PO	Same	Hypersensitivi-ties; G-I upsets	250, 333, 500 mg T 100 mg/ml I HM
Erythropoietin (Epoetin, Epogen, r-Hu EPO)	Recombinant human erythropoietin	100 units/kg 3 times/week SQ until RBC levels increase; then 1 time/week thereafter	Same	Anaphylaxis Hypertension G-I signs Autoantibodies may develop	2000, 3000, 4000, 10,000, and 20,000 I HM
Esmolol (Brevibloc)	Beta-blocker with very rapid onset-offset	0.05–0.1 mg/kg/min (50–100 microg/kg/min) IV CRI titrated to effect	Same	Contraindicated with bradycardia, congestive heart failure	10 mg/ml HM
Estradiol cyclopentane-propionate (ECP)	Estradiol to terminate pregnancy			Repeatedly shown to be toxic to bone marrow Unpredictable abortifacient Not recommended	
Estrogen-conjugated (Premarin)	Estrogen derived from pregnant mare serum Used for treating estrogen insufficiency post OVH causing incontinence	0.625 mg = 1.0 mg DES Use PO for urinary incontinence (see diethylstilbes-trol)		May induce signs of estrus	0.3, 0.625, 0.9, 1.25, 2.5 mg T HM

Ethanol 20%	Ethylene glycol toxicosis	Dilute to 20% ethanol in saline and administer 5.5 ml/kg IV q 4 h × 5 Rx, then q 6 h × 4 Rx	Dilute to 20% ethanol in saline and administer 5 ml/kg IV q 6 h × 5 Rx, then q 8 h × 4 Rx	May cause or exacerbate CNS depression Monitor hydration, electrolytes, acid-base status		
Etodolac (EtoGesic) (Lodine)	NSAID selective COX-2 inhibitor for DJD in dogs	10-15 mg/kg SID PO		GI and renal toxicity If long-term, use low dose Do not administer with ASA or corticosteroids	150, 300 mg VM 200, 300 mg 400, 500 mg HM	T C T
Etretinate (Tegison)	Synthetic retinoid used to treat disorders of keratinization in specific breeds (primarily cocker spaniels)	1 mg/kg PO SID	Total dose: 10 mg per cat PO SID	Vomiting; anemia KCS ↑ Liver enzymes Expensive	10, 25 mg HM	C

Table • App-6 F

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Famotidine (Pepcid)	H2 receptor antagonist	0.5-1 mg/kg SID-BID IV 0.5 mg/kg SID PO	0.5 mg/kg SID IV 0.5 mg/kg SID PO	Advantages over other similar agents: once a day dosage, minimal p450 inhibition	10, 20, 40 mg T OTC is 10 mg/tab or 20 mg/tab (extra strength) 40 gm/5 ml S 10 mg/ml I HM
Fatty acid nutritional supplement (Derm Caps)	Dietary supplement	1 regular capsule PO SID per 9 kg body weight; 1 ES capsule PO SID per 25-30 kg body weight; 1 “100's” capsule PO SID per 45 kg body weight			Regular, extra strength (ES), 100's C VM
Felbamate (Felbatol)	Antiseizure drug used when seizures are refractory to phenobarbital and bromide	15 mg/kg TID PO Can increase to 60 mg/kg as needed		Monitor for BM suppression Hepatotoxic Expensive	400, 600 mg T 600 mg/tsp S HM
Fenbendazole (Panacur)	Hook-, whip-, roundworms; Taenia; Paragonimus; Filaroides; Giardia; Capillaria	50 mg/kg/day for 3 days; repeat in 3 weeks Whipworms, also repeat in 3 months	Same Not FDA approved	Rare vomiting Safe in dogs with heartworms	222 mg/kg granules 100 mg/ml S VM

Fentanyl (Duragesic)	Transdermal opioid patch—usually lasts at least 72 hours; requires 12 hours to be effective Injectable is ultra short acting	Patches: 5–10 kg = 25 microg/hr 10-20 kg = 50 microg/hr 20-30 kg = 75 microg/hr >30 kg = 100 microg/hr Injectable: 0.01–0.04 mg/kg SC, IM, IV CRI: 0.003-0.006 mg/kg/hr (3–6 microg/kg/hr) IV	2.5 mg patch 0.005-0.01 mg/kg IV	Apply patch to a small clipped area on thorax Respiratory depression and hypoventilation Never cut patch Prevent human contact with gel surface of patches	2.5 mg (25 microg/h), 5 mg (50 microg/h), 7.5 mg (75 microg/h), 10 mg (100 microg/h) Patch 0.05 mg/ml (50 microg/ml) I HM Former VM injectable (Innovar) was 8× more concentrated than human injectable; do not confuse
Fenthion (Prospot) (Spot-on)	Organophosphate for flea control	4-8 mg/kg topically to unbroken skin. Follow instructions. Do not apply more than once every 2 weeks	None	Do not use with other cholinesterase inhibiting agents Do not use in puppies or sick or debilitated dogs	5.6 and 13.8% soln. VM
Ferric cyanoferrate (Prussian blue) (Radiogardase)	Thallium poisoning	100-200 mg/kg PO TID		Administer as capsule or in a glucose solution orally Constipation; vomiting	500 mg C HM
Ferrous sulfate	Iron supplemen-tation	Total dose: 100-300 mg per dog SID PO	Total dose: 50-100 mg per cat SID PO	Common side-effect: minor GI upset Overdose: severe GI signs, hypotension, collapse; delayed toxicity = pulmonary edema, liver failure. See deferoxamine.	325 mg (65 mg Fe) T 18, 44 mg Fe/ml S HM OTC
Filgrastim (Neupogen, r-Hu G-CSF)	Recombinant human granulocyte colony stimulating factor. Used for chemotherapy-induced neutropenia	1-5 microg/kg/day SQ × 3-5 days max.	1-5 microg/kg/day SQ × 3-5 days max.	Antibodies develop after several days of therapy	300 microg/ml I HM

Finasteride (Proscar)	Used for treating benign prostatic hypertrophy by inhibiting enzyme that changes testosterone to active dihydroxytes-tosterone	Total dose: 5 mg per dog (body weight 10-40 kg) SID PO		Little known about use, efficacy, or side-effects in canine medicine	5 mg T HM
Fipronil (Frontline)	Topical parasiticide for fleas and some ticks	9.7% solution Apply topically by weight once monthly	Same	Keep away from children, food, water; avoid contact with pet if fipronilis still wet on skin Use on puppies only if >10 weeks old, kittens if >12 weeks old	9.7% solution 0.29% spray VM
Fluconazole (Diflucan)	Imidazole antifungal compound–especially useful for cryptococcus or CNS/ocular mycoses	2.5-5 mg/kg PO SID or divided BID	Same; up to 50 mg BID	Expensive but also available as generic now; loading dosage first day is 2x	50, 100, 200 mg T 2 mg/ml I HM
Flucytosine (Ancobon) (Ancotil)	Aspergillosis Cryptococcus	100 mg/kg BID PO or ½ dose QID	Same	Renal, bone marrow, and hepatotoxicity. May cause G-I upset. Do not administer to pregnant animals	250, 500 mg C 75 mg/ml S HM
Fludrocortisone (Florinef)	Hypoadreno-corticism Mineralocorticoid replacement therapy	0.1 mg/5 kg/SID or BID PO. Adjust dosage by need and laboratory testing	0.1 mg/5 kg/day PO Adjust dosage by need and laboratory testing	Hypertension PD/PU Weight gain	0.1 mg T HM
Flumazenil (Romazicon)	Benzodiazepine antagonist Management of hepatoencephalopathy	0.1-0.2 mg/kg IV	Same		0.1 mg/ml I
Flumethasone (Flucort)	Anti-inflammatory Corticosteroid	Total dose: 0.06-0.25 mg SID per dog PO, IV, IM, SQ	Total dose: 0.03-0.125 mg SID per cat PO, IV, IM, SQ	Cortisone related side effects	0.0625 mg T 0.5 mg/ml I VM
Flunixin meglumine (Banamine)	Nonsteroidal anti-inflammatory analgesic agent	0.25-1.0 mg/kg SID IV, IM, SQ, PO Maximum 3-5 days dosage	0.25 mg/kg SID IV, IM Maximum 3-5 days dosage	Platelet coagulopathy Ulcerative gastritis; risk often outweighs benefit of use Use with extreme caution Use 3-5 days only Not licensed for small animal use	50 mg/ml I HM
Fluocinolone 0.01% with 60% DMSO (Synotic)	Topical steroid plus DMSO for serious otic infection and inflammation	2-12 drops BID	2-4 drops BID	Systemic steroid effects Wear gloves (to avoid transcutaneous absorption by owner/vet)	0.1% otic soln VM

Fluorouracil (Adrucil)	Chemotherapy agent for carcinoma or sarcomas	150 mg/m2 IV weekly; or, 2-10 mg/kg IV weekly	Do not use	Part of a chemotherapy protocol Bone marrow toxicity, GI toxicity, and neurotoxicity possible	50 mg/ml I HM
Fluoxetine (Prozac)	Serotonin reuptake inhibitor	0.5-2 mg/kg SID PO	1.0 mg/kg SID PO	Used to treat behavioral disorders; lick granuloma Efficacy uncertain	10, 20 mg C 4 mg/ml S HM
Fluticasone (Flovent)	Inhaled glucocorticoid	1 puff as needed up to SID-BID	Same	Need inhaler apparatus; some patients reluctant to use mask. Maximum effect only after 7-14 d of use See chapter for discussion of use of mask in cats	7.9 and 13 g inhalation canisters (0.044, 0.11, or 0.22 mg [44, 110, or 220 microg] per puff) HM
Folate	B vitamin	Total dose: 2.5–5 mg PO per dog SID	Total dose: 2.5 mg PO per cat SID		5 mg/ml I 5 mg T HM
Fomepizole (Antizol-Vet, 4-methylpyrazole, 4-MP)	Treatment of known or suspected ethylene glycol toxicity	22 mg/kg IV then 15, 15, & 5 mg/kg IV at 12, 24, & 36 h following initial dose, then 3-5 mg/kg IV until recovery		Dilute drug properly Monitor renal, electrolyte, and hydration status	1.5 g kit I VM, HM
Furazolidone (Furoxone)	1. Amebiasis 2. Enteric coccidiosis 3. Giardiasis	1. 2.2 mg/kg TID PO 7 times 2. 8-20 mg/kg PO 7 times 3. 4 mg/kg BID PO 7 times	Same		100 mg T 3.3 mg/ml S HM
Furosemide (Lasix, Salix)	Potent loop diuretic agent Used in acute renal failure; hypercalcemia; hypertension, CHF, ascites, and fluid retention	0.5-6 mg/kg BID-TID PO, SQ, IM, IV	0.5-4 mg/kg BID-TID PO, SQ, IM, IV	Use lowest effective dosage High doses reserved for IV use in acute severe pulmonary edema Monitor for hypokalemia; hyponatremia; and hypochloremic-alkalosis Caution: azotemia and dehydration	12.5, 20, 40, 50, 80 mg T 10 mg/ml S 50 mg/ml I VM HM

Table • App-7 G

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Gemcitabine (Gemzar)	Various forms of neoplasia	10 mg/kg IV CRI over 30 minutes 275 mg/m2 IV CRI	25 mg/m2 diluted and given IV slowly twice weekly according to chemo protocol	Very new drug in veterinary oncology, with dosage, efficacy, and side-effects poorly characterized at this time	200 mg, 1g vials I VM, HM
Gemfibrozil (Lipid)	Lipid-lowering agent	7.5 mg/kg PO BID			300, 600 mg T HM
Gentamicin (Garamycin) (Gentacin)	Broad spectrum aminoglycoside antibiotic most effective against Gram negative bacteria	6 mg/kg IV SID or 2-4 mg/kg TID, IM, SQ, IV	Same	Higher dosage given SID is preferred (less nephrotoxic) Not effective orally Do not use in renal failure or dehydrated/hypovolemic patients Reserved for serious identified infections only Not for anaerobic infections Nephrotoxic-ototoxic	50 mg/ml I VM, HM
Gentamicin otic (Gentacin otic)	Ear infections, especially Pseudomonas or Proteus	Apply TID	Apply TID	Ototoxic	3 mg/ml otic soln. VM, HM
Gentamicin ophthalmic (Gentacin)	Conjunctival/corneal infections, especially Pseudomonas	Apply q 4-8 h	Apply q 4-8 h	Rarely irritating Also made with steroids in nearly identical packaging; use with extreme caution	3 mg/g OO 3 mg/ml OS VM, HM
Glipizide (Glucotrol)	Oral hyperglycemic agent Useful in some type II diabetes mellitus in cats	0.25-0.5 mg/kg PO BID Generally not recommended	0.25-0.5 mg/kg PO BID	Hypoglycemia G-I effects Hepatopathy Loss of efficacy	5, 10 mg T HM
Glucagon	Provocative testing agent for insulinoma, diabetes mellitus, and hyperadreno-corticism	0.03 mg/kg IV	None	May induce hypoglycemia 1 unit = 1 mg	1 mg/ml I HM
Glucosamine chondroitin sulfate (Cosequin)	Chondro-protective agent for osteoarthritis	Small and medium-size dogs: 1 – 2 RS capsules PO SID Big dogs: 1-2 DS capsules PO SID or 2–4 RS capsules PO SID	1 RS capsule PO SID		Regular strength (RS) and double strength (DS) C VM

Glycerin suppositories	Constipation	1 suppository per rectum	Same or 3 ml liquid per rectum		OTC, HM
Glycopyrrolate (Robinul)	Anticholinergic preanesthetic agent	0.01 mg/kg SQ, IM, IV	Same	Tachycardia, arrhythmias, intestinal ileus, mydriasis, and photophobia	0.2 mg/ml I VM, HM
Glycosaminoglycan-polysulfated (Adequan)	Chondroprotective agent +/- healing of noninfectious, degenerative, and traumatic arthritis	2-4 mg/kg IM twice weekly for 4 weeks; then every 2-4 weeks	2 mg/kg IM q 4 days × 6 doses; then as needed	Occasional pain at injection site Inhibits coagulation	100 mg/ml I VM
GoLYTELY	Large bowel evacuant/cathartic	22 –33 ml/kg via stomach tube	20-30 ml/kg by stomach tube	Withhold food Administer twice 2 hours apart prior to scope procedure	Pwdr or conc for dilution HM
Goodwinol	Demodecosis (localized)	Apply topically SID	Same	Rotenone, orthophenyl phenol, and benzocaine mixture; efficacy not demonstrated	1.25% Rotenone O VM
Griseofulvin (Fulvicin)	Dermatophytoses	50-150 mg/kg PO SID-BID; 25-50 mg/kg SID if using microsize product (U/F); 5-15 mg/kg BID PO if using ultramicrosize product (P/G)	Same	U/F prep better absorbed than regular-decrease dosage by 50% for this formulation; P/G even more so—decrease dosage by further 30% G-I signs Teratogen Granulocytopenia Hepatopathy	125, 250, 500 mg T 250, 500 mg microsize formulation T 125, 165, 250, 330 mg ultramicrosize formulation T 125 mg/5 ml S VM/HM

Table • App-8 H

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Hemoglobin glutamer (Oxyglobin)	Bovine hemoglobin based oxygen carrying fluid. Used to treat hemolytic, blood loss, or ineffective erythropoietic anemias	10-30 ml/kg IV @ 10 ml/kg/hr in a one time single infusion. Some administer partial dosages daily instead	Not licensed Used IV by some at 15 ml/kg IV in a slow single dose or daily split doses	Overdosage may cause cardiopulmonary signs Hemoglobinuria Has no clotting factors Interferes with clin pathol testing Half life in vivo = 18 – 43 hours	125 ml I Single use bags VM
Heparin	1.Anticoagulation 2. DIC therapy	1. 200-300 IU/kg TID-QID SQ or IV for thromboembolism; ↑ PTT to 1.5-2.5× normal or ACT to 1.2-1.4× normal. 10 IU/kg TID SQ (minidose therapy for ITP). 2. 50-100 IU/kg SQ TID-QID.	5-10 IU/kg CRI. 75-150 IU/kg TID-QID SQ	Prolongs bleeding time Not thrombolytic	1000, 2000, 5000, 10,000, 20,000 40,000 mg/ml I HM
Hetacillin (Hetacin)	Similar to penicillin	10-20 mg/kg TID PO	Same	Penicillin reactions	50, 100, 200 mg T VM
Hetastarch 6% (Hespan)	Colloid and plasma volume expansion Shock; sepsis, head trauma	10-20 ml/kg/day IV	10-15 ml/kg/day IV	Rapid IV bolus initially over 5-10 min Titrate crystalloids slowly	500 ml pkg of 6% hetastarch in 0.9% NaCl I HM
Hydralazine (Apresoline)	Arteriolar vasodilator	0.5-3 mg/kg PO BID-TID	1.25-2.5 mg/kg PO BID	Hypotension, tachycardia Malaise, depression Anorexia	10, 25, 50, 100 mg T 20 mg/ml S HM
Hydrochlorothiazide (HydroDIURIL)	Diuretic Nonhormonal therapy for CDI and NDI	2-4 mg/kg PO BID initially; then decrease by 50% or to SID	1-2 mg/kg PO BID initially; then decrease by 50% or to SID	Hypokalemia Exacerbates digitalis tox Dehydration	25, 50, 100 mg T HM

Hydrochlorothiazide/spironolactone (Aldactazide)	Diuretic plus aldosterone inhibitor (combination for humans— best to separate in VM)	Use on basis of 1 mg/kg of spironolactone SID-BID orally	Rarely used	Often used in conjunction with furosemide in chronic, recurrent CHF	25/25 mg T 50/50 mg T HM
Hydrocodone bitartrate (Hycodan)	Narcotic antitussive	0.22 mg/kg SID-QID PO	Rarely used	Sedation C-III substance	5 mg T 1 mg/ml S VM, HM
Hydrocortisone acetate 1% cream	Topical corticosteroid for focal dermatitis	Apply topically BID-QID	Same	Prolonged usage may result in iatrogenic Cushing's syndrome	1% O HM
Hydrogen peroxide	Emetic	0.25 – 0.5 ml/kg PO (3% solution). Repeat once in 5 - 15 minutes PO if emesis does not occur	Same	Do not use if a caustic agent was ingested; if level of consciousness is decreased; or if unable to swallow	3% topical HM
Hydromorphone (Dilaudid)	Analgesia; preanesthetic	0.1 – 0.2 mg/kg SQ, IM, or IV once or PRN up to q 2-4h. Reduce slightly in older dogs	Same	Vomiting common immediately post injection; bradycardia; dysphoria in some cats	1, 2, 4, 10 mg/ml I HM
Hydroxyurea (Hydrea)	Chemotherapeutic compound Disorders of RBC excess, especially polycythemia vera and right-to-left cardiac shunts	20-25 mg/kg SID-BID PO; when PCV ↓, then 25 – 50 mg/kg EOD PO	10-15 mg/kg SID PO then EOD based on PCV	Anorexia, vomiting. Monitor CBC regularly	500 mg C HM
Hydroxyzine (Atarax)	H1 receptor antihistamine for allergic skin disorders	1-2 mg/kg BID-TID PO	0.5-1 mg/kg BID-TID PO	Sedative	10, 20, 50, 100 mg T 10 mg/5 ml S 20, 50 mg/ml I HM

Hyoscyamine (Levsin)	Inhibits acetylcholine Inhibits propulsive G-I motility	0.003-0.006 mg/kg TID PO	Same—infrequently used	Useful in IBS and functional intestinal disorders Dry mouth; urinary retention; tachycardia	0.125 mg T 0.125 mg/5 ml S 0.375 mg ER 0.5 mg/ml I HM

Table • App-9 I

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Idoxuridine (Herplex) (Stoxil)	Used for treating feline herpes keratoconjunctivitis		1 drop q 4 h initially; then q 6-8 h	Occasional ophthalmic irritation	0.1% OS HM
Ifosfamide (Ifex)	Various neoplasms	350-375 mg/m2 IV once q 3 weeks for 3 treatments max		Efficacy under investigation; dosing interval according to chemo protocol; pretreat with mesna and IV diuresis to reduce risk of hemorrhagic cystitis Neutropenia	50 mg/ml I
Imidacloprid (Advantage)	Topical treatment for adult and larval stage of fleas	Apply topically to intact skin Dose monthly by body weight from prepackaged cards	Same	Avoid contact with skin, food, or water	9.1% VM
Imidocarb (Imizole)	Babesia gibsoni and canis Ehrlichia canis Hepatozoonosis	5-7.5 mg/kg IM or SQ once Repeat in 2-3 weeks		Painful injection—give IM Cholinergic effects	120 mg/ml I VM
Imipenem (Primaxin)	Broad spectrum bactericidal-static carbapenem antibacterial	2-10 mg/kg slow IV (over 30 minutes) TID – QID × 3–5 days	Same	Adverse effects possible: GI, CNS, hypersensitivity; reduce dose if renal compromise	250, 500 mg vials I HM
Imipramine (Tofranil)	Tricyclic antidepressant Behavioral changes, narcolepsy, cataplexy	0.5-2 mg/kg BID-TID PO	0.5 mg/kg SID-BID PO or total dose 2.5-5 mg per cat BID PO	Drowsiness; behavioral changes	10, 25, 50 mg T 125 mg/ml I HM
Immunoglobulin (Gammagard S/D)	Treatment of primary immunodeficient states; also IMHA, ITP, and CLL	0.5-1.5 g/kg slow IV infusion		Must be given IV Very expensive Hypersensitivity Not rec'd as 1° therapy	2.5, 5, 10 g single dose vials I HM

Insulin (Humulin R, N, U) (PZI)	1. Diabetes mellitus 2. Diabetic ketoacidosis 3. Severe hyperkalemia 4. Alternatively and preferably, regular insulin in the ketotic state should be given hourly or by CRI	REGULAR: 0.25-0.5 U/kg initially IM or SQ; then q 4-6 h NPH: 0.5-1.0 U/kg SID–BID SQ All insulins may be diluted with diluents provided by drug company for more precise administration of small doses Hourly 0.2 u/kg followed by 0.1 u/kg. Can be decreased by 25-50% if low K+ a concern. Constant low dose infusion: 2.2 u/kg added to 250 ml 0.9% NaCl given at 10 ml/hr to equal 0.1 u/kg/hr	NPH: total dose (starting): 1-2 U per cat SQ SID-BID. LENTE, ULTRALENTE, PZI: total dose 1-3 U per cat SQ SID–BID Same in the cat as in the dog for hourly IM administration 1.1 u/kg added to 0.9% NaCl given at 10 mg/hr to equal 0.05 u/kg/hr	Dosage very variable—adjust and monitor accordingly These are average approximate dosages Maintain hydration Avoid hypoglycemia and hypokalemia See Chapter for information about chronic use; BID Rx: additional information	100 U/ml I HM, VM I
Interferon (Roferon)	Immune modulator with antiviral and antiproliferative effects Used for FELV-FAIDS; Leukemia; Lymphoma; FIP	1 IU/5 kg body weight PO every 2 weeks to stimulate appetite	Total dose: 30 IU per cat PO 7 days on; then 7 days off	Studies uncontrolled Used mostly in FeLV+ cats	3, 18, 36 million IU per vial I HM
Ipecac syrup	Induce vomiting	0.25 – 0.5 ml/kg PO; can repeat once after 5-15 minutes if no vomiting	Same	Do not use with activated charcoal (ineffective)	70 mg/ml S OTC, HM Many oral OTC 50 mg/ml I HM
Ipodate (Oragrafin)	Oral radiographic contrast agent with antithyroid effects; used for hyperthyroidism		Total dose: 15-100 mg per cat PO BID, titrated based on clinical response and T3	Blocks T4 conversion to T3; therefore, blood monitoring = serum T3 levels	500 mg C HM
Iron-dextran injection (Imferon)	Iron deficiency anemia	10 mg/kg in divided doses IM or total dose 100-300 mg/day per dog PO	Same-IM or total dose 50-100 mg/day per cat PO	Irritating IM	Many oral OTC 50 mg/ml I HM
Isoproterenol (Isuprel)	B-adrenergic agonist	0.2 mg in 250 ml 5% dextrose, IV CRI at a rate of 0.05-0.1 microg/kg/min; titrate to effect adequate HR	0.5 mg in 250 ml 5% dextrose, IV to effect adequate HR	↑HR ↑ or ↓ BP CNS stimulation Arrhythmogenic	0.2 mg/ml (=200 microg/ml) I HM

Isosorbide dinitrate	Oral vasodilator			No recognized therapeutic efficacy in small animals	
Isotretinoin (Accutane)	Sebaceous adenitis Keratinization disorders Mycosis fungoides	1-2 mg/kg BID PO Reduce dosage after 1 month if improving	Total dose: 5-10 mg SID per cat PO	GI and CNS effects may occur; if so, reduce dosage by 50% or stop Teratogen	10, 20, 40 mg C HM
Itraconazole (Sporanox)	Antimycotic imidazole compound for blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, M. canis dermatophytosis	5-10 mg/kg SID-BID PO	5-10 mg/kg SID PO 1.5-3.0 mg/kg SID PO	Must be taken with food; open capsules and place pellets in food if necessary. Antacid GI drugs will reduce efficacy	100 mg C 10 mg/ml S HM
Ivermectin (Heartgard-30) (Ivomec)	GABA agonist antiparasiticide Heartworm prophylaxis; microfilariacide	Heartworm prophylaxis: 0.006 mg/kg (6 microg/kg) PO once monthly Microfilaricide: 0.05 mg/kg (50 microg/kg) once PO 2-4 weeks post adulticide Rx	Heartworm prophylaxis: 0.024 mg/kg (24 microg/kg) SQ; repeat in 3-4 wks (usually under 0.1 cc)	Do not use in collies or other dogs hypersensitive to drug CNS; vomiting; anaphylaxis Can give injectable solution PO Of ? value in treating feline heartworm disease; see Chapter 207 for suggestions	68, 136, 272 microg T 10 mg/ml (=10,000 microg/ml) I VM
	Endoparasites Sarcoptic mange	0.2 mg/kg (200 microg/kg) PO 0.3 mg/kg (300 microg/kg) PO or 0.2 mg/kg (200 microg/kg) SQ 2x-14 days apart	Same Same		
	Demodectic mange	0.05 mg/kg (50 microg/kg) PO; increase to 0.3 mg/kg (300 microg/kg) by day 5; increase to 0.6 mg/kg (600 microg/kg) once daily PO after 30 days if necessary	Same		
	Otodectic mange	0.3 mg/kg (300 microg/kg) PO, SQ 2x–14 days apart	Same		

	Cheyletiellosis	0.3 mg/kg (300 microg/kg) SQ 2x–21 days apart	Same		

Table • App-10 K

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Kaolin/pectin	G-I tract protectant	1-2 ml/kg every 2 to 6 hrs PO	Same	May limit absorption of other Rx May constipate	Many OTC preparations T/S VM, HM
Ketamine HCl (Ketamine) (Ketaset) (Vetalar)	Dissociative analgesic anesthetic agent Short-action when given IV in healthy dogs/cats— 10-20 min	When diazepam (at dose of 0.5 mg/kg) given IV first: immediately follow with ketamine 5-7 mg/kg IV bolus for sedation and minor procedures (diazepam [5 mg/ml]: ketamine mixture in ratio of 1:1 or 2:1 → use 1 ml/10 kg IV)	Restraint: 11 mg/kg IM Anesthesia (but does not provide deep analgesia): 22-33 mg/kg IM or 2.2-4.4 mg/kg IV	Eyes remain open → use ophthalmic ointment Salivation, seizures, respiratory depression, laryngospasm, hypothermia Do not use in renal failure or glaucoma; reduce dose by 50-75% if stable but systemically ill; avoid if hypertrophic cardiomyopathy	100 mg/ml I VM, HM
Ketoconazole (Nizoral)	Antifungal agent Prototheocosis Inhibits adrenosteroid hormone synthesis	10–15 mg/kg BID PO Long term 10 mg/kg SID PO Cushing's Rx: 15 mg/kg BID PO	5 - 10 mg/kg BID PO or SID Long term: 10 mg/kg EOD PO	Anorexia, nausea, vomiting, constipation Hepatotoxicity Begin lower and titrate upwards to avoid side effects; must be given with food	200 mg T HM
Ketoprofen (Orudis KT; Ketofen)	Nonsteroidal anti-inflammatory	1-2 mg/kg PO BID 1 – 2 mg/kg SQ, IM, or IV once or SID up to 3 days max.	1 mg/kg SQ, IM, IV once	GI ulceration Renal effects possible	25, 50, 75 mg C 12.5 mg T HM OTC 10, 100 mg/ml I VM
Kitten Milk Replacer® (KMR)	Milk replacement	–	30 ml/1/4 lb BW PO daily divided into 3-6 meals	–	OTC VM

Table • App-11 L

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Lactulose (Cephulac, Chronulac)	Stool softener	0.25-0.5 ml/kg BID-TID PO	Total dose: 1-5 ml per cat TID PO	Loosens stools; diarrhea; flatulence; cramping	666 mg/ml S HM
	Hepatic encephalopathy is treated by acidifying colon contents, trapping NH4 that is then expelled	20 ml/kg as a retention enema; 3 parts lactulose plus 7 parts water		May use per rectum in hepatic coma patients	
Laxative paste (Laxatone, Cat-a-Lax, etc.)	Oral laxative Hairball RX	½-2 inches PO daily until nonconstipated; then weekly or as required	Same	Large amounts daily could result in malabsorption, therefore avoid giving oral Rx simultaneously	OTC S VM
Leflunomide (Arava)	Autoimmune disorders (IMHA, ITP, sterile meningitis, systemic histiocytosis)	1.5- 4 mg/kg PO SID		New agent; beneficial and adverse effects sparsely documented to date; GI and bone marrow effects possible Seek trough serum level of 20 microg/ml	10, 20, 100 mg T HM
Levamisole (Levasole) (Ripercol) (Tramisol)	Heartworm microfilaricide Immune stimulant Feline lungworms	10 mg/kg PO SID 7-14 days as a microfilaricide 2.5-5 mg/kg PO EOD for immune modulation	2.5-5 mg/kg PO EOD for immune modulation 10-20 mg/kg PO EOD for Aleurostrongylus and Capillaria	Salivation, vomiting Neurotoxic Sudden death Not FDA approved for small animal medicine	184 mg T 136 mg/ml S 11.5% gel VM
Levetiracetam (Keppra)	Third-line anticonvulsant for refractory seizures	20 mg/kg PO TID in addition to KBr and phenobarbital		Clinical vet use very new; few adverse effects reported Can up titrate if starting dose ineffective Expensive	500 mg T HM

Levothyroxine sodium (Soloxine) (Synthroid)	Synthetic thyroid hormone replacement therapy	0.04 mg/kg BID PO	Total dose: 0.05-0.1 mg per cat SID PO	Thyrotoxicosis Do not give only on basis of low T4 (clinical signs and other lab results). Adjust dose based on response and blood levels	0.025, 0.05, 0.075, 0.125 0.15 mg T HM 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8 mg T VM
Lidocaine (Xylocaine)	Ventricular arrhythmias Local anesthesia	2-4 mg/kg IV over 1-2 minutes, then 0.5-2 mg/kg every 20-60 minutes, or 0.04–0.08 mg/kg/minute (40-80 microg/kg/minute) constant rate IV infusion Inject up to 4 mg/kg SQ for local anesthesia	0.25-1.0 mg/kg slowly over 5 min; give 1 mg bolus to 4 mg, max over 5 min; use diluted solution as CRI 0.01–0.04 mg/kg/minute (10-40 microg/kg/minute)	Give initial bolus **slowly** Seizures, hypotension Maintain current IV indwelling catheter **Use only in life-threatening arrhythmias**	10, 20 mg/ml I HM
Lime sulfur solution (Lym Dyp) (Sulfodip)	Bacterial and fungal dermatosis Sarcoptic mange	Dip once-twice weekly, let air dry; use 4-6 weeks (ideally until 2-3 fungal cultures are negative)	Same	Offensive odor Stains furniture Wear gloves to avoid hypersensitivity	2% dip VM
Lincomycin (Lincocin)	Staphylococcal and anaerobic infections Some Mycoplasma infections	15-25 mg/kg BID-TID PO, IV, IM	Same	Vomiting Hepatotoxicity Do not use in combination with chloramphenicol or erythromycin	250, 500 mg T HM 100, 200, 500 mg T 50 mg/ml S 100 mg/ml I VM
Liothyronine, T3 (Cytobin) (Cytomel)	T3 suppression testing	0.004–0.006 mg/kg (4-6 microg/kg) TID PO	0.0044 mg/kg (4.4 microg/kg) BID-TID PO 0.025 mg (25 microg) PO per cat TID for 8 dosages as testing agent for T3 suppression	Thyrotoxicosis	5, 25, 50 microg T HM
Lisinopril (Zestril) (Prinivil)	Angiotensin converting enzyme inhibitor	0.75 mg/kg SID PO	0.25 mg/kg SID PO	Monitor BUN/CR Lethargy Anorexia	2.5, 5, 10, 20, 40 mg T HM
Lithium carbonate (Eskalith, Lithotabs)	Increased production of all cell lines by bone marrow	21-26 mg/kg/day PO	Unknown	Nausea, diarrhea, vertigo	300 mg C 450 mg ER HM

Lomustine (CCNU-Cee Nu)	Nitrosourea alkylating agent for relapse or failure to respond to LSA therapy	60-90 mg/m2 PO once every 3 weeks		Neutropenia may develop after 7 days; GI adverse effects Its active metabolites reach the CNS	10, 40, 100 mg C HM
Loperamide (Imodium)	Antidiarrheal, acute colitis	0.1-0.2 mg/kg TID PO	0.1-0.15 mg/kg BID PO	Discontinue if not effective within 48 h	OTC 2 mg C 1 mg/5 ml S HM
Lufenuron (Program)	Insect development inhibitor Inhibits chitin synthesis 1.Prevents flea eggs from developing into adults 2. Coccidioidomyosis 3. dermatophytosis	1. 10 mg/kg PO once q 30 days 2. 5-10 mg/kg PO SID 3. 54–68 mg/kg PO once	1. 30 mg/kg PO 1 ×/month or 10 mg/kg once every 6 mo by SQ injection 3. 51–266 mg/kg PO once	Expensive as long term daily Rx for fungal disease; efficacy in dermatophytosis questionable May be combined with milbemycin for control of fleas, heartworms, roundworms, and whipworms	Sold in packets for varying wt. By tablet, S Solution, or 10 mg/ml T inject. I

Table • App-12 M

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Magnesium hydroxide (Milk of Magnesia)	Antacid	Total dose: 5-10 ml per dog PO q 4–6 hrs		Cathartic agent at 3-5 times the antacid dosage Rarely used because high dosing frequency and rebound acid secretion	77.5 mg/g S OTC HM
Mannitol 20%	Osmotic diuretic used to treat acute glaucoma, cerebral edema, and oliguria/anuria	0.5-1 g/kg IV slowly over 15-20 minutes for anuria. Double dosage for acute glaucoma or cerebral edema	Same	Rehydrate patient prior to use Can repeat twice if renal output is not increased Resolubilize (by warming) if crystallized, ensuring to cool to body temp before administering	100 mg/ml (10%), 200 mg/ml (20%) I HM
Marbofloxicin (Zeniquin)	Fluoroquinilone class antibiotic	2– 4 mg/kg SID PO	Not Licensed	Anorexia and vomiting Not rec'd for rapidly growing dogs due to possible arthropathy	25, 50, 100, 200 mg T VM
Mebendazole (Telmintic)	Hook-, whip-, and roundworms	22 mg/kg with food once daily for 3 days		Repeat as indicated V/D may develop Hepatopathies have been incriminated in a small number of cases	VM
Meclizine (Bonine, Dramamine II, Antivert)	Antiemetic	1.25 mg/kg PO SID		Lethargy, CNS depression possible	12.5, 25, 50 mg T OTC HM
Medetomidine (Domitor)	Synthetic alpha-2 adrenoreceptor agonist. Provides sedation-analgesia as chemical restraint for healthy exercise tolerant dogs. Useful for sedation of cats with hypertrophic cardio-myopathy	0.005–0.02 mg/kg (5–20 microg/kg) IM as a single agent. Used by some in association with butorphanol, ketamine, morphine, or oxymorphone	0.02 mg (20 microg/kg) IM	Do not use if hypertensive Allow dog or cat to rest quietly after admin Do not use in older, sick, or debilitated dogs Reversed with equal volume of atipamezole Reflex brady-cardia is result of drug-induced hypertension; do not treat with atropine or other anti-bradycardiac drugs	1 mg/ml I VM
Medium chain triglycerides (MCT oil)	Used in protein losing diseases–lymphangiectasia; and when long-term triglyceride intake should be reduced-chylothorax	1-2 ml/kg daily in food	Same	May be distasteful Efficacy not demonstrated	OTC HM

Medroxy progesterone acetate (Depo-Provera, Provera)	Long acting progesterone compound used for decreasing male dog libido and aggression, rarely as a contraceptive; in cats for psychogenic and military dermatitis and inappropriate elimination	10-20 mg/kg IM, SQ every 4 months	Total dose: 50-100 mg per cat IM, SQ every 4 months	Overdosage may cause cystic endometritis, diabetes mellitus, hypoadreno-corticism, mammary hyperplasia/adenocarcinoma Local alopecia may occur Carefully weigh risks versus benefits	T2.5, 5, 10 mg T 150, 400 mg/ml I HM
Megestrol acetate (Ovaban, Megace)	Oral progestogen used for delaying estrus; treat K-9 pseudopregnancy; canine and feline behavioral modification eosinophilic granuloma and some chronic feline skin disorders	Anestrus Rx: 0.5 mg/kg PO × 32 days Proestrus Rx: 2.0 mg/kg PO × 8 days Behavior modification: 2-4 mg/kg SID PO for 14 days; then decrease and stop after 6 weeks	Total dose: 5-10 mg SID per cat PO × 7 days; then twice weekly. Same dose as for dog for behavioral modification	See specific diseases. Do not use in pregnant pets or pets with uterine problems Avoid use with mammary tumors or hyperplasia May cause polydipsia, polyuria, polyphagia, diabetes mellitus	5, 20 mg T VM 20, 40 mg T HM
Melarsomine (Immiticide)	Arsenical for treatment of adult heartworms	2.5 mg/kg SID IM for 2 doses 24 hours apart or 1 dose; then, 30 days later 2 dosages IM 24 hr apart	None	Painful—give in epaxial muscles Cellulitis or salivation may occur PTE occurs when worms die	50 mg/vial I VM
Meloxicam (Metacam) (Mobic)	COX-2-inhibiting nonsteroidal anti-inflammatory drug (NSAID). For treatment of osteoarthritis; perioperative pain management	0.1 mg/kg PO, SC SID (may be preceded by single 0.2 mg/kg loading dose PO, SC, IV)	Chronic use: 0.025 mg/kg PO SID (can be preceded by peri-operative dose below as loading dose). Peri-operative pain control: 0.3 mg/kg PO, SC, IV once only	Gastrointestinal signs (vomiting, anorexia)	1.5 mg/ml (=0.05 mg/drop) S 5 mg/ml I VM 7.5, 15 mg T HM
Melphalan (Alkeran)	Multiple myeloma Lymphoreticular neoplasms Alkylating agent	0.1 mg/kg SID PO for 10 days; then 0.05 mg/kg SID PO; or 1.5 mg/m2 PO SID for 7-10 days or 7 mg/m2 SID × 5 days q 3 weeks	Same	Anorexia, nausea, vomiting Leukopenia, thrombo-cytopenia, and anemia	2mg T HM
Meperidine HCl (Demerol)	Narcotic analgesic with short term (1-4 hrs.) effect	5-10 mg/kg IM or slow IV PRN	2-4 mg/kg IM PRN	Watch for signs of narcotic overdosage, i.e. sedation, depression, seizures, hypotension Reverse with naloxone	50, 100 mg/ml I 50, 100 mg T 10 mg/ml S HM

Meropenem (Merrem IV)	Carbapenem antibiotic	8 mg/kg SQ BID		Clinical vet use very new; efficacy and side-effects sparsely reported at present	500, 1000 g vials I HM
Mesalamine (5-ASA) (Asacol) (Pentasa)	Inhibits prostaglandin production in the colon Irritable bowel syndrome; ulcerative colitis	10-20 mg/kg TID PO		Clinical vet use limited; efficacy unproven at present Monitor for KCS May be infused rectally (enema formulations)	400 mg T 250 mg C 4 g/60 ml enema HM
Mesna (Mesnex)	Urothelial protection preceding ifosfamide chemotherapy	Dose is 20% of ifosfamide dose		Administered as pretreatment before ifosfamide: reconstitute as 20 mg/ml and give calculated dose as IV bolus, followed by 9 ml/kg 0.9% NaCl IV over 30 minutes, then ifosfamide	100 mg/ml I HM
Methimazole (Tapazole)	Feline hyperthyroidism Palliative Rx for canine functional thyroid neoplasia	Total dose 2.5-5 mg BID per dog PO	Total dose 2.5-5 mg PO per cat BID-TID	Anorexia, vomiting, and blood dyscrasias; intense facial pruritus Monitor CBC and T4 Start at ½ dosage—then increase after 7-10 days based on clinical response and T4 level	5, 10 mg T HM
DL-Methionine (Methigel) (Albeta)	Urinary acidifier	0.2-1 g/kg TID PO	0.5-1 g SID PO	Contraindicated if renal failure, acidosis, pancreatic disease, hepatic insufficiency/encephalopathy. G-I irritability	15 mg/ml S 200, 300, 500 mg T,C OTC, VM, HM
Methocarbamol (Robaxin)	Muscle relaxant	20-45 mg/kg PO BID-TID	Same	Ataxia; sedation; ptyalism; emesis	100 mg/ml I 500 mg T HM
Methotrexate	Antimetabolite, antineoplastic agent that inhibits folic acid reductase Used to treat some cancers or for immuno-suppression Sclerosing cholangio-hepatitis	0.06 mg/kg SID-EOD PO 2.5 mg/m2 SID-EOD PO	2.5 mg/m2 PO q 2–3 days	Leukopenia, G-I bleeding hepatotoxicity. See specific cancer or disease state	2.5 mg T 2.5 mg/ml I HM
Methylene blue (new methylene blue)	1. For treatment of methemoglobinemia in dogs 2. As intraop insulinoma Dx test	1. 1-2 mg/kg slow IV once 2. dilute 3 mg/kg in sterile saline and administer as CRI		Use once only Can induce Heinz body hemolytic anemia Islet cell tumors=purple (vs. pale blue background), best contrast 30 min. after onset of CRI	10 mg/ml I HM

Methylprednisolone acetate (Depo-Medrol)	Repositol corticosteroid. For intralesional skin injections; feline asthma; eosinophilic granuloma complex	1-2 mg/kg IM, SQ	Same Total dose: 10-20 mg per cat	Glucocorticoid contraindica-tions and side effects	20, 40, 80 mg/ml I VM, HM
Methyl prednisolone sodium succinate (Solu-Medrol)	Soluble corticosteroid. Acute shock. Spinal Cord injury within 8 hours of trauma	30 mg/kg slow IV once, then 15 mg/kg IV in 2–6 hours	Same	GI ulcers very common; assess need for this Tx based on acuity (time frame) and severity	40, 125, 500, 1000, 2000 mg/vial I HM
Methyltestosterone	Anabolic drug Androgenic steroid Used in testosterone responsive incontinence	0.5 mg/kg PO	Same	May increase creatinine and glucose levels	10 mg C HM
Metoclopramide (Reglan)	Antiemetic with both central (chemoreceptor trigger zone) and peripheral (gastrointestinal) effects Increases LES pressure; promotes gastric emptying	0.2-0.5 mg/kg BID-QID PO, SQ or 1-2 mg/kg/day given as IV infusion over 24 hours	Same	Do not use with G-I obstruction, with phenothiazines, or with narcotic analgesics. Atropine blocks effect. May increase seizure activity Extrapyramidal effects	5, 10 mg T 1 mg/ml S 5 mg/ml I HM
Metoprolol (Lopressor) (Toprol XL)	B1 selective blockade May provide support for CHF animals on traditional therapy	0.4-1 mg/kg BID-TID PO. SID for extended release	Total dose: 2-10 mg per cat SID-BID PO	Lethargy, depression Decreased HR Beta-blockade-induced CHF Always begin low and titrate up	50, 100 mg T 50, 100, 200 mg ER 1 mg/ml I HM
Metronidazole (Flagyl)	Anaerobic infections of the mouth, pulmonary, G-I tract, and liver Also, Giardia, Entamoeba, Balantidia, Pentatrichomonas, and Trypanosoma Irritable bowel disease (IBD) Small bowel bacterial overgrowth syndrome	10-20 mg/kg BID PO	10-20 mg/kg BID PO	Anorexia and vomiting. Neurotoxicity and hepatotoxicity may develop at high and/or prolonged dosages Hepatic metabolism; use 7.5 mg/kg PO BID if liver disease	250, 500 mg T 500 mg/100 ml I HM
Mexiletine (Mexitil)	Type 1B antiarrhythmic drug used to treat ventricular arrhythmias	4-10 mg/kg BID-TID PO		Anorexia, depression CNS signs Side effects rare	150, 200, 250 mg C HM

Mibolerone (Cheque)	Prevents estrus (dogs only) Pseudocyesis Synthetic androgenic, anabolic steroid	Total dose per dog for estrus suppression: 1-11 kg: 30 microg/day PO per dog 12-22 kg: 60 microg/day PO per dog 23-45 kg: 120 microg/day PO per dog >45 kg, or German Shepherd dog (mix) 180 microg/day PO pe dog Pseudocyesis: 10 times above dosage for 5 days PO		Do not use in pregnant dogs or in those with renal or hepatic disease	100 microg/ml S VM
Miconazole (Conofite)	Topical antifungal	Apply BID to lesion Continue after resolution of lesions for 2 weeks	Same	Contact hypersensitivity Caution re zoonosis if dermatophytosis (gloves)	OTC, topical cream, and solution HM
Midazolam (Versed)	Benzodiazepine tranquilizer	0.1-0.3 mg/kg IV, IM, SQ (lower end of range if IV)	0.05-0.3 mg/kg IV, IM, SQ (mid- to lower end of range if IV and/or if combined with ketamine)	Caution in liver disease Avoid with glaucoma	1 mg/ml and 5 mg/ml I VM HM
Milbemycin (Interceptor)	Anthelmintic action in heartworm prevention and hookworm control Demodectic mange Pneumonyssoides caninum	0.5-1.0 mg/kg orally once monthly 0.5-2.3 mg/kg SID-BID PO 2-4 weeks for Demodex, longer if skin scrapings fail to clear mites. May use low dose × 30 days; 2 × after if necessary 0.5-1.0 mg/kg/week for 3 weeks		Test for heartworms prior to initial administration	2.3, 5.75, 11.5, and 23 mg T VM
Misoprostol (Cytotec)	Prostaglandin E1 analog Used for gastric ulcers	2-8 microg/kg BID-TID PO		Secretory diarrhea, vomiting, anorexia May induce abortion in pregnant animals Side effects are dose dependent	100, 200 microg T HM
Mitoxantrone (Novantrone)	Chemothera-peutic agent closely related to doxorubicin	5 mg/m2 once every 3 weeks IV	6.25 mg/m2 once every 3 weeks IV	Depression, G-I signs, leukopenia, hepatotoxicity, extravasation injury	2 mg/ml I HM

Morphine sulfate	Narcotic analgesic Acute CHF as adjunctive therapeutic agent to relieve anxiety and to vasodilate	0. 25-1.0 mg/kg every 2 to 6 h IM, SQ, IV, epidural. Or sustained release PO: 1.5-3.0 mg/kg BID (ER) PO	0.25-0.75 mg/kg every 2 to 6 hours IM, SQ	Hyperexcitability in cats Vomiting, respiratory and CNS depression Hypotension, especially if given IV	30 mg ER 5, 10, 20 mg suppository 10, 20 mg/5 ml S 15, 30 mg T 2, 4, 5, 8, 10, 15 mg/ml I HM
Moxidectin	Heartworm prophylaxis	3 microg/kg PO once monthly- removed from market 2004		Safe in collies Not FDA approved—removed from market due to adverse reactions-2004	30, 68, 136 microg T Large animal product available as 1.3 g tube VM

Table • App-13 N

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Naloxone (Narcan)	Narcotic antagonist	0.04 mg/kg IV, IM, SC	Same	The effect of the narcotic may last longer than the naloxone, requiring redosing This is particularly true in end stage liver disease, portosystemic shunts, or with drugs that are P-450 blockers	0.02, 0.4, 1 mg/ml I HM
Nandrolone decanoate (Deca-Durabolin)	Anabolic steroid and bone marrow stimulant	1 mg/kg/week IM	0.5-1.0 mg/kg week IM	Give deep IM Do not administer to pregnant or hepatoinsufficient animals	100 and 200 mg/ml I HM
Naproxen (Naprosyn) (Aleve)	Nonsteroidal anti-inflammatory	1.2-2.8 mg/kg once daily or every other day PO Avoid use if possible	Do not use	Severe GI ulceration very common; renal, CNS. Not a preferred drug 32-92 T ½ in dogs	200, 250, 375, 500 mg T 125 mg/5 ml S HM
Neomycin (Biosol)	Aminolgly-coside used orally for G-I tract bacterial overgrowth and hepatoencephalopathy	10-20 mg/kg BID-TID PO	Same	Ototoxicity and nephrotoxicity are rare with oral dosage In severe intestinal disease, toxicity may be more likely.	200 mg/ml S 100, 500 mg T VM, HM
Neostigmine (Stiglin, Prostigmin)	Anticholinesterase agent for myasthenia gravis	0.01-0.05 mg/kg IM, SQ, PRN	Same	Muscarinic effects: vomiting, diarrhea, bradycardia are reversed by atropine	0.25, 0.5, 1 and 2 mg/ml I 15 mg T HM
Niacinamide (nicotinamide)	Usually used in combination with a tetracycline for immune-mediated dermatopathies	<5 kg: 100 mg TID PO 5-10 kg: 250 mg TID PO >10 kg: 500 mg TID PO		GI adverse effects possible Flushing of mucous membranes	50, 100, 125, 250, 500 mg T HM
Niclosamide (Yomesan)	Tapeworm anthelmintic	154 mg/kg PO; fast 24 hours before; repeat in 2-3 weeks	Same	Occasionally soft stools	VM

Nitenpyram (Capstar)	Flea infestation Inhibits insect specific nicotinic receptors	Dogs up to 11 kg: total dose 11.4 kg PO per dog, max. SID Dogs > 11 kg: total dose 57 mg PO per dog, max. SID	Total dose: 11.4 mg PO per cat, max. SID	Onset of action rapid (minutes-hours) but duration of activity limited (day[s]) Irritability-complaints of hyperactivity if fleas are jumping off and dying	11.4, 57 mg T VM
Nitrofurantoin (Dantefur) (Macrodantin)	Urinary tract infections Ointment for superficial wounds	4 mg/kg q 8 h PO	Same	Oral form used only for urinary tract infections	50, 100 mg T 5 mg/ml S 25, 50, 100 mg macrocrystals C HM
Nitroglycerin 2% ointment (Nitrol ointment)	Transdermal venodilator for reducing cardiac preload in acute CHF	Apply ¼-2 inches TID-QID topically to skin	Apply 1/8–¼ inch TID topically to skin	May cause hypotension Apply with glove to hairless region, i.e. pinna or inguinal Clinical efficacy questionable	2% O HM
Nitroprusside (Nipride)	Arterial dilator Venodilator	1-7 microg/kg/min IV CRI	1-2 microg/kg/min IV CRI	Hypotension Cyanide toxicity Use 2-3 days IV maximum	50 mg/vial I HM
Nizatidine (Axid)	H2 receptor antagonist	5 mg/kg SID PO		Has GI prokinetic effects	75, 150, 300 mg T HM
Norepinephrine (Levophed)	B1 and alpha agonist used to treat shock	1-2 ml in 250 ml of 0.9% NaCl, IV CRI to effect	None	Hypertension Tachycardia	1 mg/ml I HM

Table • App-14 O

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Octreotide (Sandostatin)	Somatostatin analogue with primary inhibitory effect on intestinal secretions Insulinoma; glucagonoma	Total dose: 10–40 microg (0.01–0.04 mg) per dog SQ TID		Nausea, vomiting, abdominal discomfort	50, 100, 500 microg/ml IHM
Olsalazine (Dipentum)	Salicylate Anti-inflammatory activity in ulcerative colitis (5-ASA)	5-20 mg/kg TID PO	Unknown	See Sulfasalazine	250 mg C HM
Omeprazole (Prilosec) (Losec)	Proton pump acid blocker; used in reflux esophagitis and hyperacidity syndromes	0.7 mg/kg SID PO	Total dose: 5 mg per cat PO SID	Few side effects noted May interact with cyclosporine	10, 20 mg C HM
Ondansetron (Zofran)	5-HT3 receptor antagonist (serotonin inhibitor) Used in conjunction with emetogenic cancer chemotherapy Used in protracted vomiting unresponsive to other treatments	0.05 –0.2mg/kg IV bolus BID	Same	Used before and for 48 h following specific IV cancer Rx	4, 8 mg T 2 mg/ml I 1.25 mg/ml S HM
Oral rehydration solution (ORS; Pedialyte)	Oral electrolyte and glucose replacement	Up to maintenance (60 ml/kg/day) + replacement (based on physical exam) PO divided into several doses as low-cost rehydration/volume expansion	Same		Many HM OTC
O,p′-DDD (Lysodren) (Mitotane)	Hyperadrenocorticism Selective necrosis of the zona fasciculata and reticularis of the adrenal gland	50 mg/kg divided twice daily with food to effect (approx. 5-10 days); then 25-50 mg/kg once every 7-14 days to effect; with food	None	Vomiting, diarrhea, weakness Mineralocorti-coid deficiency Best if given in divided doses Best if given with meal	500 mg T VM
Orbifloxacin (Orbax)	Fluoroquinolone antibiotic	2.5-7.5 mg/kg SID PO	Same	May cause arthropathy in immature dogs	5.7, 22.7, 68 mg T VM
Orgotein (Palosein)	Superoxide dismutase activity causes anti-inflammatory response	5 mg SID SQ for 7 days; then every other day or as needed		Unsubstantiated effects	5 mg/vial I VM

Oxacillin (Prostaphlin)	Penicillin derivative used for staphylococcal skin infections	22-40 mg/kg TID PO	Same	Best if not given with food	250 mg/5 ml S 250, 500 mg C 250 and 500 mg, 1 and 2 g I HM
Oxazepam (Serax)	Appetite stimulant (oral benzodiazepine agent)		Total dose: 2.5 mg per cat PO once. Do not use long term since it may induce hepato-toxicity	Overdosage results in sedation and incoordination	10, 15, 30 mg C 15 mg T HM
Oxtriphylline (Choledyl)	Bronchodilator (theophylline derivative)	4-10 mg/kg TID PO	4-10 mg/kg TID PO	Vomiting, diarrhea, hyperexcitability	100, 200 mg T 400, 600 mg ER HM
Oxymorphone (Numorphan)	Narcotic agonist for analgesia, anesthetic induction, and minor procedures	Anesthesia: 0.1-0.2 mg/kg IM, SQ; 0.02-0.05 mg/kg IV Analgesia: 0.03-0.2 mg/kg IV, IM, SQ, PRN	0.01-0.2 mg/kg IV, IM, SQ, PRN	Respiratory and CNS depression Hypotension, sedation, feline hyperexcitability Panting (dogs) Reverse with naloxone	1, 1.5 mg/ml I HM
Oxytetracycline (Terramycin)	Broad spectrum bacteriostatic agent Also used for rickettsiae, mycoplasma, and spirochetes Used for treating small bowel bacterial overgrowth	10-20 mg/kg TID-QID PO As o.o., apply BID-QID	Same	Do not use in pregnancy (last trimester) or in first month of life (dental staining) G-I side effects Do not administer with antacids, dairy products, or intestinal adsorbents	50, 125 mg/ml I 250 mg C HM
Oxytocin (Pitocin, Syntocinon)	Posterior pituitary hormone used for uterine inertia; to stimulate milk flow; vasopressive effects and as an antidiuretic	Obstetrics: 5-25 U IM total dose q 30 min or 1-2 U/kg. Milk production: 2-10 units IM Intranasal spray	Obstetrics: 2 units/kg IM q 30 min Milk production: 1 unit IM	Do not use if birth canal obstructed Refrigerate vial, warm syringe before injection	10 U/ml I 40 U/ml nasal spray HM

Table • App-15 P

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Pamidronate (Aredia)	Bisphosphonate compound Hypercalcemia e.g. due to cholecalciferol intoxication	0.65–2 mg/kg diluted in 0.9% NaCl and given as IV CRI		Clinical vet use very new; efficacy and adverse effects sparsely reported at present	30, 60, 90 mg vials I HM
Pancreatic enzymes (Pancrelipase) (Viokase)	Pancreatic exocrine insufficiency	½-2 tsp pwdr in 1# (500 g) canned food or 2 cups moistened dry food.	Same proportional to size of feeding	Avoid inhaling powder dust Viokase brand has superior efficacy	VM, HM
Paregoric®	Antidiarrheal	0.05-0.06 mg/kg BID-TID PO	None	May cause constipation	OTC, HM S
Paroxetine (Paxil)	Selective serotonin reuptake inhibitor	Total dose: 2.5–5 mg PO per dog SID	Total dose: 1.25–2.5 mg PO per cat SID	Behavior changes, anorexia possible	10, 20, 30, 40 mg T 12.5, 25 mg ER (Paxil CR) T HM
Penicillamine (Cuprimine) (Depen)	Chelating agent for lead, copper, and mercury Used to aid in the prevention of cysteine urolithiasis Cu storage disease	10-15 mg/kg PO BID		Administer on empty stomach if tolerable May cause vomiting, skin eruptions, and vascular lesions Monitor CBC	250 mg (Depen) T 125, 250 mg (Cuprimine) C HM
Penicillin, benzathine (Benzapen)	Gm + infections; some activity against anaerobes; bactericidal	20,000-40,000 units/kg q 48-72h, IM, SQ	Same	Do not use with penicillin hypersensitivity Do not use if serious infection is suspected IM or SQ injection only	150,000 U/ml I HM
Penicillin G procaine	Gm + infections; some activity against anaerobes	20,000-40,000 units/kg q 12-24 h IM, SQ	Same	Solution for injection is opaque= for IM/SQ injection only Penicillin hypersensitivity contraindicates	300,000 U/ml I VM

Penicillin G potassium or sodium	Gm + infections; some activity against anaerobes	20,000-40,000 units/kg q 4–6 h IV, IM, SQ	Same	Penicillin hypersensitivity contraindicates May contain high levels K+ Solution for injection should be completely transparent Not very effective orally	1 million, 5 million, 10 million, and 20 million U vials I HM
Penicillin-V	Gm + infections; bactericidal; effective orally	5.5-11 mg/kg TID-QID PO	Same	250 mg = 400,000 units Penicillin hypersensitivity	250, 500 mg T 125, 250 mg/5 ml S Many other sizes HM
Pentazocine (Talwin)	Narcotic agonist/antagonist used for short term analgesia	1-3 mg/kg IM, 2-6 mg/kg PO	2-3 mg/kg SQ, IM, IV	May cause salivation and/or sedation Reverse with naloxone May cause dysphoria in cats	30 mg/ml I HM Often combined with other Rx VM, HM
Pentobarbital (Nembutal)	Status epilepticus Anesthesia	Anesthesia: 10-30 mg/kg IV slowly to effect Seizures: 3-15 mg/kg IV slowly to effect	Anesthesia: 10-30 mg/kg IV slowly to effect Seizures: 3-15 mg/kg IV slowly to effect	Respiratory depression and hypotension may develop if used with or after diazepam	50 mg/ml I Available as tablets, elixir, suppositories VM, HM
Pentoxifylline (Trental)	Increases plasticity of cell membranes; used in many dermatoses, including dermatomyositis	10 - 25 mg/kg PO BID		Clinical vet use very new; few adverse effects reported so far	400 mg T HM
Phenobarbital	Long acting barbiturate used for seizure control Occasionally used as a sedative	1-2 mg/kg PO BID-TID; OK to titrate slowly up to 16 mg/kg/day in divided doses May be given IV as a bolus of 2-15 mg/kg slowly for status epilepticus followed by 2-6 mg/hr CRI Maintain serum levels at 15-45 microg/ml prior to each dose of Rx	2 mg/kg PO BID	Ataxia, sedation, pu/pd. Long term (esp. if >35 microg/ml serum levels) hepatotoxicity occurs Initial adjustment period is required If using higher dose IV, monitor respirations Controlled substance Available combined with phenytoin—not generally recommended	8, 16, 32, 65, 100 mg T 15, 20 mg/5 ml S 30, 60, 65, 130 mg/ml I HM

Phenoxybenzamine HCl (Dibenzyline)	Alpha adrenergic receptor blocking agent Urinary incontinence due to detrusor-sphincter dyssynergia	0.25-1.0 mg/kg PO BID	Total dose: 2.5-10 mg PO per cat SID-BID	May result in vomiting, hypo/hypertension, rapid HR, miosis No effect on postprostatic urethra of cats	10 mg C HM
Phenylbutazone (Butazolidin)	Nonsteroidal anti-inflammatory	10-22 mg/kg BID-TID PO	6-8 mg/kg BID PO (1 week on, 1 week off)	Use lowest effective dosage Do not exceed 800 mg/day May cause vomiting, G-I ulceration, BM suppression Incidence of toxicosis is high Not recommended	100, 400, 1000 mg T VM, HM
Phenylephrine (Neo-Synephrine)	Post-synaptic alpha adrenergic stimulant used 1. as nasal drops for rhinitis or 2. as IV infusion for treatment of hypotension	1. 1-2 drops intranasal pediatric soln SID-TID 2. 1–3 microg/kg/min as IV CRI, adjusted to effect	Same	May cause nasal irritation if used chronically Vasoconstriction and pupillary dilation if given parenterally (constant BP monitoring necessary)	10 mg/ml I Oph, and intranasal OTC products HM
Phenylpropanolamine HCl (Proin)	Alpha adrenergic agonist used for treating hormone responsive urinary sphincter hypotonus (incontinence) by increasing urethral smooth muscle activity	1 mg/kg PO TID	1-2 mg/kg BID-TID PO	Anxiety, dizziness, hypertension, tachycardia, urinary retention No longer available as human OTC product	25,50 mg T VM
Phenytoin (Dilantin)	Anticonvulsant agent	10-40 mg/kg PO TID 5-10 mg/kg slow IV	Not recommended	Ataxia and vomiting Monitor for hepatotoxicity Metabolized very rapidly Considered second line agent at best	50 mg T 30, 100 mg C 6, 25 mg/ml S HM

Phosmet dip (Paramite)	Organophosphate dip for fleas, ticks, and canine sarcoptic mange	2 tbsp (1 oz) per gallon H_2O Sponge on and let air dry	Do not use	Wear gloves to administer; use once weekly maximum Do not use if under 8 weeks old Fever, salivation, seizures, and CNS signs suggest organophosphate toxicity; use atropine injection and wash off dog	11.6% dip VM
Phosphate enemas (Fleet)	Treatment of constipation	For large dogs use one adult bottle; for medium dogs use ½ bottle or a pediatric enema. Not suggested for use in small dogs	Not recommended	May cause severe hyperphosphatemia and hypocalcemia if < 10 kg Do not use if dehydrated, with renal or cardiac failure or in very sick animals	OTC, HM
Pilocarpine oph. soln.	Miotic agent useful in glaucoma KCS	1. 1 drop in affected eye BID-QID 2. For KCS: 2-5 drops in food SID	Same	Ciliary spasms Systemic signs rare when used topically Adjust dose according to time and response	0.25, 0.5, 1, 2, 3, 4, 6, 8% OS HM
Pimobendan (Vetmedin)	Oral positive inotrope and vasodilator Effective adjunct Rx in CHF caused by DCM in Dobermans but not Cockers	0.25 mg/kg PO BID	None	Not approved for vet or human use in U.S.A.	1.25, 2.5, 5 mg C VM
Piperazine	Ascarid infection	50-100 mg/kg PO	Same	Repeat in 3 weeks Vomiting and diarrhea may occur at higher dosages	250 mg T 100 mg/ml S VM, HM
Piroxicam (Feldene)	NSAID As primary or secondary Rx for bladder TCC due to immunomodulatory effect	0.3 mg/kg EOD or SID PO		G-I irritation Must open capsules and put in food for most animals Often coadministered with Misoprostol	10, 20 mg C HM

Potassium chloride inj.	Treatment and prevention of hypokalemia	Add to IV fluid per liter based on serum K+ level Serum K: 3.5-5.0 mEq/l = add 20 mEq KCl/l 3.0-3.4 =30 2.5-2.9 = 40 2.0-2.4 -= 60 <2.0 = 80	Same	Never infuse rapidly or administer over 0.5 mEq K+/kg/h Monitor K+ regularly	2, 10, 20, 30, 40, 60, 200, 400, 1000 Meq/ml I HM
Potassium citrate (Urocit-K)	Inhibits Ca oxalate crystal formation in urine Alkalinizing agent for urine	75 mg/kg BID PO 1-2 mEq/kg/day PO	100-150 mg/kg PO	Gastrointestinal irritation 5 mEq = 540 mg	5, 10 mE q T HM
Potassium phosphate	Hypophosphatemia	0.01–0.03 mM/kg/hr IV	Same	Hyperphosphatemia; recheck serum levels after 6 hours and adjust or stop In potassium phosphate, 1 mM phosphate = 33 mg/dl phosphate Avoid calcium-containing fluids	5, 10, 15, 30, 50 ml vials (3 mM PO4 and 4.4 mEq K per ml for all) I HM
Potassium salts (Kaon®Elixir) (Micro K Extencaps)	Potassium supplements in various oral formulations	¼ - 1 tab (tbsp) (caps) BID-TID PO	1/8 – ¼ (tbsp) (caps) BID-TID PO	Dose according to deficit Monitor serum K May cause gastric irritation	Many OTC preparations, different sizes VM, HM OTC HM
Pralidoxime chloride (2-PAM) (Protopam)	Reactivates cholinesterase inactivated by organo-phosphate	20-50 mg/kg IM or SQ; then BID–TID as needed	20 mg/kg IM or SQ TID–QID as needed	Monitor patient continuously; avoid IV administration (may cause acute laryngospasm) Do not use for carbamate toxicity	1 g vial I HM
Praziquantel (Droncit)	Taenia, Dipylidium, Echinococcus, Heterobilharzia	Use according to instructions on product according to weight; PO or SQ, IM	Same	Fasting not required Do not use in puppies under 4 weeks or kittens under 6 weeks of age	23, 34 mg T 56.8 mg/ml VM 600 mg T HM

Prazosin (Minipress)	Alpha adrenergic antagonist Balanced vasodilator Decreases ureteral smooth muscle tone	Total dose: 0.5-2 mg per dog BID or TID PO	0.5 mg/kg PO BID	Hypotension Depression, malaise	1, 2, 5 mg C
Prednisolone, prednisone	Anti-inflammatory-antipruritic immune system suppression Chemotherapy	Anti-inflammatory: 0.5-1 mg/kg/day PO, IM, SQ Immune suppression: 2-4.4 mg/kg/day usually orally 40 mg/m2/day × 7 PO; then 20 mg/m2 EOD PO	Same	PP/PU/PD; suppression of HPA axis–Cushing's syndrome Taper dosage if used long term	1, 2.5, 5, 10, 20, 25, 50 mg T 1 mg/ml S 10, 25 mg/ml I HM
Prednisone ophthalmic suspension (Pred Forte)	Steroid responsive inflammation of the lids, conjunctiva, sclera, cornea, and anterior segment of the eye	1 drop in affected eye BID-QID	Same	Variable strength products (0.12-1%) used as required Do not use with purulent, viral, or fungal infection or with corneal ulcers Systemic side effects are possible but rare	0.12, 0.125, 1% OS HM
Prednisolone sodium succinate (Solu-Delta-Cortef)	Soluble corticosteroid used IV for shock of multiple causes	5-33 mg/kg IV slow bolus Repeat up to q 6 h Spinal injury: 30 mg/kg IV	Same	Causes vomiting if administered too rapidly	100, 500 mg vials IVM
Primidone (Mylepsin)	Anticonvulsant medication converted to phenobarbital	10-20 mg/kg/day initially; up to 50 mg/kg/day given BID-TID PO (adjust based on serum phenobarbital levels)		Causes pu/pd/pp, sedation, and ataxia Often hepatotoxic with prolonged use No benefit over phenobarbital; no longer recommended	50, 250 mg T 50 mg/ml S HM
Procainamide (Pronestyl; SR) (Procan-SR)	Ventricular arrhythmias	6-20 mg/kg IV slowly over 30 min then CRI 0.02–0.04 mg/kg/min (20-40 microg/kg/min) CRI (if life threatening) 6-20 mg/kg q 4 h IM 6-20 mg/kg q 6 h PO	1-2 mg/kg bolus IV; then 0.01–0.02 mg/kg/min (10-20 microg/kg/min) CRI	Available as sustained release tablet for TID administration This is a negative inotrope Use serum levels for long-term dosing adjustments May cause hypotension, tachycardia, and ECG changes	100, 500 mg/ml I 250, 375, 500 mg C 250, 500, 750, 1000 mg ER HM

Prochlorperazine (Compazine)	Antiemetic	0.11-0.44 mg/kg SQ IM BID-QID	Same	Sedation, hypotension Do not use in epileptic patients Available also in suppository formulation	5 mg/ml I 1 mg/ml S 5, 10, 25 mg T 10, 15, 30 mg ER HM
Propantheline (Pro-Banthine)	Anticholinergic agent used for treating diarrhea, bradycardia syndromes, and detrusor hyperreflexia	0.2–0.5 mg/kg SID-TID PO Increase to effect for bradycardia syndromes	Same	Tachycardia, dry mouth, constipation, mydriasis, ileus, urinary retention	7.5, 15 mg T HM
Propioni bacterium acnes (Immuno-regulin)	Immune modulator/ potentiator	0.03-0.07 mg/kg IV at 2-3 day intervals	Total dose: 0.5 ml per cat IV 1-2 times a week	No controlled studies	0.4 mg/ml I VM
Propofol (Diprivan) (Rapinovet)	Ultrashort (5-7 min) acting anesthetic No cumulative effect with repeated administration	3-6 mg/kg IV	Same	Give slowly over 1-2 min in equal dosages to effect	10 mg/ml I HM, VM
Propranolol (Inderal)	Beta adrenergic blocking agent used for treating supra-ventricular arrhythmias, some ventricular arrhythmias, and feline hypertrophic cardio-myopathy	For acute tachycardias: 0.1-0.5 mg IV total dose per bolus No more frequently than 1 bolus q 1-3 min to 5 mg maximum Administer until the rate slows Chronic use: 0.2-1.0 mg/kg BID PO, usually start low and titrate dosage upward to effect	0.25-0.5 mg IV bolus slowly 2.5-5.0 mg BID, PO, begin low and titrate dosage	Anorexia, apnea, depression, ataxia Bradycardia, negative inotropic effect Potentiates A-V nodal depression of digoxin and calcium channel blockers Underlying cause of tachycardia (e.g. heart failure, hypovolemia) must be addressed before IV propranolol	10, 20, 40, 60, 80, 90 mg T 60, 80 120, 160 mg ER 4, 8, 80 mg/ml S 1 mg/ml I HM
Propylthiouracil (PTU)	Feline hyper-thyroidism	Not used	10 mg/kg BID-TID PO	Immune mediated hemolytic anemia and thrombo-cytopenia Anorexia, vomiting, and lethargy Risk of adverse effects frequently outweighs potential benefit	50 mg T HM

Prostaglandin (PGF2-alpha) (Lutalyse)	1. Open cervixpyometra 2. Abortive agent at 31-35 days	1. Day 1: 0.1 mg/kg SQ once Day 2: 0.2 mg/kg SQ once Days 3-7: 0.25 mg/kg SQ SID 2. 0.1 mg/kg SQ TID × 2 days, then 0.2 mg/kg TID SQ × 3-7 days (or until fetuses are expelled)	1. 0.1 mg/kg SQ BID × 5 d 2. 0.5-1 mg/kg SQ × 2d	Panting, salivation, vomiting, diarrhea, and tachycardia lasting about 30 minutes Should be given under hospital supervision	5 mg/ml I VM
Pseudoephedrine (Sudafed, others)	Hormone-deficient urinary incontinence of bitches	0.2 – 0.4 mg/kg PO BID – TID		Narrow window between therapeutic and toxic doses; use with caution if sympathetic drive could be harmful (heart disease, hypertension, hyperthyroid-ism, etc.) or if CNS abnormalities	30, 120 mg T HM, OTC
Psyllium mucilloid (Metamucil)	Bulk laxative; stool softener	2-10 g SID-BID in moistened food	2-4 g SID-BID in moistened food	Titrate dose based on stool consistency May also be used for treating fiber-responsive diarrhea	OTC HM
Pyrantel pamoate (Nemex, Strongid-T)	Roundworm and hookworm anthelmintic	5-10 mg/kg PO	10 mg/kg PO	Repeat in 3 weeks Safe at recommended dosages and in dogs with heartworms	22.7, 113.5 mg T 2.27, 4.54, 50 mg/ml S VM
Pyridostigmine bromide (Mestinon)	Anticholinesterase agent used for treating myasthenia gravis	0.2-2 mg/kg BID-TID PO	0.25 mg/kg PO maximum of once daily	Available as soft tablet and syrup (60 mg/5 ml) Vomiting, diarrhea, salivation, and weakness may develop	60 mg T 180 mg ER 12 mg/ml S 5 mg/ml I HM
Pyrimethamine (Daraprim)	Toxoplasmosis Neosporosis	0.5-1 mg/kg SID PO × 48 h; then 0.25 mg/kg PO SID × 14 d	Same	Often used with sulfonamides to treat toxoplasmosis May need to supplement with folic or folinic acid Teratogenic	25 mg T HM

Table • App-16 Q

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Quinacrine (Atabrine)	Giardiasis Enteric coccidiosis	10 mg/kg SID PO 5-12 days	11 mg/kg SID PO × 5 days	May cause enteric signs Considered second line agent	100 mg T HM
Quinidine (Quinidex)	Type Ia antiarrhythmic agent used mostly for ventricular dysrhythmias	6-20 mg/kg TID-QID PO, IM	Not recommended	Do not give IV or use with digitalis Negative inotropic agent Available in long acting tablet forms	100, 200, 300 mg T 275, 300, 330 mg ER 80 mg/ml I HM

Table • App-17 R

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Ramipril (Altace)	ACE inhibitor	0.1-0.125 mg/kg PO BID	Same	Description of clinical vet use, efficacy and adverse effects is limited	1.25, 2.5, 5, 10 mg C HM
Ranitidine HCl (Zantac)	H2 histamine receptor antagonist	1-2 mg/kg BID–TID PO, SQ, IM, slow IV	Same	GI prokinetic effects IV bolus may cause immediate vomiting	75, 150, 300 mg T 15 mg/ml S 25 mg/ml I HM
Rutin	Benzopyrone recommended for treatment of chylous pleural effusion. Reportedly potentiates macrophage function		50 mg/kg TID PO Total dose 250 mg TID per cat PO or 500 mg BID per cat PO	Generally purchased in health food stores	500 mg T OTC

Table • App-18 S

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
S-Adenosyl Methionine (SAMe) (Denosyl)	Adjunctive treatment for certain liver diseases; steroid hepatopathy. Acetaminophen toxicity	15-20 mg/kg daily. Total dose per dog: 90 mg PO SID (small dog), or 225 mg PO SID (large dog)	Total dose per cat: 90 mg PO SID		90, 225 mg T VM HM-OTC
Salmeterol (Serevent)	Inhaled long-acting beta-2 agonist bronchodilator	1 puff as needed SID-BID	Same	Takes >1 hr to take effect	6.5, 13g inhalation canisters (0.025 mg [25 microg] per puff) HM
Selamectin (Revolution)	Endectocide—topical for fleas, ticks, ear mites, heartworms, sarcoptic mange, intestinal hookworms, and roundworms	6 mg/kg topically 1 ×/month	Same	Use in dogs or cats over 6 weeks old For heartworm prevention: Give within 1 month of first exposure to mosquito and continue until within one month of last exposure	Pkg per wt L VM
Selegiline (deprenyl) (Anipryl) (Eldepryl)	Restores central dopamine levels—MAO inhibitor Used to treat cognitive dysfunction syndrome, May be helpful in selected PDH canine Cushing's cases	PDH: 1 mg/kg/day × 30 PO then OK to ↑ to 2 mg/kg/day CDS: 0.5 mg/kg daily; may double dose after 1 month if ineffective	Not rec'd	Low level of effectiveness reported	2, 5, 10, 15, 30 mg T VM 5 mg C, T HM
Sildenafil (Viagra)	PDE 5 inhibitor used for the treatment of Pulmonary hypertension	0.05-0.1 mg/kg PO BID-TID	Unknown	Clinical usefulness seen but no controlled studies have been reported	25, 50, 100 mg T HM
Silver sulfadiazine (Silvadene Cream)	Topical antiinfective preparation for complications of burns	Apply to burn area BID as necessary	Same	Hypersensitivity to sulfonamides	10 mg/g O HM

Sodium bicarbonate	Metabolic acidosis	mEq/day = (desired serum [HCO3] – present serum [HCO3]) × 0.3 × wt (kg) Administer 50% over 15 minutes and recheck serum levels; then give the balance over 24 h	Same	Alkalosis, hypernatremia, CHF, hypokalemia Correct inciting factors concurrently (or prior to HCO3 Tx); 84 mg NaHCO3 contains 1 mEq HCO3	0.6, 1 mEq/ml I 5, 10 grain T HM
Sodium iodide 20%	Sporotrichosis	15 mg/kg TID PO	Same	Monitor for iodinism: fever, ptyalism, G-I signs Contains 0.1 mg iodine/ml	20% I VM
Sodium stibogluconate (Pentostam)	Leishmaniasis	30-50 mg/kg SID SQ, IV or 10-20 mg/kg IM SID × 20-28d.		Not available in USA except through CDC	100 ml vials (100 mg/ml) I HM
Sotalol (Betapace)	Classes II and III antiarrhythmic agent used primarily for treating ventricular tachyarrhythmias	2.2-6.6 mg/kg BID PO	5-20 mg. per cat BID PO Dosage based on limited experience in cats	Beta effects seen at low dosages; type III effects at higher levels Begin low and titrate upwards to effect	80, 120, 160, 240 mg T HM
Spironolactone (Aldactone) Spironolactone with hydrochlorothiazide (1:1 combination= Aldactazide, Spirozide)	Protects against AC E escape and limits fibrosis in the heart muscle Potassium sparing diuretic; inhibits aldosterone Hydro-chlorothiazide is a potassium depleting diuretic	1-4 mg/kg SID-BID PO	Same	Usually used with other diuretic agents Monitor potassium (hyperkalemia) Used with ACEI agents usually 1×/day and at low dose Best if use noncombination products to obtain correct dosages	25, 50, 100 mg T HM 25/25/mg T
Stanozolol (Winstrol)	Anabolic steroid used for treating anorexia, debilitation, and anemia	0.1-0.2 mg/kg SID-BID PO Total dose: 25-50 mg IM per dog weekly	0.1-0.2 mg/kg SID-BID PO Total dose: 12.5-25 mg per cat IM weekly	Contraindicated in pregnancy Hepatotoxicity in cats	2 mg T 50 mg/ml I VM, HM

Streptokinase (Kabikinase) (Streptase)	Thrombolytic drug Arterial or pulmonary thrombo-embolism	90 000 IU/kg IV over 30 minutes, then 45 000 IU/kg per hour × 7–12 hrs based on response	Same	Bleeding diathesis; hyperkalemia from reperfusion Intracardiac thrombus= absolute contraindication Complications cancel benefits in feline aortic thromboemboli	250 000, 600 000, 750 000, 1.5 million unit vials I HM
Succimer (*meso*-2,3 dimercaptosuccinic acid) (Chemet)	Lead toxicity	10 mg/kg PO TID × 10-17 days			100 mg T HM
Sucralfate (Carafate)	Complexes with proteinaceous materials in stomach, thereby preventing undesirable effects of acids on the gastric mucosa	Total dose: ¼-1 tab per dog TID-QID PO	Total dose: ¼ tab per cat BID-QID	May constipate Interferes with absorption of many drugs administered concurrently	1 g T HM
Sulfadiazine (Suladyne)	Bacteriostatic agent used for treating 1. toxo-plasmosis and nocardiosis 2. soft tissue/urinary tract infections	1. 90-120 mg/kg BID PO; follow by 50 mg/kg BID PO 2. 30 mg/kg PO SID	Same	Sulfonamide precautions	500 mg T VM, HM
Sulfadimeth-oxine (Bactrovet, Albon)	Bacteriostatic agent used for treating toxoplasmosis, nocardiosis, and coccidiosis	50 mg/kg PO day 1; then 25 mg/kg PO SID	Same	KCS, nephrotoxicity, and hypersensitivity	400 mg/ml I 125, 250, 500 mg T 50, 125, mg/ml S VM, HM
Sulfadimethoxine-ormetroprim (Primor)	Potentiated sulfonamide	27-55 mg/kg SID PO on day 1; then 13.5-27.5 mg/kg SID thereafter for a maximum of 21 days	None	Sulfonamide contra-indications	120, 240, 600, 1200 mg T VM
Sulfasalazine (Azulfidine)	Anti-inflammatory effect on the colon; ulcerative and idiopathic colitis	22-55 mg/kg TID PO	10-20 mg/kg BID PO 3-5 days	KCS Avoid prolonged treatment, blood dyscrasias, vomiting	500 mg T HM

Table • App-19 T

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Tacrolimus (Prograf, Protopic)	Immune-mediated hemolytic anemia and other autoimmune disorders Topical: atopy, perianal fistula	0.16 mg/kg IM SID 1 mg/kg PO SID		Sparsely reported use at this time; narrow therapeutic-toxic range, with frequent negative side-effects; these doses associated with adverse effects, so titrate to keep trough serum level 0.1–0.4 ng/ml (dogs) Vasculitis Anorexia Intussusception	1 mg, 5 mg T 5 mg/ml I 0.3% lotion HM
Taurine	Feline DCM Canine DCM in Am. Cocker Spaniels, retriever breeds, many others	50 mg/kg TID PO or total dose 500-1000 mg PO per dog BID	Total dose: 125-250 mg PO per cat BID	Switch to taurine enriched diet if relevant (many are already on balanced diet)	250 mg T OTC, HM
Tepoxalin (Zubrin)	Non-steroidal anti-inflammatory drug	10 mg/kg PO SID; may give 2× dosage first day.	Not recommended	Gastritis, diarrhea, hepatopathy, renal effects Tablets disintegrate rapidly (~4 secs)	30, 50, 100, 200 mg T VM
Terbutaline (Brethine)	Bronchodilator via beta 2 stimulation	Total dose: 0.625-5 mg PO per dog BID-TID	Total dose: 0.625-1.25 mg PO per cat BID	Excitability Vomiting	2.5, 5 mg T 1 mg/ml I HM
Testosterone	Testosterone responsive incontinence in dogs	2.2 mg/kg IM monthly	Total dose: 5-10 mg per cat IM	Hepatopathy Behavioral changes	25, 50, 100, 200 mg/ml I HM

Tetracycline	Broad spectrum antibiotic; bacteriostatic Used especially for Brucella, Chlamydia, Mycoplasma, and Rickettsia; used for pleurodesis; used with niacinamide for autoimmune dermatopathies; and as an ophthalmic ointment	10-22 mg/kg TID PO for 3 weeks Pleurodesis: 20 mg/kg in 4 ml saline/kg Oph. oint: apply TID-QID	Same	Fever, vomiting, diarrhea Do not administer with dairy products, antacids, intestinal adsorbents Do not give in last 3 wks of pregnancy or to newborns to 4 weeks of age	100, 250, 500 mg T/C 25 mg/ml S 250, 500 mg/vial I 10 mg/g OO 10 mg/ml OS HM; VM
Theophylline elixir (Elixophyllin)	Bronchodilator	6-11 mg/kg TID PO	Rarely used at 8 mg/kg TID PO	See Aminophylline Restlessness, vomiting	16 mg/ml S HM
Theophylline sustained action (Theo-Dur)	Long acting bronchodilator	5-15 mg/kg BID PO One dose may in some patients last 24 hours	Same but infrequently utilized	Hyper-excitability common Nausea, vomiting—stop drug	100, 200, 300 mg ER HM
Thiabendazole (Mintezol)	Aspergillosis, Penicilliosis, Filaroides (Oslerus), and feline eosinophilic granuloma complex	50 mg/kg SID PO for 3 days, repeat in 1 month	5-10 mg/kg SID PO 3 times weekly	Not licensed for feline use Many dosages recommended for unusual parasitic states that may or may not respond	500 mg T 100 mg/ml S VM
Thiacetarsamide (Caparsolate)	Heartworm adulticide Haemobartonellosis (M. felis)	2.2 mg/kg BID slow IV × 4 doses	1.1-2.2 mg/kg BID slow IV × 4 doses Often not rec'd	Vomiting, depression, hepatotoxicity (icterus) Nephrotoxicity Thromboembolic phenomena 7-14 days post-Rx Perivenous injection causes sloughing Acute pulmonary edema in cats	10 mg/ml I VM
Thiamine (Vitamin B1)	Thiamine deficiency	Total dose: 10-100 mg BID per dog, IM, IV, PO	Total dose: 50 mg BID per cat, IM, IV, PO	Stings IM	100, 200 mg/ml I 5, 10, 25, 50, 100, 250, 500 mg T HM

Thioguanine	Antineoplastic Acute leukemias	40 mg/m2 PO SID × 4-5 d., then q 3 d.	25 mg/m2 PO SID × 1-5 d., then q 30 d	Bone marrow, GI, hepatic adverse effects possible	40 mg T HM
Thiopental sodium (Pentothal)	Ultrashort acting anesthetic (similar to thiamylal Na)	13-26 mg/kg IV titrated to induction of anesthesia	Same	Respiratory and cardiac depression Avoid perivenous administration Ventricular bigeminy common	1, 2.5, 5 g vials I HM
Thyrotropin TSH (thyroid-stimulating hormone) (Dermathrycin) (Thyrotropar)	Hormone used for diagnosis of hypothyroidism	Total doses: 5 U per dog to 10 kg IV, IM, SQ; 10 U per dog over 10 kg IV, IM, SQ	Total dose: 2.5 units per cat IM or IV	Follow protocol for testing: pre- and 6 h post IM or IV injection	5, 10 U/vial I VM, HM
Ticarcillin-clavulanate (Timentin)	Broad-spectrum penicillin-clavulanic acid combination	50-100 mg/kg slow IV TID	40-50 mg/kg IM or slow IV TID-QID		3 g vials I HM
Tiletamine-zolazepam (Telazol)	Tranquilizer, dissociative combination agent used for chemical restraint	5-12 mg/kg IM	Same	Rapid onset; respiratory depression may occur quickly (be prepared for intubation)	100 mg/ml combined (50 mg each per ml) I VM
Timolol soln. (Timoptic)	B blocking agent used for decreasing intraocular pressures due to glaucoma	1 drop in eye BID	Same	Potentiation of beta blocking effects possible Avoid 0.25% solution (ineffective)	0.25, 0.5% OS HM
Tocainide (Tonocard)	Class Ib antiarrhythmic Agent for ventricular tachyarrhythmias	15-20 mg/kg BID-TID PO	–	Anorexia, GI signs Weakness, head bobbing; corneal dystrophy Possibly adverse renal effects May need to use with other class IA drugs for max effect	400, 600 mg T HM
Triamcinolone (Vetalog) (Kenalog)	Intermediate acting corticosteroid used PO; by injection IM, SQ, or intralesional	0.1-0.22 mg/kg IM, SQ, PO	Same	Corticosteroid effects	0.5, 1.5 mg T 2, 6 mg/ml I HM, VM
Trientine (Syprine)	Alternative to penicillamine to chelate copper	10-15 mg/kg BID PO	–	See penicillamine	250 mg C HM

Trifluridine (Viroptic)	Antiherpetic viral agent	–	At least 2-4 times daily in eyes	–	1% OS
Triiodothyronine, T3 (Cytomel, liothyronine)	Hypothyroidism; used when unable to convert thyroxine to triiodothyroxine; also diagnostically as T3 suppression test	4-6 microg/kg TID PO	4.4 microg/kg BID-TID PO T3 suppression: 25 microg total per cat dose PO TID × 7 doses, then blood for T4 and T3 (control)	Thyrotoxicosis, pu/pd/pp, nervousness, panting, tachycardia	5, 25, 30 microg T
Trilostane (Vetoryl)	Steroid analog (competitive inhibitor of 3 beta-hydroxysteroid dehydrogenase); treatment for pituitary-dependent hyperadrenocorticism/Cushing's disease	10–30 mg/kg PO SID dogs < 5 kg: 30 mg starting dose, and dogs 5 kg or greater: 60 mg starting dose		Not approved for vet or human use in U.S.A. Adrenal necrosis possible	60, 120 mg T, C VM
Trimeprazine (Termaril-P, Vanectyl-P)	Anti-inflammatory-antipruritic-antitussive agent combined with 2 mg prednisone	Total dose: ½-2 tabs PO per dog BID to effect	Total dose: ¼-½ tab PO per cat SID to BID to effect	Steroid effect; drowsiness Temail-P contains 2 mg prednisone per tablet	5 + 2 mg T 3.7 mg + 1 mg C 7.5 mg + 2 mg C VM
Trimethobenzamide (Tigan)	Antiemetic	3 mg/kg IM, PO BID-TID	None	CNS reactions; hypersensitivity	100, 250 mg C 100, 200 mg suppositories 100 mg/ml I HM
Trimethoprim/sulfadiazine (Tribrissen) (Ditrim)	Bactericidal broad spectrum combination agent against gram + and – bacteria, Toxoplasma, Nocardia, Pneumocystis	15 mg/kg BID, PO, SQ, IM Toxoplasmosis: 30 mg/kg BID PO	15 mg/kg BID PO, SQ, IM Toxoplas-mosis: 30 mg/kg BID PO	Cats: salivation; K-9: KCS syndrome; Dobermans: polyarthro-pathy; ITP Hepatotoxicity and blood dyscrasias reported at higher dosages	30, 120, 480, 960 mg T 60 mg/ml S 24, 48% I VM, HM
Trimethoprim/sulfamethox-azole (Bactrim) (Septra)	Same as above	Same as above	Same as above	Same as above	As above

Tropicamide oph. Soln. (Mydriacyl)	Mydriatic agent for eye examination	1 drop 15 min prior to ophthalmic examination	Same	Causes mydriasis and photophobia Do not use in suspected cases of glaucoma	0.5, 1% OS HM
Tylosin (Tylan)	Macrolide antibiotic used for treating colitis and small bowel bacterial overgrowth syndrome	5-10 mg/kg BID PO. May increase slowly to 40 mg/kg BID PO (Usually about ¼ tsp. in a large dog)	5-10 mg/kg BID PO	Usually used as powder sprinkled on food Bitter taste Generally found as a pig medication	50, 200 mg/ml I 3000 mg/5 ml P VM

Table • App-20 U

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Ursodeoxycholic acid (Ursodiol, Actigall)	Suppresses hepatic secretion and synthesis of cholesterol Choleretic agent via solubilizing cholesterol (sludged bile) and increase in gallbladder contractions	5-15 mg/kg SID-BID PO	7.5-15 mg/kg SID-BID PO	Anecdotal reports of benefits as antifibrosis, anti-inflammatory, cytoprotective antioxidant May induce diarrhea Contraindicated if gallbladder obstruction Minimal contribution (<10%) to measured serum bile acids level	300 mg C HM

Table • App-21 V

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Valacyclovir	Antiviral		Do not use	Severe bone marrow, renal, and hepatic toxicities common even at subtherapeutic doses	
Valproic acid (Depakene) (Depakote)	Seizures	60–100 mg/kg TID PO	Unknown	G-I disturbances initially Hepatotoxicity with chronic use Considered third line therapeutic drug	125, 250, 500 mg T 250 mg C 500 mg/ml S HM
Vasopressin (Vasopressin aqueous) (Pitressin)	Diagnostic agent for central or nephrogenic diabetes insipidus	Diagnostic: 0.5 U/kg IM to maximum 5 units after 5% weight loss from water deprivation	Same	Not available as tannate in oil	20 U/ml I HM
Verapamil (Calan and SR) (Covera-HS) (Isoptin and SR) (Verelan and PM)	Calcium channel blocking agent used principally to treat supra-ventricular tachy-arrhythmias	0.4-2.0 mg/kg BID-TID PO 0.05 mg/kg slowly IV; may repeat twice, 5–30 min between doses	Not recommended; see Diltiazem instead	Not suggested for IV use clinically if structural heart disease or systemic illness (e.g. hypovolemia) present Negative inotropic agent; usually do not use with beta blockers; may cause heart block	40, 80, 120 mg T 120, 180, 240, 360 mg ER 2.5 mg/ml I HM
Vidarabine (Vira-A)	Antiherpetic viral agent	–	Apply 4-6 times daily in eyes	–	3% OO HM
Vinblastine (Velban)	Vinca alkaloid used in cancer chemotherapy, esp. lymphoreticular and mast cell cancers Also IMT	2 mg/m2 IV q 1-2 weeks, or 0.05-0.1 mg/kg IV weekly	Same	See Vincristine	1 mg/ml I HM
Vincristine (Oncovin)	Vinca alkaloid-like vinblastine Used also for TVT	0.5 mg/m2 IV weekly TVT: 0.025 mg/kg IV weekly, maximum 1 mg per dose	Same	Perivascular irritant Leukopenia Constipation Local neuropathy	1 mg/ml I HM
Vitamin E-tocopherol (Unique E)	Vitamin E Antioxidant Steatitis Discoid lupus	Total dose: 100-400 IU PO per dog SID	Total dose: 30 IU PO per cat SID daily	May use serum tocopherol levels to adjust dose	700 mg C HM

Vitamin K1 (Phytonadione) (Aquamephyton) (Mephyton) (Veta-K1)	Coumarin, indanedione, diphacinone, brodifacoum, and other anticoagulant rodenticide intoxications and coagulopathy due to decreased levels of Vit K dependent clotting factors	Load with 2.5-3.3 mg/kg SQ multiple sites, then 1.1-3.3 mg/kg BID PO Do not give IV For replacement therapy in chronic hepatopathies: 2.5 mg SQ. IM, or PO BID × 3-5 days, then once weekly	Same	Anaphylaxis if given IV; 2nd generation anticoagulants usually require 3-4 weeks of therapy Use parenteral form if inhibited absorption Hepatotoxicity with chronic use	5 mg T 25 mg C 2, 10 mg/ml I VM, HM

Table • App-22 W

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Warfarin (Coumadin)	Anticoagulant Inhibits vit K epoxide reductase, blocking activation of vitamin K dependent factors	0.1-0.2 mg/kg SID PO to maintain PT at 1.5-2× baseline	Total dose: 0.2-0.5 mg per cat for most cats PO SID	Fatal or nonfatal hemorrhage; widely variable interindividual effects require close monitoring	1, 2, 2.5, 3, 4, 5, 6, 7.5, 10 mg T 2 mg/ml I HM

Table • App-23 X

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Xylazine (Rompun)	Agent with sedation and analgesia of 15-30 minutes Emetic effect in cats	0.66-2.0 mg/kg IM 0.66-1.1 mg/kg IV	Emetic agent: 0.44-1.1 mg/kg IM or IV	Many side effects include arrhythmias, hypotension, sensitization to halothane anesthesia Reversal with yohimbine	20 mg/ml I VM

Table • App-24 Y

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Yohimbine (Yobine)	Alpha-2 (xylazine) antagonist	0.1-0.25 mg/kg slow IV 0.2-0.5 mg/kg IM, SQ	Same	Apprehension, salivation, tremors, excitability	2 mg/ml I VM

Table • App-25 Z

GENERIC NAME (TRADE NAME IN PARENTHESES)	INDICATIONS/DRUG TYPE	CANINE DOSE	FELINE DOSE	COMMENTS	HOW SUPPLIED
Zafirlukast (Accolate)	Leukotriene receptor antagonist Feline asthma		Total dose: 5 mg per cat PO SID	New drug; very limited use in veterinary medicine at this time	10, 20 mg T HM
Zinc oxide	Promotes healing of irritated or abraded skin	Apply a thin film BID	Same	G-I effects and hemolytic anemia if chronically ingested in large amounts	OTC, HM O
Zinc sulfate, acetate, gluconate, or methionine	Zn responsive dermatoses Copper storage disease	5-10 mg/kg elemental Zn BID PO	7-10 mg/kg SID PO for hepatic lipidosis	G-I irritability – administer with food Zn induced hemolysis if plasma levels exceed 1000 mg/dl Zn levels require special blood tubes (normal rubber caps contain Zn)	66, 100, 200, 220 mg T 1 mg/ml I HM
